Types of child abuse and their aetiology, recognition and outcome

Area child protection committees in England and Wales maintain the Child Protection Register and develop procedures and policies for each locality. In England, the estimated rate of children under the age of 18 years registered annually on the Child Protection Register is around 25–30 per 10 000 children. Seventy per cent of registered children are under 10 years of age. Male and female genders are represented equally, but girls account for 60 per cent of those registered for sexual abuse.73 The categories under which children can be registered are physical abuse, sexual abuse, emotional abuse and neglect.

According to the Department Of Health, in the early to mid-1990s, 1.45 per cent of the 11 million children in England (i.e. 160 000 children) were subject to a child protection enquiry each year. Of these, 15 per cent were placed on the Child Protection Register and 2 per cent were taken into public care.74

Physical abuse

Physical abuse includes actual or likely physical injury, or failure to prevent injury or suffering resulting in significant danger or substantial risk of impairment of bodily functions, disfigurement or death. This can include Munchausen by proxy syndrome, which at its most extreme can result in death (e.g. by suffocation or deliberate poisoning). Features such as delay in seeking medical attention, vague and inconsistent accounts of the cause of the injury, and
repeated presentations with injuries should raise the suspicion of physical abuse.

Sexual abuse

Sexual abuse refers to involvement of dependent, developmentally immature children and adolescents in sexual activities that they do not truly comprehend, to which they are unable to give informed consent, or that violate the social taboos of family roles. Sexual abuse may involve physical contact, including penetrative or non-penetrative acts and non-contact activities, such as involving children in looking at, or in the production of, pornographic material or watching sexual activities, or encouraging children to behave in sexually inappropriate ways. Some abusers deliberately befriend the victim, ‘grooming’ them over time towards eventually engaging them in sexual activity. The majority (85–95%) of abusers are male, and the majority of children know their abuser before the abuse starts.

Emotional abuse

Emotional abuse refers to persistent or severe emotional maltreatment or rejection leading to actual or likely severe adverse effects on the behavioural and emotional development of the child. Emotional abuse can involve habitual criticism, humiliation, ridicule, harassment, threat and persistent rejection. Emotional abuse and neglect tend to occur together.

Neglect

Neglect refers to the failure to protect a child from exposure to danger or a lack of attention to daily needs and care to a degree that may result in significant impairment of the child’s development or health. Severe neglect is life-threatening and can lead to long-term or severe psychological and physical harm due to the persistent unavailability of parent or guardian. The child is often left alone, and there is non-organic failure to maintain weight and frequent illness and infection because of poor hygiene.

Aetiology

A systemic model proposed by Finkelhor outlines the theories of risk, causation and maintenance of sexual abuse.75 Prominent factors include:

- motivation to sexually abuse (5–9% of undergraduate males expressed sexual interest in children);
- absence of internal inhibitors (through use of alcohol and drugs, stress, cognitive distortion, e.g. minimization of harmful effects);
- absence of external inhibitors (lack of supervision, availability, access);
- absence of child’s resistance by virtue of age, disability, neglect or social isolation.

As children try to adjust, this often results in secrecy, helplessness, entrapment and accommodation, and delayed, unconvincing disclosure and retraction. Thus, sexual abuse, similar to other forms of abuse, has a varied aetiology involving the interaction of several factors.

Interventions and outcome

In the UK, the responsibility for child protection rests primarily with social services. The process leading to intervention by social services starts with someone reporting a concern about possible abuse in a particular child. If the concerns are deemed to warrant further investigation, then a referral to the child protection team takes place. The child protection team then decides whether there is a need for immediate protection (e.g. removing the child from their home and placing them in care) and plans the investigation (which could include interagency discussion, interviewing the child, medical examinations and interviewing members of the family). Other subsequent actions may include convening a child protection conference, developing a protection plan, carrying out a more comprehensive assessment of the child and family, prosecuting the abuser, and referral for therapy. Serious abuse often results in the removal by the courts of parental rights, with parental responsibility then passing to social services.

Once abuse has occurred, there is limited success in treatment. Many children remain in the care system for the rest of their childhood once they have been removed from their family of origin.73 Thus, prevention acquires a high priority. Prevention can be at different levels:73

- **Primary prevention:** involves universal services for the whole population, such as housing, financial support, high-quality childcare, family and child development centres, promoting good parenting practices, and public awareness campaigns.
- **Secondary prevention:** involves targeted services by identifying high-risk populations and offering intervention before abuse and neglect occur, such as targeted home-visiting, school- and hospital-based social services, and targeted therapeutic groups.
- **Tertiary prevention:** involves specialist services for treatment of families where parents and caregivers have already abused their children, such as interdisciplinary services to ensure treatment, care, counselling, management and support, and the use of child-friendly courts.

However, there is no clear evidence of a reduction in abuse associated with any of the above strategies. Therapeutic interventions in relation to the consequences of trauma following abuse may include individual psychotherapy (including eye movement desensitization and reprocessing), group therapy and family therapy.

The potential consequences and outcomes for those who are abused as children are discussed above (see Effects of early and continuing experience on later child, adolescent and adult development and functioning).
INTERACTION BETWEEN PSYCHIATRIC DISORDER AND PHYSICAL ILLNESS

Chronic illness and disability are associated with an increased prevalence of psychiatric disorders. Approximately 30–40 per cent of children with a severe paediatric illness also have a co-morbid psychiatric disorder. Illnesses affecting the brain have a stronger association with subsequent and concurrent psychiatric disorders compared with illnesses that do not affect the brain. In Rutter and colleagues’ Isle of Wight study, rates of psychiatric disorder were 44 per cent among children with structural brain disorders, 29 per cent among children with idiopathic epilepsy, 12 per cent among children with non-cerebral physical disorders, and 7 per cent among children free from physical disorders. Many other studies have confirmed this differential prevalence rate.

Although it is important to recognize higher rates of psychiatric disorder in people with physical disorders, it is just as important to recognize that an undiagnosed physical disorder may first present as a psychiatric disorder. Thus, petit mal absences may present as poor concentration, a malabsorption syndrome may first present as hyperactivity, and a variety of endocrine and metabolic disorders may first present as psychosis.

Physical presentation of psychiatric disorder

Physical symptoms often present in the absence of known organic disease. These are often referred to as ‘somatization’, ‘dissociation’ or ‘conversion’ disorders. Many of these conditions involve apparent neurological symptoms, such as convulsions (pseudo-seizures), paralysis or incoordination (dissociative movement disorders). In younger children, headaches and abdominal pain are common presentations often associated with a stressful situation (e.g. difficulties at school). A difficult question facing the clinician is how aggressively to investigate or challenge a child and family with negative findings in the face of anxieties or coping strategies that the child is ‘needing’ to have the symptom for.

A variety of other psychiatric disorders may first come to the attention of the medical profession via a physical presentation, including eating disorders (e.g. through weight loss, abnormal blood biochemistry, amenorrhoea), depression (through needing treatment for self-harm), hyperactivity and other behavioural disorders (e.g. due to frequent visits to casualty following dangerous and impulsive acts).

CONDUCT DISORDER

Prevalence

From the preschool period to middle childhood, there is a decrease in the frequency of temper tantrums and oppositional behaviours. Oppositional problems occur in 5–10 per cent of non-clinical samples. In the Isle of Wight study, Rutter and colleagues found an overall prevalence for conduct disorder of 4.2 per cent among 10- and 11-year-olds. The Ontario Child Health Survey found a rate of 5.5 per cent in 4- to 16-year-olds, while the Christchurch and Dunedin longitudinal study found a rate of 3.4 per cent among 15-year-olds. Little information exists from studies in non-industrialized countries, although available evidence suggests that much lower rates of conduct and other behavioural disorders are found. Conduct disorder is more common in boys than girls. Although the majority of studies find that conduct disorders are more common in an urban than a rural setting, some have not found this urban/rural split.
Aetiology

The three most significant associated factors found in the Ontario Child Health Survey were family dysfunction, parental psychopathology and low income (which had a greater effect on children aged 4–11 years than on adolescents). Conduct problems are associated strongly with other disruptive behaviour problems (including ADHD, delinquency and substance misuse), certain internalizing disorders (particularly depression and anxiety), specific developmental disorders, low IQ, family discord, large family size and parental psychopathology.

Presentation

Presentation may be with persistent antisocial behaviour such as fighting, stealing, destruction of property, fire-setting, truancy, cruelty (e.g. to animals), lying and lack of remorse. Conduct disorder can be situation-specific or more pervasive (which is usually more serious). It can also be subdivided into socialized (acts performed along with a peer group) and unsocialized (acts performed alone, which is usually a more serious disorder).

Treatment

With much evidence suggesting an important causal role in the quality of parenting and caregiving, it is not surprising that interventions targeted more towards the parent/carer rather than the young person with the diagnosis are the most common and for which the most evidence for effectiveness is available. Popular parent management training (PMT) programmes include the approaches developed by Patterson and Guillon and the group approach developed by Webster-Stratton. These PMT programmes draw on operant-behavioural and cognitive-behavioural approaches involving developing consistent strategies that reward desired behaviours and ignore or provide negative consequences for undesired behaviours. Approaches that draw on a wider theoretical approach are more popular for use with families of adolescents with conduct disorders. These include functional family therapy, multi-systemic therapy and the seven-steps programme. Other approaches with some supportive evidence include school-based interventions and the use of therapeutic foster care. There is little evidence to support the use of individual therapy (e.g. anger management) on its own or medication on its own.

Outcome

In the classic study by Robins, 45 per cent of children with conduct disorders went on to develop an antisocial personality disorder. Disturbance of conduct is a significant risk factor for substance use. Those individuals who manifest disturbances of conduct earlier in life go on to commit more severe criminal offences. There is a high continuity between failure in school associated with conduct problems and adult unemployment.

Hyperactivity disorders

Prevalence

The American Psychiatric Association estimates the rate of ADHD in school-age children (5–18 years) to be between 3 per cent and 5 per cent. Screening with behavioural questionnaires identifies 10–20 per cent of the population as affected. When more stringent ICD-based criteria are used, about 0.5–2 per cent prevalence rates are found. ADHD occurs much more frequently in males than females, with a ratio of 3–4:1 from population-based studies. Lower rates have been reported in studies in some developing countries.

Aetiology

It is often claimed that hyperactivity disorders including ADHD have a primarily genetic basis, albeit through being at the pathological extreme of a normal distribution. However, this claim is contested (see Aetiology of child psychiatric disorders, above). In addition, population twin studies find that symptoms of ADHD share overlapping familial and genetic influences with other neurodevelopmental traits, including reading ability, general cognitive ability, dyspraxia and symptoms of pervasive developmental disorders. ADHD in children and adolescents is also associated with impaired family relationships, higher rates of family conflict, being in foster care, and poverty/lower social class.

Presentation

ADHD describes a constellation of poor concentration, hyperactivity and impulsiveness that has been present from an early age. These behaviours must be present in at least two situations (e.g. home and school), associated with impairment of social or academic functioning, present before the age of 7 years and not explained better by another disorder. ICD criteria are more stringent; unlike the DSM, however, the ICD has a category for hyperkinetic conduct disorder, reflecting the common association of hyperactivity with antisocial behaviour. Co-morbidity is high: 30–50 per cent of children with ADHD have co-morbid conduct disorders, 15–75 per cent have a mood disorder, 25 per cent have an anxiety disorder, 40 per cent have oppositional defiant disorder, and 50 per cent have speech or language impairments.

Treatment

Recent years have witnessed a phenomenally rapid increase in the use of stimulant medication, usually methylphenidate.
in its various forms, from short-acting to long-acting preparations. Although effective in reducing ADHD symptoms in the short term, emerging evidence has cast doubt on the long-term effectiveness of stimulants, which, together with increasing concern about risks associated with their use, is likely to result in a more limited role for psychoactive medication in the management of ADHD in coming years. Other treatment approaches include PMT, behavioural therapy, elimination diets and essential fatty acid supplementation.

Outcome

The factors found in childhood to be the most highly predictive of a poor outcome include a family history of ADHD or hyperkinesis, psychosocial adversity and co-morbidity with conduct, mood and anxiety disorders.

SCHOOL-ATTENDANCE PROBLEMS

Prevalence

Non-attendance at school may be the result of truancy (which is often associated with a conduct disorder) or school refusal (which is often associated with an emotional disorder). School refusal affects approximately 1 per cent of school children across the primary and secondary school levels. Truants are more commonly male, whereas school refusal is equally common in boys and girls. There are three main incidence peaks for school refusal: at age 5 years (school entry often associated with separation anxiety), at age 11 years (most common age when transfer from primary to secondary school occurs) and at age 14–16 years.

Aetiology

Truants are associated with having other antisocial symptoms, a family history of antisocial behaviour, academic or learning difficulties, and a large family size. School refusers are associated with having other emotional symptoms, a family history of anxiety, satisfactory to good academic performance, and a smaller family size. In some children, school refusal is associated with a wish to stay at home (e.g. due to concerns about the wellbeing of a parent) rather than a wish to avoid school.

Presentation

In school refusal, there is an inability to go to school or stay in school associated with extreme anxiety. Somatic symptoms may occur that are sometimes fictitious in order to avoid going to school.

Treatment

Problems at school, such as bullying and learning difficulties, need to be dealt with. Treatment then focuses on getting the child back to school as soon as possible. If there is a chronic problem, then a carefully planned graded return involving support from other agencies such as school and education welfare is often required. Little and often is usually better than leaving large gaps between days spent at school. Supplementary interventions for specific problems may also be needed.

Outcome

Prognosis is usually good, particularly in younger children and with successful early intervention.

EMOTIONAL DISORDERS SPECIFIC TO CHILDHOOD

These include anxiety disorders, depression, somatization and conversion disorders.

Prevalence

The Isle of Wight study found a prevalence of 2.5 per cent for emotional disorders in 10- and 11-year-olds. The Dunedin and Christchurch longitudinal studies found a prevalence of anxiety disorders of 7 per cent at age 11 years, with this figure rising to just under 20 per cent by age 18 years. Anxiety disorders are equally frequent in boys and girls until adolescence, after which there is a predominance of girls. Children with separation anxiety disorder (SAD) usually present at a younger age. Although SAD becomes less common as adolescence is approached, generalized anxiety disorder (GAD) then becomes more frequent. Panic disorder is rare before puberty. Post-traumatic stress disorder among at-risk child populations (e.g. who have been exposed to violence or trauma) has been found to have prevalence rates of 3 per cent to 34.5 per cent. Depression is rare in pre-adolescents. Unexplained somatic symptoms are common in children: 2–10 per cent of children experience aches and pains that are mostly unexplained.

Aetiology

As with all child psychiatric disorders, no clear causal pathways have been identified, and aetiology is considered multifactorial. Factors associated include genetics through temperament (early traits of shyness and passivity), parenting style (e.g. high expressed emotion), parental anxiety, traumatic life events and social adversity.

Presentation

SAD presents as a preoccupying worry that something may happen to the principal attachment figure or figures or that
something may lead to the child being traumatically separated from them. About 75 per cent of children with SAD present with school refusal. Other common associated symptoms include nightmares, social withdrawal and unexplained physical symptoms. Phobic disorders include specific fears (e.g. of animals or the dark), which usually resolve spontaneously, and more generalized fears in older children (e.g. social phobias and school phobias), which may not resolve and can evolve into a GAD.

**Treatment**

Anxiety disorders are more commonly treated among children in middle- and upper-class families, despite being more common in lower social classes. Treatment is usually with psychosocial therapeutic approaches, including cognitive-behavioural therapy (CBT), family therapy, anxiety management, modelling, in vivo exposure and relaxation training.

**Outcome**

The outcome depends on several factors, including the presence of co-morbidity and severity. Up to 80 per cent of children with anxiety disorders go into remission during the first year after developing symptoms. Nearly all children with SAD recover; however, some children with GAD who are more severely affected may go on to develop other anxiety disorders that persist into adulthood.

**DEPRESSION, OBSESSIVE-COMPULSIVE DISORDER AND SCHIZOPHRENIA IN ADOLESCENCE**

Adolescence is generally thought of as the period that extends from the onset of puberty to the attainment of physical maturity (i.e. about 12–20 years). During adolescence, there are rapid biological and psychological changes and a need for intensive readjustment to family, school, work and social life. The multiplicity of changes includes physical, cognitive, social and emotional changes. Factors that contribute to poor adjustment include poor peer relationships, poor family relationships and support, unresolved childhood disorders, low motivation for changing, social disadvantage, family breakdown, brain injury and poor scholastic achievement. Adolescence is essentially a social construction. It is primarily culture rather than biology that decides when adolescence begins and ends, what behaviour is appropriate during this time, when sexual behaviour such as dating and sexual intercourse is accepted, how normal turmoil, unhappiness, rebellion and antisocial behaviour are, how much responsibility young people should be given, and so on.

A widely held view is that from mid-puberty onwards, people in their teens can suffer from psychiatric disorders that are more similar to those seen in adults than in earlier ages.

**Depression**

**Prevalence**

Findings in the Oregon Adolescent Depression Project show that the cumulative prevalence of major depressive disorder (MDD) up to age 18 years is 28 per cent (35% for girls, 19% for boys). The Dunedin and Christchurch longitudinal studies identified 6.6 per cent of their sample of 15-year-olds as meeting criteria for mood disorder. By age 18 years, this had increased to 22.1 per cent. Depressive disorders are equally frequent in boys and girls until adolescence, after which (from age 14 years) there is a predominance of girls. There is evidence from both clinical studies and population surveys that mild to moderate depressive disorder is becoming more common and beginning earlier. Figures on prevalence are complicated by a rapid change in the way child and adolescent depression has been conceptualized. Before the late 1980s, childhood depression was viewed as very rare, different from adult depression, and not amenable to treatment with antidepressants. A shift in theory, and consequently practice, then took place as influential academics claimed that childhood depression was more common than previously thought (8–20% of children and adolescents), resembled adult depression, and was amenable to treatment with antidepressants (often resulting in antidepressants becoming a first-line treatment).

**Aetiology**

Important influences include family environment, including depression in parents, marital disharmony, depressive temperament and personality, and chronic adversity. Comorbidity is the rule rather than the exception and is probably explained by common risk factors, such as family adversity. Anxiety and conduct disorders are the most commonly associated disorders.

**Presentation**

The diagnostic criteria for depressive disorder in children and adolescents are the same as those for adults. Depressive disorders are partly defined by somewhat arbitrary reference points on a continuum of sadness, lethargy and pessimism. A diagnosis of MDD in children and teenagers requires a minimum 2-week period of pervasive mood change towards sadness or irritability, and loss of interest or pleasure. There needs to be a clear change in functioning, accompanied by impairment in social or other role performance. Diagnosis of major depression also requires the presence of some biological characteristics, such as loss of appetite, insomnia, and reduced energy or libido in adolescents. Children tend to show more anxiety and anger, fewer vegetative symptoms and less verbalization of hopelessness than do adults.
Treatment
Of particular importance is assessment of suicidal risk (which, if significant, is an indication for in-patient treatment). In general, the more severe the symptomatology and the degree of impairment, the more urgent the necessity for early commencement of treatment. There is good evidence to support the use of psychological therapies as the primary treatment modality, including CBT, interpersonal therapy and family therapies. Although the use of selective serotonin reuptake inhibitors (SSRIs) for childhood depression became popular during the 1990s and early twenty-first century, following the discovery that drug companies had been manipulating both the data and conclusions most reviews have concluded that SSRIs confer little if any benefit to under-eighteens with depression at the same time as exposing them to small but significant risks, in particular of precipitating suicidal ideation. The 2005 National Institute for Health and Clinical Excellence (NICE) guidelines on childhood and adolescent depression recommend only fluoxetine to be used and only if the patient has not responded to psychological approaches after a period of 3 months.

Outcome
Most patients recover within a few months. A small proportion of patients go on to have a more chronic relapsing course, although a larger proportion may experience sub-threshold symptoms. It has been argued that childhood depression is a precursor of adult depression, however, the reliability of this claim has been disputed.

Obsessive–compulsive disorder
Prevalence
Obsessive–compulsive disorder (OCD) is an uncommon condition in childhood, with an overall point prevalence of 0.25 per cent. It is extremely rare in young children, but the point prevalence rises to 0.6 per cent in 13- to 15-year-olds.

Aetiology
Although brain imaging studies in adults and children show evidence of central nervous system abnormalities, successful treatment, including psychological treatment, results in a return to ‘normal’ morphology and metabolic activity, suggesting that brain imaging abnormalities reflect the effects of an OCD mental state as opposed to its cause. Rates of OCD are about four times greater in relatives of index cases.

Presentation
OCD symptoms fall into four main groups: checking and ruminations, fear of contamination, symmetry and ordering, and hoarding (rare in childhood and adolescence). OCD seems to present at two stages: in the early school years (when boys predominate) and in adolescence (which is more common and when girls predominate).

Treatment
First-line treatment is psychological and involves behavioural techniques such as exposure and response prevention (ERP). Training parents to supervise ERP is used particularly with younger children. Other components that can be added to ERP include cognitive strategies and relaxation. Second-line treatment includes medication, particularly fluoxetine or clomipramine. Medication should be started at a low dose, with careful monitoring, particularly early in treatment, for possible side effects.

Schizophrenia
Prevalence
Psychosis is extremely rare before 13 years of age. After age 13 years, the incidence rises rapidly during adolescence, reaching a peak incidence at around 25 years of age. The teenage population prevalence is about 2–3 per 1000. There is a slight excess of males in early-onset psychosis.

Aetiology
Developmental abnormalities, dyspraxia, dyslexia, and speech and language disorders are more common in people who subsequently develop early-onset schizophrenia. A number of conditions that can cause neurological impairment, such as tuberous sclerosis, partial complex seizures and leukodystrophies, are associated with an increased likelihood of developing a psychosis or psychotic symptoms. Together, these suggest a pre-existing neurological vulnerability in at least some patients who subsequently develop a psychosis. Although claims have been made that schizophrenia is a neurological condition associated with a pattern of progressive grey-matter loss, leading (for example) to increase ventricular size, most studies have not controlled properly for the effects of antipsychotics, which also cause atrophy of the brain, and international follow-up studies find a more positive prognosis than previously thought. A growing body of literature has also found a strong association between a history of trauma or abuse in childhood and subsequent psychosis in later life. Thus, schizophrenia is now thought of as a more heterogeneous group of disorders.

Presentation
Schizophrenia is characterized by distortions of thinking and perception, delusions, hallucinations, and disorganized or unusual behaviour. Negative symptoms such as apathy, social withdrawal, poverty of speech and incongruent emotional responses may also be present, but these are rarer in younger patients. In children and adolescents, scholastic...
ability and self-care may be affected and could be the first signs of a developing psychosis.55

**Treatment**

There is a lack of clear empirical evidence on which to base treatment-planning. However, as child-, adolescent- and adult-onset schizophrenia have many similarities and continuities, using the adult literature has predominated, with treatment strategies being aimed at symptom control, minimizing long-term effects and preventing relapse.60 In addition to using antipsychotic medication such as risperidone or olanzapine for acutely distressed patients and as a maintenance to prevent relapse, and/or a benzodiazepine such as lorazepam to aid with stabilization of acutely distressed patients, early intervention, psychosocial and psychoeducational approaches have received increasing attention. For example, a broad international, largely user-inspired movement, known as the ‘recovery movement’, helps patients by focusing on how to manage their lives and regain a sense of ‘citizenship’ in order to combat the problems of social exclusion, stigma and therapeutic nihilism.

**Outcome**

Although one study found that 80 per cent of 51 adolescents diagnosed with schizophrenia still had the diagnosis several years later,129 the majority of studies have found that 50 per cent or more of adolescents diagnosed with schizophrenia are found to have no illness or a different, less severe, diagnosis on follow-up.125

**ANOREXIA NERVOSA**

**Prevalence**

A median prevalence rate for eating disorders in the 15–20 years age group is estimated at 1.2–1.4 per 1000.130 This figure relates to young people in the developed Western world; eating disorders are much less common in non-affluent societies. The distribution of childhood-onset anorexia nervosa between social classes seems to be fairly similar to that in adults, with an overrepresentation of higher social classes.131 The condition is rare at age 12 years but reaches about 1 in 200 girls at age 16 years. There is evidence that both anorexia nervosa and bulimia nervosa are becoming more common and more evenly distributed in social class.132

**Aetiology**

Like most child psychiatric disorders, eating disorders are conceptualized as having multifactorial causation, including biological vulnerability, sociocultural factors and adverse life events. Heritability is high in anorexia but not so with bulimia nervosa. The uneven distribution of eating disorders across populations suggests an important role for prevailing societal attitudes to female body image and size in the context of changing gender roles. Reports of anorexia nervosa in adults and children from African, Asian, Caribbean and Chinese populations suggest that an increasing incidence in these populations is related to exposure to and adoption of Western values.55

**Presentation**

Anorexia nervosa is characterized by self-induced weight loss leading to low weight (typically below 85% expected weight or a body mass index (BMI) of less than 17.5), fear of fatness or weight gain, disturbed body image, and amenorrhoea in postmenarchal females. Bulimia nervosa is characterized by recurrent episodes of binge eating; a preoccupation with eating, often including compulsions to eat; and compensatory behaviours to reduce weight, such as dietary restriction between binges, self-induced vomiting, excessive exercise and laxative abuse. In both conditions, body weight and shape become central to self-evaluation. The disorders occur mainly in females, although 5–10 per cent of cases in adolescents and young adults occur in males. Anorexia nervosa and bulimia nervosa are rare in younger children.80

**Treatment**

Treatment is usually a mixture of psychological therapies, particularly family therapy, together with medical management of physical consequences of low weight and a weight-restoration programme. Typically, a minimum target weight of 95 per cent of expected average body weight is aimed for.132 In cases of amenorrhoea secondary to weight loss, the return of a regular menstrual cycle is a good indication of a return to a physiologically healthy weight. There is no robust evidence to demonstrate that in-patient treatment achieves better outcomes than out-patient treatment;133 however, in-patient admission may be preferred in patients who are at a dangerously low weight in order to manage and monitor their physical state in a safe environment.

**Outcome**

Predictors of good outcome include healthy family functioning and a severe negative life event as precipitant.134 A long-term follow-up study found that two-thirds of people who had an adolescent eating disorder were free of it 10 years later, although about half had a different psychiatric disorder.135 Mortality in anorexia nervosa with an age of onset before 18 years is up to 11 per cent, with a mean mortality of 2.16 per cent across studies.80
DELIBERATE SELF-HARM IN ADOLESCENCE

Prevalence

In the Western world, suicide is extremely rare before age 14 years, rises rapidly in mid- to late adolescence, and then remains steady until another rise in old age. Suicide increased in males from the 1960s to the 1990s, but then it began to reduce again. It is much more common in boys than girls, occurs mainly in males with a history of aggression, and often occurs when the young person is intoxicated.\textsuperscript{136} Surveys show an overall adolescent attempted suicide rate in Western countries of 8–9 per cent, with a rate of 2–3 per cent requiring medical attention.\textsuperscript{136} Suicidal ideation is common in teenagers, with rates of about 15–20 per cent.\textsuperscript{137}

Aetiology

Self-harm is most strongly predicted by the presence of depressive disorder (in girls) or by a previous suicidal attempt (in boys). Other influences include stress, co-morbid psychiatric disorders (such as depression), family conflict, previous self-harm, a family history of suicide or self harm and perinatal morbidity; sometimes, exposure to knowledge about other actual or fictional suicides can result in mini-epidemics of copycat behaviour.\textsuperscript{136}

Presentation

Deliberate self-harm is the most common cause of admission of young people to a general hospital ward and is much more common in females than in males. The most common method is ingestion followed by cutting (although cutting has increased in frequency in recent years). Although preplanning of a suicide attempt has been considered an indicator of intent, research has shown little correlation between preplanning and successful suicide in youth.\textsuperscript{137}

Treatment

Admission to a medical/paediatric unit is often needed for treatment of any physical complications (such as poisoning) or to an adolescent in-patient unit for assessment and treatment of any coexisting psychiatric disorders (such as depression with suicidal ideation). On discharge, the young person and their parents may require advice on staying safe, such as keeping tablets and knives out of reach at home. Further treatment should be arranged to treat any co-morbid psychiatric disorders.

Outcome

The prognostic significance of a suicide attempt ranges from benign to serious, with later completed suicide. This heterogeneity of outcome has made prediction and classification of self-harm problematic. Predictors of recurrence after an attempt include male sex, use of a method other than pills or cutting, persistent suicidal ideas, psychotic symptoms, complications arising from substance abuse or alcohol consumption, a history of previous attempts, and having no adult guardian to supervise them on discharge.\textsuperscript{136}

SUBSTANCE MISUSE

Prevalence

It is difficult to give precise prevalence rates, as these vary between countries and within countries over time. In addition, variations in methods of assessment, definition and population studied make comparing the findings of epidemiological studies problematic. However, there appear to be some broad generalizations that can be made from studies on children and adolescents in the past couple of decades in Europe and North America:\textsuperscript{138}

- Alcohol and nicotine are the most frequently used substances, closely followed by marijuana, with inhalants (e.g. glue-sniffing), amphetamine, ‘downers’ (e.g. sleeping pills) and hallucinogens. Cocaine and opiate use is generally rare in under-eighteens, although this may be changing.
- Between one-half and three-quarters of older adolescents have tried an illicit drug.
- 20–40 per cent of those who have used drugs have tried more than one.
- About 1 in 12 of those who take drugs are regular or heavy users.
- Illicit drug use is uncommon in children under the age of 12 years but becomes more frequent during the teenage years.
- Drug use overall is about as common in girls and boys, but there are gender differences in the types of drug used.
- Overall, drug use in young people increased during the 1990s.
- Drug use is more frequent among young people with poor scholastic achievement.

Aetiology

Predisposing factors include environmental factors (e.g. widespread availability of drugs, poverty, parental substance misuse, use of drugs among peers, family conflict, scholastic failure) and individual risk factors (e.g. low self-esteem, persistent behaviour problems, co-morbid psychiatric disorder).\textsuperscript{139} Protective factors include easy temperament, good intellectual ability and supportive family and social circumstances.\textsuperscript{139}

Presentation

Adolescents who misuse substances differ from adults who do this in a number of ways: they have shorter drug
Mental handicap and developmental disorders

1065

Part 6: Clinical specialties

histories, less involvement with certain drugs (particularly opiates), more binge drinking and more polydrug use. ICD-10 uses the following subdivisions for substance misuse:

- **Acute intoxication**: resulting in a disturbed level of consciousness.
- **Harmful use**: a pattern of psychoactive substance use that is causing physical or mental damage to health.
- **Dependence**: a cluster of behavioural, cognitive and physiological phenomena that develop after repeated and regular substance use.
- **Withdrawal state**: a group of symptoms occurring on absolute or relative withdrawal of a substance after persistent use of that substance.

**Treatment**

Treatment begins with prevention, such as reducing or eliminating exposure and decreasing risk factors. Treatment of people with a substance-misuse problem often includes multi-agency involvement, such as education, child and adolescent mental health services, youth offending, social services, accident and emergency departments, and drug and alcohol services. A variety of individual, educational, family and group approaches, including psycho-education, motivational interviewing, detox regimes and specific substance-misuse treatment programmes, exist. Physical problems associated with alcohol and drug misuse, such as poor nutrition, overdose, severe intoxication, human immunodeficiency virus (HIV) and hepatitis, also need treatment.

**Outcome**

The younger people are when they first use drugs, the more likely they are to progress from experimental usage to dependence. Longitudinal studies have shown that considerable risks are associated with substance misuse, especially with respect to suicide, accidental deaths, delinquency, depression and psychosocial dysfunction more broadly.

**MENTAL HANDICAP AND DEVELOPMENTAL DISORDERS**

**Generalized mental handicap**

Table 70.1 shows levels of mental handicap based on ICD-10.

**Prevalence**

The use of an IQ below 70 as the sole criterion would result in prevalence rates of 2–3 per cent, based on a normal distribution curve. However, if some degree of impairment is added as a criterion, then prevalence reduces to about 1 per cent. In the Isle of Wight study, 2.5 per cent of children could be classified as having mental retardation, but about 1.3 per cent had impairments sufficient to require services. In the Aberdeen study of 8- to 10-year-olds, the rate was 2.4 per cent for mental retardation but 0.9 per cent when impairment was added. When compared with the general population, individuals with mental retardation are at much greater risk for having a psychiatric disorder or severe emotional or behavioural dysfunction.

**Aetiology**

Historically, researchers have described two groups. One group demonstrates a clear biological cause for their developmental delay; the other has no clear cause and tends to be thought of as part of a continuum in the normal distribution. Although there is not a comprehensive model to explain the increased rate of psychiatric disorder in this population, the following factors are associated with psychopathology in people with mental retardation: atypical motivational styles, increased risk of failure experiences, less differentiated self-concepts, re-enforcement of negative behaviours, poor communication skills, lack of assertiveness skills, peer rejection, compromised social intelligence, family stress, increased rates of seizure disorders, abnormal neurological functioning, and higher than usual risk of genetic anomalies.

**Presentation**

Diagnosis rests primarily on the use of formal measures of intellectual functioning. However, use of IQ as the sole criterion is problematic, as many people in the mild mental retardation range have no adaptive impairments, cope relatively well with the demands of daily life, and therefore do not come to the attention of professionals. People with accompanying psychopathology often present with emotional or behavioural difficulties, coupled with learning difficulties at school.

**Treatment**

In addition to diagnosing and treating any accompanying physical disorder (such as epilepsy), treatment for accompanying psychopathology is similar to treatment of people...
without mental retardation, but with some modifications to take into account the patient’s level of functioning and communication. A variety of psychosocial interventions, including behaviour therapy, psychotherapy, systemic interventions and educational interventions, as well as psychopharmacology have been found to be helpful.\textsuperscript{144}

\textbf{Outcome}
The majority of people with mild mental retardation go on to live independently and successfully. The more severe the retardation, the greater the likelihood that further support and input from a variety of services will be required.

\section*{Specific delays in speech, language and reading}

\textbf{Prevalence}
Specific delays in speech and language are common, with an estimated incidence of 3–10 per cent.\textsuperscript{145} Estimates of the incidence of specific reading difficulties range between 1 per cent and 9 per cent.\textsuperscript{146} Accurate estimates are difficult due to disagreements about cut-off points between ‘normal’ and delayed.

\textbf{Aetiology}
Most theories on aetiology assume a biological cause for the delay, although this is complicated by what some authors refer to as a ‘cult of developmentalism’, resulting in an unnecessarily rigid focus on age-specific developmental tasks, which can cause considerable anxiety to parents and educators and introduce competitiveness into child development from a very early age. This makes a more relaxed approach to development, which accepts the different rates at which different individuals develop, much harder to achieve.\textsuperscript{60,147}

\textbf{Presentation}
Specific developmental disorders are differentiated from pervasive developmental disorders and general learning difficulties (mental handicap) by having an overall IQ above 70 or a non-verbal IQ above 70 for developmental disorders of speech and language. These children’s difficulties are out of line with what is expected for their age and general cognitive difficulties. They include speech and language delays, specific reading difficulties (dyslexia), spelling difficulties (dysgraphia), arithmetic problems (dyscalculia), and problems with motor coordination (dyspraxia). Disorders of speech and language are often associated with a wide range of academic, social, emotional and behavioural problems.\textsuperscript{148}

Increased prevalence of almost all specific developmental disorders has been found in children presenting with a psychiatric disorder.\textsuperscript{149} Most studies find three to four times more boys with specific developmental delays; however, this may be a reflection of coexisting behavioural problems making boys more likely to receive a referral for extra help at school.\textsuperscript{150}

\section*{Treatment}
Treatment is largely educational and includes speech therapy and extra assistance at school, such as an individual education plan or, in more severe cases, a statement of special educational needs.

\textbf{Outcome}
Many children are simply ‘late developers’ and catch up over time. In a study of 4-year-olds with poor language, most of whom were receiving speech therapy, about half no longer had these difficulties by the time they were 5.5 years old.\textsuperscript{151}

\section*{Pervasive developmental disorders (including autism and Asperger’s syndrome)}

\textbf{Prevalence}
A study in preschool children found a rate for ASD of 45.8 per 10 000 children.\textsuperscript{152} The National Autistic Society, using an estimated prevalence of 91 per 1000 of the population, estimates that there are around 535 000 people with ASD in the UK and claims that the majority of these may go undiagnosed.\textsuperscript{153} ASDs are three to four times more common in males than females.

\textbf{Aetiology}
A specific medical cause is found in only a minority of people with autism, albeit more often in those with pronounced learning problems. Epilepsy occurs more commonly than usual in autism, particularly in people with moderate to severe learning difficulties. Evidence points to genetic factors playing a role in causing ASD, with twin and family studies suggesting an underlying genetic vulnerability to ASD; however, this conclusion has been criticized (see Aetiology of child psychiatric disorders, above). Postmortem and brain scan studies have shown that a number of brain structures may be implicated in autism, although there is no consistent finding or core pathology identified. Severe deprivation (as described in some Romanian orphanages) is also associated with significant developmental delay and autistic patterns of behaviour.\textsuperscript{144}

Thus, autism is a phenomenological rather than an aetiological diagnosis. It describes a behavioural phenotype that may be arrived at by numerous different aetiological pathways, operating by mechanisms that we do not understand. Furthermore, some authors have pointed out that our changing concept of autism owes more to ideological shifts expanding the notion than to new scientific knowledge.\textsuperscript{155,156}

\textbf{Presentation}
Autism is a behaviourally defined disorder, characterized by qualitative impairments in social communication, social interaction and social imagination (the core triad of symptoms), with a restricted range of interests and often stereotypic repetitive behaviours and mannerisms. Sensory
hyposensitivities or hypersensitivities to the environment are also common. In DSM-IV, autism is classified as belonging to the pervasive developmental disorders (PDD). There are five subcategories listed under PDD:

- **Autistic disorder.**
- **Asperger’s syndrome:** relatively good verbal language, with milder non-verbal language problems, and restricted range of interests and relatedness.
- **PDD-NOS:** non-verbal language and other problems that do not meet the strict criteria for other PDDs.
- **Rett’s disorder:** a rare X-linked dominant progressive neurodevelopmental disorder of girls, with poor head growth and microcephaly (prevalence: 1 in 10 000 children). Clinical features include rapid deterioration of behaviour and language, loss of purposeful hand movements, progressive spasticity and ataxia, acquired microcephaly and seizures.
- **Childhood disintegrative disorder:** a rare neurodegenerative disorder (prevalence: 1 in 10 000 children). There is a loss of functioning after 2 years of normal development, with regression of language, social skills, adaptive skills, play, motor skills and continence.

In common practice, Rett’s disorder and childhood disintegrative disorder are often considered mainstream medical disorders and are not usually dealt with within services for ASD.

**Treatment**

Medical examination and investigations are usually required to detect or exclude known organic causes (e.g. hearing problems, tuberous sclerosis), assess neurological deficits, and test for known chromosomal abnormalities such as fragile X syndrome. There are no specific treatments for autism. Treatment for autism is geared largely towards management and support of the associated difficulties that it produces for the individual and their family, with a few requiring multi-agency lifelong integrated care. Behavioural, educational and dietary interventions are used widely. Medications are often used to help families manage behavioural problems, such as aggression, self-injurious behaviour, obsessive–compulsive symptoms and tantrums, which keep the person with ASD from functioning more effectively at home or school. However, the use of medications remains controversial, as there is little evidence to support their producing improved outcomes while exposing children to side effects.

**Outcome**

Although outcome studies in autism suggest that the disabling features and cognitive style are lifelong, the current fashion for retrospectively diagnosing the great and the good as having had autism (e.g. Einstein, Newton) suggests that at least people some can look forward to exceptionally good outcomes. The fact that IQ levels are the best predictor of future ability to undertake a job and live independently casts doubt on the usefulness of adding autism as a diagnosis for some children.

---

**ENURESIS AND ENCOPRESIS**

**Enuresis**

**Prevalence**

At the age of 7 years, 15–22 per cent of males and 7–15 per cent of females were found to have nocturnal enuresis. By 18 years, about 1 per cent of males and a lower proportion of females were found to have nocturnal enuresis.

**Aetiology**

Nocturnal enuresis tends to run in families, as 70 per cent of affected children have a parent or sibling who was late in becoming dry. Nocturnal enuresis is twice as common in MZ than in DZ twins. Other factors may include lack of vasopressin release during sleep or nocturnal insensitivity of renal tubules to vasopressin, incoordination of voiding mechanisms, reduced functional bladder capacity, developmental delay (e.g. late puberty), urinary tract infection or obstruction, and constipation. Environmental factors include stressful life events, social disadvantage, larger family size, teenage pregnancy and mother’s smoking.

**Presentation**

The presentation is characterized by involuntary voiding of urine, by day or night, which is abnormal in relation to the individual’s mental age and is not a consequence of a lack of bladder control due to any neurological disorder, to epileptic attacks, or to any structural abnormality of the urinary tract. The condition is generally not diagnosed in children under the age of 5 years or in people with a mental age of less than 4 years.

**Treatment**

After excluding physical causes, management can include education, a behavioural programme, enuresis alarms, desmopressin and tricyclic antidepressants.

**Outcome**

Nocturnal enuresis rarely leads to any lasting problems and is not considered an indicator for mental health problems in later life.

**Encopresis**

**Prevalence**

Most Western children achieve faecal continence in their second year. Faecal incontinence occurs in about 10 per cent of 3-year-olds, less than 5 per cent of 4-year-olds and 1.5 per cent of 5- to 7-year-olds. At 10–12 years, faecal incontinence occurs in 1.3 per cent of boys and 0.3 per cent of girls. It is very rare after 16 years.
Aetiology

Faecal incontinence may be an abnormal continuation of normal infantile incontinence, be secondary to a medical problem (e.g., constipation, which can in itself be caused by physical or psychological factors), be a monosymptomatic disorder secondary to psychological factors, or be part of a wider psychiatric disorder (e.g., emotional disorder or conduct disorder). Encopresis is also associated with other developmental delays such as enuresis, sensorimotor incoordination, slow language development and learning disability.159

Presentation

Presentation is with repeated voluntary or involuntary passage of faeces in places not appropriate for that purpose. The frequency needs to be more than once a month for the diagnosis to be made, and it should not be attributable to a general medical condition.

Treatment

Diagnosis and treatment of organic factors (e.g., constipation) is required. Advice on toilet routine is often used as is appropriate management of any coexisting psychiatric disorder. Particular therapeutic strategies such as externalizing the symptom have also been used successfully.160

Outcome

Encopresis usually resolves spontaneously before adolescence. Poor outcomes are associated with developmental disorders, learning difficulties, non-compliance with treatment, disorganized or chaotic family life, and serious social disadvantage.161

TIC DISORDERS

Prevalence

Transient tics are commonplace among children, with community surveys indicating that 1–13 per cent of children manifest twitches, tics or other mannerisms at some time, with the highest prevalence being in children aged 7–11 years.162 Tourette’s syndrome is rare, with a prevalence rate of about 4.5 per 10 000 among 16- and 17-year-olds, according to the largest study to date.163

Aetiology

The aetiology of tics and Tourette’s syndrome remains unknown. Popular aetiological theories for Tourette’s syndrome include genetic and perinatal difficulties.164

Presentation

Transient tics are characterized by one or more simple motor tics, usually confined to the face or neck, which wax and wane in severity over the course of weeks or months. Tourette’s syndrome typically begins in early childhood with bouts of simple motor tics such as eye-blinking or head-jerking. These tics eventually become more persistent and can incorporate virtually any voluntary movement of any portion of the body. Complex motor tics may appear, as may phonic tics such as throat-clearing, grunting, and more complex phonic tics such as coprolalia (excessive and uncontrollable use of foul or obscene language). Tourette’s syndrome has a high co-morbidity, particularly with ADHD and OCD.164

Treatment

Transient tics resolve spontaneously and thus require no treatment. Tourette’s syndrome is treated with supportive psychotherapy and psychoeducation, which is usually sufficient for the majority of patients. Where the child’s symptoms are causing significant impairment in day-to-day functioning, other treatments aimed at controlling the involuntary movements may be indicated, including CBT and medication such as haloperidol, sulpiride, risperidone or clonidine.164

Outcome

In Tourette’s syndrome, the worst severity has been found to occur at about 10 years of age, with about half of those afflicted being virtually symptom-free by 18 years of age.165

FAMILY CONFLICT PROBLEMS

Family conflict does not represent a diagnostic category, but it is associated with a wide variety of adverse outcomes. For example, marital conflict is associated with child and adolescent behaviour problems, including aggression and poor social functioning,166 and has also been found to predict later depressive symptoms, delinquency, alcohol problems,167 lower levels of closeness to parents, poor self-esteem, and higher levels of distress and violence in the offspring.168 Assessing the impact of family conflict is complicated by the large cultural variations found in family structure, parenting beliefs and practices, and availability of resources, which thus need to be taken into account in any assessment and treatment.5 Family therapy approaches (see Aetiology of child psychiatric disorders, above) are the most common therapeutic methods used to try to alleviate family conflict.

CONTINUITIES OF CHILDHOOD PSYCHIATRIC DISORDER INTO ADULT LIFE

The literature on continuities of childhood psychiatric disorder is at an early stage, due to the practical and
methodological challenges involved in setting up the type of longitudinal research required. Below is a summary of some of the emerging findings.

**Anxiety disorders**

Overall, the history of any anxiety disorder in childhood or adolescence is associated with a significant increase in risk for an anxiety disorder occurring in adult life, although the specificity for the same condition recurring is low. A history of a child or adolescent anxiety disorder also increases the risk of substance misuse, poor socialization, depression and educational underachievement; however, the majority of affected children have a good prognosis, being virtually indistinguishable from well controls at follow-up.

**Depression**

Clinical follow-up studies have shown that adolescent depression is associated with a high risk of depressive relapse extending into the third decade. The risk of recurrence was unaffected by co-morbid diagnoses. Those with depression and conduct disorder also had increased rates of suicide, alcoholism, substance misuse and antisocial personality disorder. The relationship between cause and effect is difficult to establish. For example, poor social adjustment in adults is associated with recurrent adolescent depressive episodes and could be a function of the effects of depression or of persistent adverse social circumstances leading to depression.

**Obsessive–compulsive disorder**

Unlike anxiety disorders, OCD in childhood, should it recur, tends to recur as OCD. As many as one-half of those with childhood OCD have recurrent episodes into adult life. Other co-morbid disorders such as depression and personality disorders may also arise over time.

**Hyperactivity disorders**

For many children with a childhood diagnosis of ADHD, outcomes are generally good, with about two-thirds showing no evidence of any mental disorder in adulthood and being gainfully employed. However, compared with ‘normal’ controls, children with a history of ADHD complete less schooling, hold lower-ranking occupations, have social skills deficits and are more prone to misuse substances.

**Conduct disorders**

In general, the available evidence suggests a persistence across the life course for childhood-onset conduct disorders, whereas adolescent-onset cases tend to remit in early adulthood in the majority of cases.

---

**Some methodological problems**

A number of methodological issues are apparent with longitudinal and other research into long-term outcomes. First, the use of categorical diagnoses for childhood and adult psychiatric disorders based on questionnaires may have only a limited relationship with levels of functioning. Second, high rates of co-morbidity (when the subjects were children and again as adults) makes it difficult to establish the relationship between the childhood and subsequent adult disorder. Third, the studies are unable to differentiate cause and effect (is it the diagnosis or continuing social adversity that may have caused the mental health problems in the first place and that is contributing most to adverse outcomes?). Finally, the studies rarely take into account the possible effects of labelling and any treatment received (e.g. continuing morbidity as a result of toxic side effects of medications taken, and the effect on self-worth together with the psychosocial adversity that arises as a result of becoming a psychiatric patient).

---

**TREATMENT IN CHILD PSYCHIATRY**

Child psychiatry sits at the confluence of many different systems of knowledge: medical, psychological, social, paediatric, anthropological, cultural and so on. In addition, child psychiatrists have to become proficient at working not only with children and young people but also with the variety of adults who care for these children and young people. Thus, child psychiatrists need to develop competence in working within a variety of modalities – biological, psychological and social – and in particular need to be able to engage with the young people and also the system of care around them. Familiarity with family and systemic approaches (see Assessment of children and adolescents, above) is therefore important.

In terms of a relationship between methods of treatment and outcome, robust conclusions about specific methods are difficult to establish because of a huge variability in the quality of the research, bias in reporting (e.g. with drug-industry-sponsored trials), inadequate follow-ups and lack of attention to cultural issues.

The most marked change in the past couple of decades in the practice of child psychiatry in most Western countries with established child psychiatric services has been the rapid increase in the use of psychopharmacology. In particular, the use of antidepressants for depression, stimulants for ADHD, and antipsychotics such as risperidone for behaviour problems have all taken place against a backdrop of aggressive marketing from the pharmaceutical industry. However, we are now aware that the widespread use of SSRIs antidepressants in under-eighteens occurred before any data on their safety and efficacy in this age group were available and that the studies, when they did take place,
suffered from conflicts of interest, which led to suppression of data. A more objective review of studies using SSRIs in depression leads to the conclusion that SSRIs do not confer significant clinical advantage over placebo and may expose the recipient to unnecessary risks, particular of precipitating suicidal ideation.

Unfortunately, this scenario is not limited to SSRIs. The largest and most influential study on the use of stimulants in ADHD, when it published its findings on the outcome 3 years after the start of the study, found that the advantage seen in patients treated with stimulants compared with those who received behaviour therapy alone had, after 14 months of treatment, been lost; however, patients on medication were now significantly shorter and lighter. This, together with reviews that highlight that we have no evidence to support the contention that treatment with stimulants improves outcome as adults, suggests that, as with SSRIs, it is likely that stimulants have been used too indiscriminately and before robust evidence on their safety and effectiveness was available. This is a problem for child psychopharmacology, particularly as we have limited data on the possible long-term effects of psychiatric drugs on the developing brain and because much of current child psychopharmacology is based on experience and evidence of drugs as they are used in adults, with little robust data on their safety and efficacy in children. As we have discovered with SSRIs, it is likely that we will find different safety and efficacy profiles in under-eighteens, suggesting much greater care needs to be taken in the use of psychotropics in this age group. It is likely, therefore, that in the coming years the use of psychotropics in under-eighteens will be re-evaluated. Predicting from the emerging evidence, this may mean that psychotropics will have a more limited remit than at present, being reserved for patients with more severe impairments and being used in conjunction with non-pharmaceutical approaches as opposed to standalone treatments.

For most of the disorders reviewed in this chapter, there are psychosocial treatments that are grounded solidly in empirical support as standalone treatments. Moreover, the preponderance of available evidence indicates that psychosocial treatments are safer than psychoactive medications. Thus, groups such as the American Psychological Association Working Group on Psychoactive Medications for Children and Adolescents and NICE guidelines on child and adolescent mental health disorders are now recommending that, in the majority of cases, psychosocial interventions should be considered first.

**Indications for in-patient and day-patient care**

In-patient treatment is indicated when the problems are severe or complex and in the following situations:

- 24-h psychiatric nursing care is required.
- The young person has a rapidly deteriorating condition.
- Out-patient treatment has been unsuccessful.
- There is considerable diagnostic uncertainty.

Day-patient places are a scarce resource, with many units not having provisions for day placements. In those units that do, indications for referral are similar, although the young people referred do not require 24-h nursing care. In-patient units are a mixture of general (the majority) and specialist (e.g. eating disorder, learning difficulty, forensic). The units typically offer a mixture of therapies in addition to the therapeutic milieu and have a hospital school attached to the unit.

**DESCRIPTION OF A TYPICAL CHILD PSYCHIATRIC SERVICE**

CAMHS are multidisciplinary services with a variety of specialists with training in child and adolescent mental health problems working in them. Different teams have different professionals, depending on national expectations and local factors. Who is in any particular team largely depends on local circumstances (e.g. funding levels, ease of recruitment, availability of any particular professional group, any training or research activities going on there). Different professionals working in CAMHS teams include child and adolescent psychiatrists, clinical psychologists, psychotherapists, family therapists, social workers, specialist nurses, art therapists, occupational therapists and educational psychologists.

CAMHS are organized structurally into four tiers:

- **Tier 1** is aimed at all children and includes all primary healthcare professionals, primary mental health clinicians, teachers, youth workers and welfare officers.
- **Tier 2** is aimed at children at risk of mental health problems and those with mental health problems that require a single professional's input. Professionals working at this level include primary mental health clinicians, child psychiatrists, child psychologists, social workers, paediatricians, educational psychologists, emotional behavioural support workers, specialist nurses and therapists.
- **Tier 3** is aimed at children with recognized psychiatric disorders and includes those that require specialist CAMHS input with a multidisciplinary team working together in a clinic setting.
- **Tier 4** is highly specialist services for children with more severe disorders, including in-patient units.

Other important agencies and institutions that have extensive contact with CAMHS include the following:

- **Paediatrics:** many community (as opposed to hospital) paediatricians run clinics for behavioural disorders, where children with conditions such as ADHD and autism are diagnosed. Referral can come directly from the general practitioner (GP) but also through medical
officers (doctors attached to schools). Usually assessments are confined to questions of diagnosis, and treatments tend to revolve around the use of medication and sometimes advice about behavioural strategies. Paediatricians sometimes provide input into a CAMHS team, and members of CAMHS teams (particularly child psychiatrists) sometimes provide input into paediatric teams (e.g. liaison psychiatry on paediatric wards, input into a child development team or centre).

- **Schools**: if the problem is solely or primarily school-based, then the school or education authority has processes and professionals who may get involved. Schools have several services that they can call on to help them with a particular pupil or problem. These include the emotional behavioural support service (EBSS), which helps the school to devise strategies for pupils with emotional or behavioural problems, and educational psychologists, who can assess pupils for learning difficulties and other emotional, behavioural and academic issues. Some schools also employ school counsellors. In addition, all schools and education authorities should have policies and procedures for issues such as bullying. Children in the UK with persistent problems relating to their learning or their behaviour should be given an individual education plan (IEP), which, if the difficulties are severe enough, can lead to an application for a statement of special educational needs. A statement provides pupils with extra input, such as extra teaching, support, mentoring or attendance at a special school such as an emotional behaviour disorder (EBD) school or a mild learning difficulties (MLD) school.

- **Social services**: anyone can request input from social services, but their involvement tends to be around issues such as child protection (see Child protection, above), family support (particularly for families with a disabled child), fostering and adoption, and parenting support and advice.

- **Voluntary**: the voluntary sector includes a variety of organizations that vary from locality to locality. Some may have been set up to support the needs of particular groups (e.g. particular ethnic minority communities; support for children with particular diagnoses such as ADHD; parenting advice groups; counselling for specific events, such as domestic violence, bereavement, victims of abuse) and others are national (e.g. Young Minds, Parentline, National Autistic Society). Thus, each locality has its own specific mixture of local and national groups.

- **Others**: a variety of private therapists are qualified or experienced in working with children and families and run private organizations providing a variety of services for both educational and mental health problems (e.g. services for children with dyslexia, eating disorders, neurodevelopmental disorders, private fostering).

---

**KEY POINTS**

- Approaches to assessment and treatment of mental health problems in children and adolescents are characterized by two key features: development and context. Children are changing as they mature physically and psychologically, and so a developmental perspective is necessary. Children are also dependent on adults in a variety of caregiving roles to make decisions on their behalf, and therefore an engagement with the child's context, such as family, school and social services, is necessary for comprehensive assessments and effective interventions.

- Beliefs about what makes up normal or abnormal childhood, child development and child-rearing vary both within and between cultures. Attempts to impose a universal system for defining what should count as abnormal behaviour for a child is therefore problematic. We should be aware that professional beliefs, including those in mainstream child and adolescent psychiatry, are not immune from making this mistake, particularly as no physical or psychological markers accompany the commonly defined disorders. In multicultural societies, high-quality services need to be aware of this in order to engage with services users’ perspectives and to develop approaches that make sense to children and families from diverse backgrounds.

- Awareness of child-protection procedures and legal processes for protecting children is vital for any professional working with children. There are four categories of child abuse: sexual abuse, physical abuse, emotional abuse and neglect. Child abuse is associated with a large number of potential adverse consequences for the victim.

- Classification of child psychiatric disorder is taken mainly from the ICD-10, although some categories commonly used in clinical practice (e.g. the diagnosis ADHD) come from the American DSM-IV. In ICD-10, the main groups of diagnoses relevant to children and adolescents’ mental health are: mental retardation; disorders of psychological development (which refer mainly to specific learning difficulties and developmental disorders such as autism); and behavioural and emotional disorders with onset usually occurring in childhood and adolescence (which covers disorders that are conceptualized as being specific to childhood and adolescence, such as hyperkinetic disorders, conduct disorders and emotional disorders). In addition, a number of disorders placed in other groupings and that occur more commonly in over-eighteens (e.g. schizophrenia) can also be used for children and adolescents.

- Due to differing approaches to classification and categorization of disorders and differing cut-off points used in research, epidemiological studies have produced figures for the prevalence of child psychiatric disorders that range from about 7 per cent to about 30 per cent of school-aged children.

- As there are no identified physical or psychological markers, clear aetiological pathways have not been found for any child psychiatric disorder. However, research has established a number of associated risk factors, including biological (e.g. being male, having a chronic physical illness – particularly one that affects the nervous system – and low IQ) and psychosocial (e.g. poverty, parental discord, parental psychopathology, disrupted attachments, violence, living in an urban setting, living in a rich country with a high level of social inequality).
As child psychiatry sits at the confluence of many different systems of knowledge, competent child psychiatrists need to develop an ability to work in a variety of modalities including biological, psychological and social. In particular, treatment approaches need to engage with the young person’s context, such as family and school, where resources to help the young person’s mental health problems can often be found. In recent years, child psychiatry has moved towards greater use of psychopharmacology; however, it has now become apparent that much of this change was stimulated more by good marketing than by good science. The place of psychopharmacology is likely to be more limited than recent prescribing trends suggest, as evidence shows that safer alternatives are available and that the drugs that have become more widely used in young people (SSRIs, stimulants, antipsychotics) are associated with risks but no proven long-term benefits.

INTRODUCTION

There have always been people with learning disability. The effect such a disability will have on an individual will be determined to some extent by the degree of the disability, interacting with family support, opportunities, and the level of sophistication demanded by the society in which they live. It is likely that industrialization and ever-increasing competition have made it progressively more difficult for people with learning disability to fit in and succeed in the UK without help, although the availability and quality of help has improved considerably over the same time.

Current provision for people with learning disability is organized in England on a borough-wide basis (approximate populations of 250 000), with considerable budgets coming from the local authority and the National Health Service (NHS) to offer all kinds of support, in addition to central government funding via channels such as housing benefit. The learning disability budgets of these boroughs are substantial (many tens of millions of pounds annually), of which a small proportion is spent on local specialist health teams.

There has been a revolution in the model of care for people with learning disability in the past 30 years. It has always been the case that the majority of these peoples’ needs have been met by families; however, situations inevitably arise requiring the support of statutory services. This may be secondary to difficult behaviour (possibly related to psychiatric illness), the death of parents, a desire to be independent, or other factors.

In the 1960s, and many years before, the standard model of statutory care was institutionalization in one of the giant (1000+ beds) hospitals built by the Victorians and situated on the periphery of large cities and towns. Various legislation since this time, including Better Services for the Mentally Handicapped¹ and Valuing People,² along with the effect of scandals relating to standards of care in these institutions and coupled with a more liberal attitude, have resulted in the complete closure of almost all these buildings, with a shift of care into the community.

As a result, people with learning disability who are not living with their parents or family and who require additional support now live in flats, small group homes or small hostels, or with adult carers. Support is available from paid carers, and many organizations have sprung up to provide such support, the level and amount being tailored to the needs of the individual, from a carer visiting on a weekly basis to assist with bills and budgeting, to having 24-h support from two or more carers. Imaginative packages of care are available; for example, an individual with learning disability can continue to live in their family home following the death of their parents, with daily live-in support from a care provider 24 h a day, 7 days a week, the carer sharing the house with the service user. Some of these care packages are extremely expensive, and it remains to be seen whether tax payers and governments will be prepared to continue to fund increasingly expensive options.

Further attempts have been made at social integration, with some success, although it still remains very difficult for a person with a learning disability to hold down a job on the open market, find a partner, get married or have children. It is very uncommon for a person with learning disability to afford, own or use private transport, something hugely valued by people without learning disability. Being slow, particularly in busy places such as cities, meets with very low tolerance, and being different at school may result in bullying. There are opportunities for many interesting day activities and college courses, and some sheltered and voluntary work schemes, but it remains difficult for a person with a learning disability to interact with the rest of society in a meaningful way.

The attitude of society to people with learning disability can be seen as ambivalent. On the one hand, people with Down syndrome may be hugely valued by their families and admired in general through successful national organizations such as the Chicken Shed Theatre Company, while at the same time scientific effort is spent by the same society to perfect prenatal diagnosis of fetuses with the condition so that termination can be offered to parents.

Along with the push towards integration, there has been a similar push for people with learning disability to have full access to the health services available to everyone else. At its most basic level, this means being registered with a general practitioner (GP). It is also required that physicians, surgeons, dentists and other specialist health professionals should be able to successfully treat people...
with learning disability with expectations as high as those of anyone else, while recognizing that extra input may be required, including issues around increased health need, difficulties in obtaining a history in someone who is non-verbal, performing investigations when the subject does not wish to cooperate, and considering issues such as consent.3

There remain limited specialist health services for people with learning disability, in the main organized on a borough-wide basis and usually based in a combined team with social services (forensic, psychotherapeutic and a few other specialist services may be regional). Typically, this specialist health team comprises a small number of psychiatrists (one or two being consultants), a few nurses, occupational therapists, psychologists, speech and language therapists and psychotherapy services (including music, drama and art therapies, and often aimed at people who have limited verbal skills). The complement of a borough-wide health team may be between 10 and 30 individuals, sometimes backed up by a limited number of specialist learning disability psychiatry admission beds (approximately six per district, the private sector providing admission services where none are available locally through the NHS). The age range served is typically 18–65 years, although a few services see children and most services continue to be involved in the care of more elderly people whom they have known for a long time.

Psychiatric illness in people with learning disability is common. Problems of definition make exact figures difficult, but there is probably at least double the prevalence in this group compared with the rest of the population.4 In addition, the most common behaviour type, challenging behaviour,5 is largely peculiar to this group. Medicines used by psychiatrists are the same as those used in the general population, although doses prescribed are often smaller due to existing brain damage and sensitivity to side effects.

There are many specific syndromes and conditions associated with learning disability, each in turn having its own associations (e.g. Down syndrome and dementia). There is a large amount of epilepsy, probably 50 times the prevalence of that in the non-learning disabled population (rates increasing with greater brain injury and therefore increasing in more severely disabled people). People with learning disability require far more social support and input than non-learning disabled people and may also require extra help with daily living skills, finding employment, communication and many other issues that others take for granted, such as being able to check they are given the correct change at a shop. Research into learning disability is extremely important but is unlikely to be pursued by mainstream services.

The outlook for a person with a learning disability has improved considerably in the past 40 years. A better, longer and more interesting life should be expected, although the goal of real integration with society remains, to some degree, elusive.

DEFINITION

It is important for learning disability services to be able to define who has a learning disability. Other specialist services, for example paediatrics, restrict their activity to their client group, who are easily characterized by age. Whether someone has a learning disability can be far more subjective, and yet it is important to try to make or exclude the diagnosis for various reasons, including the appropriateness of services for the individual, budgeting, and the fact that doubt may cause an individual to be ignored by all services; for example, at the interface between mental health and learning disability, unless a definite diagnosis is made, and in the context of stretched services, both services may choose to assume that the other service is providing help, when in reality neither is.

The three criteria required to make a diagnosis of learning disability are:

- arrested or incomplete development of mind;
- difficulties in adaptive functioning;
- occurring within the developmental period.

The International Classification of Diseases, version 10 (ICD-10)6 and the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)7 have similar definitions of learning disability, although ICD-10 mentions arrested or incomplete development of mind, which may be deduced from intelligence quotient (IQ) testing.8,9 DSM-IV specifically mentions such testing, learning disability being suggested by an IQ of 70 or less (two standard deviations from the mean).

Both classifications also stress the importance of problems in adaptive functioning, implying that in certain situations a low IQ may not interfere with the person’s ability to be independent in activities of daily living, including washing, cooking and travelling. Finally, both classifications require that the disability occurred during development (in DSM-IV, ‘the onset is before 18 years’).

IQ measures are certainly important and appear to correlate with various desirable social outcomes; for example, in the USA, higher IQ has been reported to be associated with higher earnings, less chance of imprisonment, lower unemployment and less chance of divorce. These are clearly averages, but they do not necessarily apply to a specific individual. In addition, other factors are important when looking at ultimate performance, for example the ability to concentrate for a prolonged period of time and the amount of determination put towards completing a task. IQ seems to give some sort of indication of the potential an individual has of completing a novel task, but it cannot indicate whether that potential will be used in the real world.

The average IQ of a population is 100, the standard deviation ± 15 points and the standard error 5 points (Figure 71.1). IQ is normally distributed, but with a slight bulge in the lower IQ range. IQ is thought to be inherited through
multiple genes, in a similar way to height, accounting for the normal distribution. The effect of upbringing on IQ, which may be significant, presumably also operates in a fairly random way and therefore also leads to a normal distribution of scores. The bulge at the lower range is then caused by specific abnormalities, such as Down syndrome and fragile X syndrome.

Ability to socialize is probably as important as IQ when considering the capability of a person to exist in society. In this respect, there has been recent interest in the concept of emotional intelligence.

The population mean IQ score is 100. Two standard deviations from the mean represents approximately 5 per cent of the population and is made up of people with an IQ above 130 and below 70. Therefore, approximately 2.5 per cent of the population has an IQ in the learning disability range. This number is increased by approximately a further tenth (0.25%), representing people with congenital causes for their low IQ (e.g. Down syndrome, fragile X syndrome). On IQ testing, therefore, almost 3 per cent of a population might be expected to have an IQ in the learning disability range. This figure is different from that found in population studies on the prevalence of learning disability, often coming out at about 1 per cent.

The difference may be explained in various ways. Low IQ may not always be associated with problems in adaptive functioning, people with learning disability may not be ‘picked up’ by services, there may be greater mortality in the low IQ group, and some people with low IQ will not have a learning disability because their problem (e.g. brain injury following a road traffic accident) occurred after the developmental period.

Specialist learning disability services may have a maximum of 1000 patients on their lists in an average borough, representing less than 0.5 per cent of the total population. This low percentage is probably explained by the reasons stated above and the likelihood that many people with an IQ in the learning disability range either look after themselves or are cared for by their families and never come to the attention of specialist services.

Within the learning disability group, further categories are sometimes used, defined to some extent by IQ. ‘Mild’ learning disability covers approximately 80 per cent of this population and spans an IQ range from 70 to 50. A person with mild learning disability might be expected to have minimal or no physical or sensory problems, to hold down sheltered employment, and to survive with limited support. ‘Moderate’ learning disability spans an IQ range between 50 and 35 and represents approximately 10 per cent of people with learning disability. These people may be able to help with personal care and travel independently in familiar places, but they require greater levels of support at home. ‘Severe’ and ‘profound’ learning disability (IQ ranges 35–20 and 20 or less, respectively) make up the remainder. These people require higher levels of support and may suffer from various physical problems, including epilepsy.

DEVELOPMENT

The human brain develops from ectodermal tissue and, unlike in other species, continues to do so after birth. It reaches its maximum weight at about 10 years of age, with the major growth spurt taking place after birth.11 There appear to be critical periods of development.12 Early in pregnancy metabolic upsets or teratogens may produce malformations, while in the mid-trimester neuronal multiplication is at risk. From the last trimester up to 2 years after birth the brain growth spurt takes place, involving glial multiplication, dendritic arborization and synaptogenesis and a high rate of myelination. Poor conditions at any stage may prevent proper brain development, including understimulation. This has been well demonstrated by Hubel and Wiesel,13 who won the 1981 Nobel Prize for medicine and physiology for their work looking at the critical period for understimulation of cortical neurons in cats. The resulting effect was permanent change of cell function and appearance in the visual cortex.

There are various, somewhat predictable factors associated with problems in brain development, including maternal malnutrition,14,15 excessive alcohol use16 and possibly smoking.17,18 Various drugs taken by the mother may also cause problems for the fetal brain, of which anticonvulsants are particularly important.19 Exposure to radiation and severe infection may also cause difficulties for the fetus.

Lack of a specific nutrient may result in a specific condition, for example congenital hypothyroidism associated with a lack of iodine. Alternatively, abnormally high levels of a chemical may damage cerebral function, as in phenylketonuria.
There are a number of well-recognized genetic causes of learning disability. These may involve whole chromosomes (and therefore a large number of genes), the most important being Down syndrome. Some learning disability is related to single gene abnormality on the X chromosome (fragile X syndrome20). There are also autosomal dominant abnormalities (tuberose sclerosis21) and autosomal recessive causes of learning disability (phenylketonuria22).

The essentially normally distributed IQ graph suggests multifactorial causes for the majority of people with learning disability, probably caused by the interactions of a number of genes working with various environmental hazards, some of which are listed above. A paper from Brazil describes magnetic resonance imaging (MRI) of 146 children with an IQ of less than 70.23 Fifty per cent of the scans were reported as normal, while focal thinning at the junction and body of the splenium of the corpus callosum, ventricular asymmetry, periventricular leucomalacia, gliosis and arachnoid cysts were found in the other 50 per cent. Maternal stress and altered blood pressure were the most frequent prenatal findings in the mothers of these children.

A more comprehensive understanding of the genes that appear to be important in the development of learning disability is continually evolving with the identification of autosomal recessive non-syndromic mental retardation genes (ARNSMR).24 In this context there are even reports of therapeutic interventions in animal models of mental retardation with ‘medicines’ designed to overcome these gene effects,25 an example being the work of McBride and colleagues, who demonstrated that synaptic plasticity and courtship behaviour can be restored in a Drosophila model of fragile X syndrome by treatment with metabotropic glutamate receptor antagonist or lithium.26 For the foreseeable future, however, it is very likely a significant although small proportion of people will be born with learning disability. The most acceptable intervention that may alter this proportion is prenatal care, particularly avoidance of recognized risk factors.

Table 71.1 lists some of the potential causes of learning disability.

### SOCIAL FACTORS

There are many difficulties to be faced by people with learning disability and their parents and carers. Parents may have to come to terms with sadness at the loss of a normally successful child and a real prospect that their son or daughter will never become fully independent. They may also be required to cope with possible burdens of social stigma, self-blame and many practical difficulties in relation to health. These burdens can be overwhelming and may result in a desire to put the child into social care, or they may put sufficient strain on the parents’ relationships to precipitate parental separation. None of this is certain, however, and many parents cope superbly, offering an excellent quality of life to their son or daughter. Indeed, recent research has reported lower levels of divorce in families where there is a child with Down syndrome compared with families of children with other birth defects and those of children with no identifiable disability.27,28

Schooling may present further difficulties. In the UK, there are many special schools designed for people with learning or physical disabilities. The more recent trend has been to attempt education of people with learning disability in mainstream schools, with additional help. There is considerable controversy around this policy, demonstrated to some degree by looking at the online encyclopaedia Wikipedia. In September 2007, Wikipedia’s entry on ‘mainstreaming in education’ comes with a warning that some statements may be ‘disputed, incorrect, unverified, biased or otherwise objectionable’. We suspect this reflects the strongly held but conflicting views of people in relation to this idea. Nevertheless, the article considers advantages and disadvantages of mainstreaming. Possible advantages include increased expectations leading to improved achievements and fostering of better understanding and tolerance. Possible disadvantages are that people with learning disability may feel conspicuous and socially rejected by classmates and may disrupt the learning of their normal intelligence peers through diversion of teacher time and effort to them. Jones, considering the educational needs of people with autistic spectrum disorder, states that ‘little rigorous research evidence exists to guide decisions for children with autistic spectrum disorder. This is true for educational practice generally, and for children with other special educational needs’.29 It seems that, for example, people with Down syndrome may do well in mainstream schools at a very junior level, where their excellent social
skills and emotional intelligence will allow integration, but they may require and be happier with transfer to a special school when intellectual demands and expectations increase.

In England the process by which a child with special educational needs receives the additional educational support they need is called ‘statementing’. This is an assessment carried out by the local educational authority designed to determine the child’s needs in school and what provision will be granted to that child. Possible outcomes include placement in a special school or additional one-to-one support in mainstream classes.

The home environment is very important in determining the later result of an inherited or environmental risk of learning disability, and it is likely that a stimulating home life will improve the IQ score, regardless of where the individual is educated. Other factors, including diet, may also be important.

In the middle of the twentieth century, an idea became popular that ‘refrigerator parents’, particularly mothers, might be causing the devastating condition of autism in their offspring. These parents were thought to be emotionally cut off, cold, and unresponsive to their children, thereby creating an unhappy dull family environment and ultimately causing the social difficulties of their autistic sons and daughters. Such ideas are now discredited. If parents of autistic children appear in any way strange or cut off, then this is much more likely to be due to the stress of caring for a person with autism, although it is recognized that some parents may have autistic traits themselves, which is likely with any partially genetically determined condition.

It is becoming increasingly likely that the best treatment for autism, a syndrome with many possible causes and contributory factors, is intensive early intervention with something like social flooding. Children with autism avoid social contact if they can, possibly because of excessive anxiety, and may as a result become progressively cut off from everyone else, exacerbating their difficulties. Intensive social interaction started at as young an age as possible, and aimed at forcing social contact and integration, has been reported to be successful in the treatment of this very disabling condition, although perhaps because of the extremely intensive requirements of the programme (40+ h/week of individual therapy for a period of at least 2 years) it is not widely used or available. Bearing in mind the extreme suffering and difficulties faced by people with autism, the lack of successful treatments and the effect it has on their parents and carers, it seems that this social intervention should receive better support than is currently the case.

**PSYCHIATRIC DISORDERS IN LEARNING DISABILITY**

There is an increased prevalence of psychiatric disorder in people with learning disability compared with the general population. Of crucial importance in making this statement is having some sort of definition of what ‘learning disability’ means. Professionals with a background in education may describe a person as having a significant or severe learning disability, while a professional from health might describe the same person as having a mild or borderline learning disability. As far as possible we will stick with the definition of learning disability as defined in DSM-IV and starting at an IQ of 70 or below.

Increased rates of psychiatric illness might be expected as a result of the brain damage itself that has caused the learning disability, coupled to a multitude of environmental factors, particularly important being bullying, abuse, loss of opportunities and loss of self-esteem. Difficulty with communication is also very important, causing frustration and anxiety, inability to make one’s needs known, and inability to express that one is in pain. Some risk factors for mental illness may, in fact, be lower in people with learning disability compared with the general population, for example drug and alcohol abuse. Fortunately, suicide appears to be relatively rare among adults with learning disability, although suicidal behaviour has been reported to be increased in adolescents.

Much of the information used to make a psychiatric diagnosis comes from what patients actually say. This is particularly important for symptoms relating to more serious psychiatric illness, such as delusional ideas, ideas of reference and hallucinations in schizophrenia. If the person is non-verbal, as may well be the case in severe or profound learning disability, assessment of these symptoms is not possible. In addition, it may be difficult for more able people with mild or moderate learning disability to understand questions related to these symptoms, and there is always the danger of people saying ‘yes’ because they either do not understand or wish to please.

In this context, the idea of change becomes very important. If, for example, a person who previously attended their day centre, appeared to enjoy it, and had always got up on time and been ready to go is now refusing to get on the morning bus, then something very important has changed. This may be secondary to physical illness or pain. It may be because the person’s favourite carer at the day centre has left for another job, or the person now sits next to someone on the bus they do not like, or they are being bullied at the day centre by a new arrival. If, however, factors such as these can be largely excluded, then psychiatric illness is a possible cause of the behaviour change.

Further enquiries may then reveal a previous history of treatment for depression, possibly a positive family history, a more general loss of interest, and some biological changes, for example sleep disturbance plus loss of appetite and uncharacteristic tearfulness. Even in a non-verbal person, it might then be reasonable to consider depression and treatment with antidepressant medication, having first considered issues relating to capacity.

Unfortunately, in practice, it is unusual for the presentation...
to be so clear-cut. Non-specific behavioural change and difficult behaviour are far more common reasons for psychiatric referral and can be secondary to underlying psychiatric illness. Careful history-taking may elicit auditory hallucinations or delusions of control or reference, suggesting schizophrenia. Paranoid symptoms and catatonia have been reported to be seen more frequently in schizophrenia associated with more severe learning disability. Mood disorders are probably relatively common in people with learning disability; rapid-cycling forms and anxiety disorders are also common. Compulsive behaviour may be secondary to an obsessive-compulsive illness or simply a feature of autism.

Biological symptoms are certainly very important in psychiatric diagnosis in learning disability. Weight loss and weight gain should be looked for, along with changes in sleep pattern. Aggression or self-injurious behaviour may sometimes be a symptom of depression, as recognized in the Diagnostic Criteria for Psychiatric Disorders for use with Adults with Learning Disabilities/Mental Retardation (DC-LD).10 Sleep disturbance can be very important. Sleeping well at night in addition to somnolence during the day may suggest many things, but possibly that the dose of a sedative antipsychotic is too high. Poor sleep and daytime wakefulness may suggest an untreated psychotic process and medicines may be considered or, if already prescribed, the dose reviewed. Otherwise inexplicable changes in behaviour, for example loss of interest in activities or withdrawal, signal the possibility of psychiatric illness.

Table 71.2 summarizes psychiatric assessment in learning disability.

An article looking at the prevalence of psychiatric disorder in learning disability produced some interesting results.4 First was a perhaps surprisingly low case rate for learning disability in their study population, of 3.3/1000 of the adult population. Of this, perhaps selected, group (who appear from the quoted figures to be less able than a more representative group of people with learning disability), mental ill health was identified in 41 per cent using clinical diagnosis, 35 per cent using DC-LD and 16 per cent using ICD-10 or DSM-IV. Almost all the difference in these rates can be explained by clinical diagnosis and DC-LD rating problem behaviours, which are not recorded by ICD-10 or DSM-IV.

- Specialist psychological testing
- Other specialist assessments, e.g. occupational therapy

EEG, electroencephalogram.

Challenging behaviour

Problem or challenging behaviours are very common in people with learning disability and may cause severe difficulties for the person with the behaviour, their carers and their environment. Perhaps in the general population people with severe challenging behaviour exist but are dealt with by the police and prisons. It seems likely, however, that challenging or problem behaviour is genuinely more common in people with learning disability compared with the general population, probably as a result of factors already mentioned, including bullying, loss of opportunities, difficulty in maintaining self-esteem and difficulties in communication. Another important factor at adolescence and beyond may be the inability of the person with learning disability to achieve independence from their parents and leave home. This coincides with maximum physical strength and can result in very difficult conflicts between children and parents, which in some respects are normal and resolved in the general population by the adolescent leaving home.

Whether challenging behaviour is eventually or helpfully viewed as an illness depends to some degree on whether there are predictable helpful treatments for the condition. Psychiatrists in learning disability are frequently consulted regarding problems of this nature. It is important to look at all possible causative factors when considering such behaviour and possible interventions.

Challenging behaviour is defined by the Challenging Behaviour Foundation (www.thecbf.org.uk) as:

- behaviour which may put themselves or others at risk, or which may prevent the use of ordinary community facilities or a normal home life. The behaviour may be in the form of aggression, self injury, stereotyped behaviour or disruptive and destructive behaviour.

There are a multitude of important considerations to be made during assessment and later when looking at a treatment plan. These include levels of staffing, day activities, social situation, loss and bereavements, physical health, medication side effects and epilepsy. Any of these may be involved in causing or maintaining the challenging behaviour.

At times, however, the challenging behaviour will be secondary to a psychiatric illness, which will require treatment in its own right. Although searching for possible causes and directing interventions at these causes is important, sometimes it may not be possible to significantly alter environmental factors, or none may be found. It may be that the behaviour is present in different environments, for example
at the weekend when the child is home with the parents, during the week at the care home, and also at the day centre, suggesting that something relating to the individual is driving, for example, persistent screaming. In such situations, the prescription of medications may be considered, accepting that such prescribing is off-licence. The practice is certainly common in people with learning disability and based on remarkably little evidence.\textsuperscript{41} Drugs used include antipsychotics, antidepressants, minor tranquillizers and mood stabilizers.

There have been small studies in the past looking at long-stay hospital populations (no longer particularly relevant, following the closure of these institutions), suggesting that zuclopenthixol and lithium may be helpful in the treatment of challenging behaviour in learning disability.\textsuperscript{42,43} A more recent systematic review found only nine randomized controlled trials that could be used for analysis, providing no evidence as to whether antipsychotic medication helps or harms adults with learning disability and challenging behaviour.\textsuperscript{44}

The Neuroleptics in Adults with Aggressive Challenging Behaviour and Intellectual Disability (NACHBID) study, organized by Imperial College, was published in 2008.\textsuperscript{45} This is a randomized controlled trial looking at the use of risperidone, haloperidol and or placebo in the treatment of aggressive challenging behaviour in people with intellectual disability, examining short- and long-term outcomes of these various prescriptions. The study was faced with major problems in recruitment (86 people entered the research against the planned target of 144), and there may have been some selection bias. The results, however, are quite striking, with no advantage being seen in any of the three treatment groups at 4 weeks. The authors conclude that ‘the routine prescription of antipsychotic drugs early in the management of aggressive challenging behaviour, even in low doses, should no longer be regarded as a satisfactory form of care.’\textsuperscript{45}

Finally, one paper has reported that it is often possible to reduce antipsychotic medication use in people with learning disability who have been prescribed medication for behavioural problems. One-third of subjects in a mixed group of hospital and community patients were able to come off tablets in this study.\textsuperscript{46} Numbers, however, were small and the researchers were not blind to the interventions.

Table 71.3 summarizes the treatments used in learning disability psychiatry.

### Other psychiatric diagnoses

Other psychiatric diagnoses will be made as in the general population, and similar treatments offered. The problem of diagnosing psychotic illness, particularly in people who are non-verbal, remains, and here reliance will have to be given to changes in behaviour and useful history, for example the presence of a positive family history of psychiatric illness. Symptoms that may be associated with psychotic illness in learning disability include behaviour change, verbal or physical aggression, social withdrawal, speaking to themselves (although this may be a normal habit), and pointing or swiping at things that other people cannot see. It may be that non-verbal forms of assessment are helpful in these situations, for example art or music therapy approaches.

Some assessment schedules are aimed at assisting in making a psychiatric diagnosis in people with learning disability, with well-recognized examples being the psychiatric assessment schedule for adults with developmental disabilities (PAS ADD) and mini-PAS ADD. The mini-PAS ADD can be administered quickly and gives an indication of psychiatric diagnosis in seven possible domains – depression, anxiety and phobias, mania, obsessive-compulsive disorder, psychosis, unspecified disorder (including dementia) and pervasive developmental disorder (autism). Both schedules require formal training before they can be used.\textsuperscript{47,48} Other schedules include diagnostic assessment for the severely handicapped (DASH) and psychopathology inventory for mentally retarded adults (PIMRA).\textsuperscript{49}

Whether psychological treatments, for example psychotherapy, are suitable for people with learning disability has been the subject of some debate. In the UK, this approach has been pioneered at the Tavistock Clinic in north London, considering issues such as loss, bereavements, sexual abuse and the effect on the individual of having a learning disability.\textsuperscript{50}

If drug treatment is prescribed, then starting at a low dose would seem sensible. There are various reasons for this, important ones being the tendency of most psychiatric medicines to lower the seizure threshold, and the possible
difficulty of identifying side effects in people with communication problems.

Epilepsy is perhaps 50 times more common in people with learning disability compared with the general population, the greater prevalence being associated with more severe learning disability and obvious brain damage. In this situation, any medicine that lowers the seizure threshold, including all antidepressants and antipsychotics, may precipitate a fit.

Considering side effects, it may be difficult for a person with learning disability to tell a carer that their muscles feel stiff (a possible side effect of antipsychotics), that they have developed a cardiac arrhythmia (a rare but possible side effect of antipsychotics and antidepressants), or that they are unsteady on their feet (possibly related to an anticonvulsant prescription). Remaining vigilant to these consequences of drug use is therefore important, and in this context a gradual introduction of a medicine would seem sensible. Further safety of prescriptions in general will occur if a comprehensive history, examination and investigations are part of the initial assessment process and are given consideration when prescribing a particular drug. In this respect, prescription of these medicines by the patient’s GP following specialist advice from the psychiatrist is perhaps the ideal, although not always possible, scenario.

There appear to be some causes of learning disability associated with specific psychiatric diagnoses. It has been reported that approximately 30 per cent of people with velocardiofacial syndrome (deletion of 22q11) will suffer from psychosis; a similar risk seems to be present for people with Prader–Willi syndrome.

**SPECIFIC CONDITIONS**

There are many different conditions associated with learning disability, some very rare. In this section we look at a few of the more common syndromes – fetal alcohol syndrome, Down syndrome, fragile X syndrome and autism/Asperger’s syndrome.

**Fetal alcohol syndrome**

Fetal alcohol syndrome, as the name suggests, is caused by maternal drinking during pregnancy. It is now often advised that alcohol intake is avoided completely by mothers from conception onwards, although it is also accepted that a mother who has drunk during this period may well have a perfectly healthy baby. It is highly probable that the majority of people reading this chapter were born to mothers who drank alcohol in pregnancy without suffering any obvious untoward consequences.

Fetal alcohol syndrome was first described in 1973, and it may be seen in about 1 in 500 births in the USA. The syndrome can include brain damage, facial deformities, growth defects, heart, lung and kidney defects, hearing and vision problems, and learning disability. There may be microcephaly, with structural abnormalities in various regions of the brain.

Diagnosis is based on the history of excessive alcohol use in pregnancy, along with growth retardation, central nervous system dysfunction or intellectual impairment, and craniofacial abnormalities (microcephaly, narrow receding forehead, flat nasal bridge, epicanthic folds, small palpebral fissures, ‘rail track’ ears, short upturned nose, smooth philtrum, thin upper lip, micrognathia (Figures 71.2 and 71.3). A clear correlation between the occurrence and severity of neuropsychological problems and the degree of alcohol exposure in utero has been reported. An older study from the Lancet reported the 10-year follow-up of 11 children who were the first to be diagnosed with fetal alcohol syndrome. At this time, two of the children were dead, one was lost to follow-up and the remaining eight were described as growth-deficient and dysmorphic. Four of these eight were described as being of borderline intelligence requiring remedial teaching; the other four were described as being severely intellectually handicapped.

More recent articles concentrate on the actual neurological problems associated with excessive maternal alcohol use, which include neuronal cell death and abnormal functioning of surviving cells. The only treatment is avoidance of alcohol during pregnancy, thus preventing fetal exposure to the chemical. Treatment of the established syndrome depends on the needs of the individual, including educational help and residential and occupational assistance to adults.

Figure 71.2 Boy with fetal alcohol syndrome, aged 9 months

With thanks to FAS Aware UK.
Similar worries relate to the exposure of the fetus to other toxins during pregnancy, anti-epileptics being an important example.\textsuperscript{67} (For more detailed information, see the website of Foetal Alcohol Syndrome Aware UK at www.fasaware.co.uk.)

### Down syndrome

Down syndrome (Figure 71.4) was first described by Langdon Down in 1866. Trisomy 21, the cause of the syndrome, was discovered by Lejeune in 1959.

There is a small risk of the child having Down syndrome in any pregnancy, although the risk increases dramatically with increasing maternal age, rising from about 1 in 1000 in a 20-year-old mother to 40 times this frequency for a 45-year-old mother.\textsuperscript{68} Paternal age is probably not important.\textsuperscript{69} Prenatal screening, including ultrasound measurements of fetal nuchal translucency and maternal blood tests, is available but not always reliable.\textsuperscript{60} Screening may indicate more invasive diagnostic procedures that put the fetus at increased risk, such as amniocentesis. Parents who would not consider termination if their son or daughter has Down syndrome should be advised to avoid having these tests. A couple who already have a child with Down syndrome should have genetic testing if they plan further pregnancies, since relatively rare translocation of chromosome 21 or other genetic abnormalities may increase the risk of them having further children with the syndrome.

Life expectancy for people with Down syndrome has improved dramatically over the years. An Australian study describes the follow-up of 1332 people with Down syndrome registered between 1953 and 2000. Average life expectancy was 58.6 years, and the oldest living person in their group was 73 years.\textsuperscript{61} This compares to an American study looking at mean life expectancy of all people with learning disability in the USA, showing a dramatic improvement over the same time, and in 1993 an average of 66.2 years.\textsuperscript{62} All aspects of medical and surgical care, including cardiac surgery, have been important factors in this success.

Down syndrome is associated with various features, including short stature, a single palmar crease, congenital heart abnormalities and characteristic facial appearance. Most people with Down syndrome also have a significant learning disability.

The various problems faced by people with Down syndrome are ultimately secondary to the additional genetic information coded for on the extra copy of chromosome 21. It is the only trisomy compatible with long-term survival, presumably due to the small size of the chromosome, and it may be secondary to overexpression of some genes with excess production of gene products (e.g. amyloid precursor protein\textsuperscript{63}). Other chromosome 21 enzymes may actually be underactive in vivo, for example superoxide dismutase.

Down syndrome is also associated with hypothyroidism, possibly depression and particularly presenile dementia. Unfortunately, the development of dementia is very likely, affecting approximately 50 per cent of people with Down syndrome between the ages of 50 and 60 years, and becoming more common thereafter. It may have a more rapid course than Alzheimer’s disease in the general population (although this may be secondary to delay in diagnosis), and it is very commonly associated with the development of swallowing problems, inhalation pneumonia and fits, often presenting as myoclonic jerks.\textsuperscript{64} Diagnosis is made by looking at the history of deterioration in the person’s skills and abilities, backed up by physical examination and investigations including routine blood tests (thyroid function tests, vitamin B12, folate, lipids), electrocardiogram (ECG), electroencephalogram (EEG) and

head scans where possible (scans may well prove too difficult for the patient, as indeed may blood tests). Various rating scales can also be used, some repeated over time and looking for significant deterioration; for example, the Adaptive Behaviour Rating System (ABAS) is carer-rated and looks at all aspects of the person’s ability and daily living skills. Other scales can be administered as a single test, for example the Cambridge Examination for Mental Disorders of the Elderly (CAMDEX).65

Ball and colleagues have suggested that there may often be a personality change in people with Down syndrome who are about to dement, with ‘frontal type’ features including reduced empathy, emotional lability, apathy, withdrawal, distractibility, disinhibition and impulsivity.66

Treatment of dementia should probably be as in the general population. Social strategies are very important, including, if at all possible, not moving the person from their home. Acetylcholinesterase inhibitors have been used with variable success,67 with most reports concerning donepezil. Memantine has also been considered.68

(For more detailed information, see the website of the Down’s Syndrome Association at www.downs-syndrome.org.uk.)

**Fragile X syndrome**

At a molecular level, fragile X syndrome (Figure 71.5) is caused by an excessive number of CGG (cytosine, guanine, guanine) repeats in a fragment of DNA in the fragile X gene (FMR1) on the X chromosome. Normal numbers of copies of the CGG triplet are about 30. There appears to be a ‘pre-mutation’ stage, with repeats in the range from 55 to 200 seen in male and female carriers.69 Expansion of the repeat sequence above 200 is known as ‘full mutation’ and results in hypermethylation at the site of the FMR1 gene, which in turn leads to underexpression of the fragile X mental retardation protein (FMRP) and the clinical characteristics of the syndrome in males and approximately 50 per cent of affected females. DNA testing is routinely available for fragile X syndrome and can reliably detect not only affected individuals but also carrier males and females.

FMRP has been found in most organs, including the brain. In cells it is seen mainly in the cytoplasm, and it may act as an RNA binding/export protein, assisting movement of molecules between the nucleus and the cytoplasm.70–72

Fragile X syndrome has been said to be the most common cause of inherited mental handicap,73 affecting 1 in 4000 males and 1 in 8000 females. It is associated with a wide range of learning disability (from mild to severe in both males and females), attention deficits, hyperactivity (which appears to diminish in adulthood), autism–like features, social phobia, poor eye contact and abnormalities of speech, including repetition, possibly reflecting the effects of physiological arousal caused by hypersensitivity to social and sensory stimuli.74 Other features include a long thin face and large ears, although these are not seen in all affected people, and large testicles after puberty. There may be a wider connective tissue disorder, with lax joints, flat feet and mitral valve prolapse. Seizures occur in approximately 20 per cent of people with the syndrome, but these usually respond well to anticonvulsants.

There is no specific treatment at present, although recent researchers have suggested that agents acting on γ-aminobutyric acid (GABA) receptors may be helpful in this syndrome.69,75

As with all types of learning disability, the main treatment is social, including an educational package designed to meet the needs of the individual, family support and social care where necessary. Genetic counselling should be offered to parents and other family members at risk of producing a child with fragile X syndrome. This may be carried out because there is an existing family member with fragile X syndrome, or in the case of learning disability of unknown cause running in a family, with or without the typical phenotype.

As with other causes of learning disability, there is the possibility, once a diagnosis is known, for parents and families to make contact with other families through relevant support groups, allowing the opportunity of learning from others, sharing experiences, gaining general support and knowing that problems are not faced alone or necessarily unique. (For more detailed information, see the website of the Fragile X Society at www.fragilex.org.uk.)

Early diagnosis is important so that the person can receive appropriate specialist help with education, speech, language and behaviour. Some behavioural disturbance, which may be associated with the syndrome, has been reported to respond to various mainstream ‘psychiatric’ drugs.76

**Autism/Asperger’s syndrome**

This is a fascinating field for researchers and other professionals for various reasons, an important one being that
autism seems to represent an illness that affects, in a rather fundamental way, one of the main satisfactions available to most people. Much of the pleasure many of us experience is during interaction with others. For whatever reason, it seems that this shared pleasure is not easily available to people with autism, leading to the main diagnostic criteria of impoverished social interaction, language problems and interest in largely non-social activities, finger-flicking being an example in more severely disabled people and an ability to memorize telephone directories being an example in more able people. Whether there is actually a difference between Asperger’s syndrome and autism is uncertain, although we tend to describe people with core symptoms and an associated learning disability (IQ below 70) as having autism, and people with core symptoms and normal intelligence as having Asperger’s syndrome.

When autism was originally described by Kanner in 1943, the condition was thought to be rare, with typical autism rates varying between 1.2 and 8.4 in 10 000 children. More recent research has put the figure higher, at 7.1 in 10 000 for typical autism and 20 in 10 000 for autistic spectrum disorder (ASD), the latter usually meaning the presence of autism, pervasive developmental disorder (DSM-IV) or atypical autism (ICD-10). Others have estimated rates as high as 116 in 10 000 for autism and ASD in children.

Autism is defined in DSM-IV by a combination of difficulties in three categories – social interaction, communication and behaviour (restricted, repetitive and stereotyped) – with difficulties in social interaction being particularly important. Onset should be before 3 years of age. Asperger’s syndrome has similar criteria, although communication difficulties are not stressed; indeed, clinically significant delays in language should be absent, as should significant delays in cognitive development.

The cause of autism is unknown, although there are many theories. It is far more common in men (male/female ratio: 4:1 for autism and 8:1 for Asperger’s syndrome), which may reflect the fact that men tend to be less verbal and possibly less socially oriented than women and therefore need less of whatever causes autism to express the syndrome. The condition is particularly hard on parents and carers, since the social rewards of loving care (e.g. a smile, hug or thank-you) may be absent or seen only rarely. In addition, the parents and carers have to deal with the difficulties of caring for a child with learning disability and, frequently, behavioural problems, which may be related to lack of empathy. Autism is a very disabling condition. It tends to be lifelong, although it often improves to some extent with age. Worse prognosis has been associated with poor baseline verbal skills. Interestingly, although people with Asperger’s syndrome or autism may recognize various difficulties that the syndrome causes them, many also value the unique way in which they are able to perceive the world in general because of their ‘problem’ and would not wish to lose it.

Multiple investigations have not uncovered much in the way of consistent biological findings. Abnormalities at synapses involving synaptic cleft binding molecules, neurelgin and neurexin, are hypothesized, and large brain sizes have been reported. There is an ‘androgen theory of autism’, proposing that ASD is due in part to elevated fetal testosterone. As with many conditions associated with learning disability, poor conditions during pregnancy and birth may be important, possible risk factors including increasing maternal age, use of medicine during pregnancy and low birth weight. Vaccination as a possible cause of autism achieved much publicity, but this link is no longer accepted. Since autism and autistic traits appear to show a certain amount of genetic inheritance, it is not surprising that genetic theories for autism exist. There is the well-known association between autism and some genetic causes of learning disability, such as fragile X syndrome and phenylketonuria; in addition, very specific genetic abnormalities have been associated with autism, an example being an inversion of the short arm of chromosome 4. This was seen in two brothers both diagnosed with autism, researchers suggesting that GABA transmission may have been impaired as a result of this inversion and possibly underlying the development of the syndrome. Aberrations in brain growth, neuronal patterning and cortical connectivity have been mentioned, and plasma serotonin levels and platelet serotonin binding are consistently found to be raised in the condition, with a negative relationship observed between plasma serotonin levels and speech development. Finally, cerebellar abnormalities have been linked to the syndrome.

It is said that people with autism have difficulties empathizing with other people and cannot put themselves in another person’s shoes (sometimes described as ‘theory of mind’). This may be through lack of practice following on from social avoidance, or through abnormal brain wiring and connectivity causing abnormal brain function, or both. The ‘theory of mind’ difficulty may be unique to people with autism, compared with other people with a similar level of intellectual handicap, and may make it hard for them to believe or appreciate others’ mental states and experiences. For example, it may be difficult for a person with autism to accept that someone else does not know something. This lack of empathy can make it very difficult to function normally in a social situation and is likely to lead to misunderstandings and suspicion, encouraging further social avoidance. Social avoidance may also be driven by increased levels of anxiety or genuine lack of interest in human interaction. A ‘central coherence’ theory suggests that people with autism find it difficult to assimilate individual pieces of information into a more coherent ordered whole.

It is widely accepted that treatment should start as early as possible, and generally the degree of success will be related to the early start, intensity and duration. Lovass therapy, for example, has been reported as being successful
in significantly improving the functioning of children with autism, although the level of resources required is huge, perhaps 40 h per week of intensive input for at least 2 years. Alternatively, the resources involved in the care of someone with ‘untreated’ autism are potentially huge, quite apart from the suffering of the patient and carers involved, and it is our belief that much more of this intensive therapy should be available to infants and young children in the UK.

Mainstream psychiatric medications have been used with varying success in autism. Selective serotonin reuptake inhibitors (SSRIs) are sometimes helpful in treating anxiety, depression and obsesssionality, and small doses of risperidone have been reported to be helpful in children and some adults with the syndrome. Indeed, risperidone is our belief that much more of this intensive therapy should be available to infants and young children in the UK.

Highly unsaturated fatty acid supplements have been tried in autism and related conditions, including dyslexia and dyspraxia, apparently with some success. Less mainstream treatments include secretin injections (one review suggests these are ineffective), a casein- and gluten-free diet (a 2004 review concluded that this is an important area for research and that large-scale randomized controlled trials are needed), and many and varied recommendations for various vitamins, trace metals and similar substances, along with avoidance of chemicals such as food colourings and preservatives. It is understandable that such a serious condition with apparently so little in the way of mainstream treatments will attract so many therapeutic suggestions. Providing they are harmless, they may be reasonable and possibly helpful in some people.

Autism is a serious and disabling condition. It seems that there are many possible causes that may lead to a similar presentation. There is probably a significant degree of brain damage at the level of synapses/neuron connectivity, but this damage does not show up on standard brain scans. A certain amount of autism may be normal and helpful in an evolutionary sense, and men seem to be nearer this condition at baseline. Most successful treatment approaches seem to involve considerable mainly social input as early as possible, something that is often not available.

ASSessment in learning DISability

Making a psychiatric assessment on a person with a learning disability is a similar process to making a psychiatric assessment on anyone else. Initially a detailed history will be taken. This may be from the individual or their carer, or both. The presenting complaint is discussed, along with other standard information, including past medical, surgical and psychiatric history. Family history of psychiatric illness is important and offers clues to diagnosis. Specific questions are asked around developmental history, including any problems during pregnancy or at birth, birth weight and developmental milestones, such as walking alone (usually occurring at about 12 months) and talking (normally some babbling at about 6 months, two-word sentences at 2 years, and longer sentences and incessant talking at 3 years). The school attended should be recorded and a note made if this is a special school for people with learning disability, in addition to any examinations entered for or passed. The current social situation should be asked about, including care arrangements and day activities.

A quick test of abilities can be carried out, asking the patient to write a short sentence or their name, read a few lines in a book, and carry out some simple arithmetic. Skills of day-to-day living should also be considered and recorded, including the ability to clean, dress and wash themselves, and the abilities to travel independently, budget and understand money. Employment history is important, including whether the patient has ever been able to work unsupported on the open market (rather unusual for a person with learning disability). Past medical history should be recorded, along with any history of epilepsy and any special investigation results, for example head MRI or EEG. Allergic reactions to drugs or foods should be asked of the carer, since the person with learning disability may not be aware of this potentially important information.

This detailed history will ideally be backed up with a physical examination and various baseline tests, including routine blood tests. Unfortunately, it is not uncommon for a person with learning disability to refuse these investigations, particularly if they do not understand the purpose of the test. Head-scanning all referrals to learning disability psychiatry is probably not practical, although it could be argued that it may be ideal, particularly since MRI scans are probably harmless (which is not necessarily the case with computed tomography (CT) scanning). Apart from helping to exclude organic brain pathology for the presentation, MRI scanning may represent a very useful baseline that can be repeated at a later stage, for example if dementia is suspected in a person with poor verbal skills. An EEG is helpful for patients with diagnosed or suspected epilepsy; it is also better tolerated than scanning and might be ordered when an MRI proves impossible.

Various psychological tests may be helpful. If not already available, an IQ test can prove useful with diagnosis and service provision, particularly for people on the borderline between learning disability and mental health services. The IQ test may demonstrate a difference between verbal and performance skills, which can have a significant effect on day-to-day functioning, or a ‘spiky’ profile, sometimes seen in autism.

Occupational therapy has many assessment tools to look at daily living skills, including the Adaptive Behaviour Assessment System (ABAS) and Assessment of Motor and Process Skills (AMPS). Speech and language therapy has its own scales and provides dysphagia assessments.

This comprehensive gathering of information can then be
backed up by reports from other services, for example schools, educational psychologists and child and adolescent mental health services, where appropriate. The patient’s GP may know the patient and family well and may be the only person with a global knowledge of all the various agencies involved, and therefore the GP is a crucial source of information.

Having completed the assessment, a care plan can be drawn up, which may include referrals to other learning disability specialists, for example family therapy via psychology. If there appears to be an obvious psychiatric illness, appropriate drug treatment may be started.

Sometimes the diagnosis is in doubt or the main problem appears to be challenging behaviour not obviously associated with a psychiatric illness and not responding to initial therapeutic interventions such as psychology or social input. Consideration may then be given to trying a medication as part of a therapeutic trial. This idea is somewhat controversial, but the practice certainly takes place, perhaps justified by the likely possibility that psychiatric illness may present atypically in people with learning disability and that psychiatric drugs may on occasions be helpful in treating behaviour seen largely in people with learning disability (e.g. the use of fluoxetine in the treatment of self-injurious behaviour).

When recommending therapy of this nature, it should be safe, carefully documented, the goals of prescription made clear, reviewed regularly and stopped if proving non-beneficial.

Making a psychiatric diagnosis in a person with learning disability is complicated and challenging and requires considerable effort. A full assessment may direct services towards the most appropriate treatment and therapeutic success.

BEHAVIOURAL PHENOTYPES

Behavioural phenotypes are typical patterns of behaviour that may be associated with certain genetic abnormalities. The concept is potentially helpful, in assisting with diagnosis and helping to explain to parents or carers one factor that may be driving challenging or otherwise difficult behaviour. Equally, however, it should not be given excessive emphasis by assuming that everyone with a certain genetic make-up will behave in a similar way or that because of a particular genetic make-up associated behaviours are unavoidable or untreatable. The behavioural phenotype also describes the typical cognitive abilities associated with a particular genotype.

Some syndromes have been reported to be characterized largely by the behavioural phenotype; for example, Smith–Magenis syndrome (deletion of 17p11.2) is associated with very demanding behaviour, severe temper tantrums, hyperactivity, aggression, self-injurious behaviour, sleeping problems, head-banging and finger-biting.

A behavioural phenotype has been reported in association with Down syndrome, although this is not consistent or inevitable. Being less likely to show maladaptive behaviour than other peers with learning disability has been mentioned along with strong powers of imitation, a lively sense of humour, obstinacy and amiability. A more recent report suggests the use of and ‘over reliance on’ social behaviours during cognitively challenging tasks.

Fragile X syndrome has been associated with a behavioural phenotype, including learning disability, autistic features, rapid and disrhythmic speech, anxiety, hand-flapping or hand-biting, shyness and avoidance of eye contact.

Prader–Willi syndrome is well known for its association with excessive eating and obesity. It is also associated with learning disability, short stature and neonatal hypotonia, the latter demonstrating the important point that certain behavioural phenotypes may be seen only at specific stages of development. Other behaviours include skin-picking, temper tantrums, compulsive behaviour and mood fluctuations. There may also be differences within the group of people with Prader–Willi syndrome, depending on the genetic subtype. Research has reported that people with the long type I 15q deletion have compulsions around personal cleanliness, and that people with the short type II 15q deletion are more likely to have compulsions around academic areas (e.g. reading and re-reading or counting).

There are many other behaviours associated with genetic causes of learning disability, including self-mutilation following spasticity and choreoathetosis in Lesch–Nyhan syndrome; sleep problems, hyperactivity and non-compliant obsessiveness in tuberose sclerosis; and hyperactivity, anxiety, compulsions, self-injurious behaviour and autistic features in Cornelia de Lange syndrome.

Study of behavioural phenotypes with an ever-increasing match to specific biochemical abnormalities may ultimately assist in the development of treatments for these conditions, along with the possibility of a better understanding of the biochemical basis of behaviour in general.

TREATMENTS

Various treatments for psychiatric illness in learning disability have already been mentioned. Biological treatments include all the mainstream psychiatric drugs, such as antipsychotics, antidepressants, mood stabilizers and minor tranquillizers. Electroconvulsive therapy (ECT) is rarely prescribed, although reports exist suggesting efficacy in treatment-resistant mood disorder and psychotic disorder.

Clozapine is used more frequently and has been said to be safe, efficacious and tolerated well, although, like lithium, clozapine is available only to people who accept regular blood tests.

Attention deficit–hyperactivity disorder (ADHD) is seen in children with learning disability and may respond to psychostimulants such as methylphenidate. This
medication may also prove useful in adults. Anti-libidinal drugs, for example cyproterone acetate, are rarely prescribed, but their use has been described in men with learning disability and aberrant sexual behaviour that cannot be managed by educational or behavioural approaches.\footnote{117}

Many people with learning disability have epilepsy. For these individuals, consideration needs to be given to the possibility of subclinical seizures causing or complicating a psychiatric presentation in addition to the side effects of the anticonvulsants themselves causing difficulties.

Of the more commonly used anticonvulsants, psychiatric side effects include depression, aggression and activation of psychosis with carbamazepine; aggression and behavioural disturbance with sodium valproate; depression, emotional lability, insomnia, irritability, aggression and psychosis with levetiracetam; confusion and hallucinations with lamotrigine; depression and suicidal ideation with topiramate; and depression, hostility, insomnia, anxiety and hallucinations with gabapentin.\footnote{118} Clearly all these side effects, and many others not listed above, are rare, but they should be considered in making a diagnosis.

Vitamin and mineral supplements have been suggested for a number of conditions, including Down syndrome, although there is little evidence that they are helpful. Highly unsaturated fatty acids have been said to be useful in autism and ASD, as have secretin injections and a gluten- and casein-free diet, but again there is little good evidence to recommend these treatments.

Educational approaches are important and early long-term intensive input to children with autism has already been mentioned. Traditionally, psychology will be involved in the behavioural treatment of problem behaviours – various forms of counselling and cognitive-behavioural therapy may be used. Behavioural approaches may look at antecedent, behaviour and consequence (ABC) charts, which might show unintentional reward for challenging behaviour. If, for example, a person with autism and poor communication is feeling socially overwhelmed, they may learn quickly that hitting out will lead to them being removed to their own room and thus avoid the social difficulties. Equally, social reward in the form of social contact may be inadvertently given for unacceptable behaviour, resulting in perpetuation or worsening of the presentation. This may be particularly relevant in unstimulating environments.

Counselling may be verbal or through other mediums such as art or music. In less verbal therapies, patients may be invited to comment on their use of musical instruments or their pictures and drawings and helped in this way to express difficult feelings or thoughts, which may then be therapeutic. The Books Beyond Words series, published by the Royal College of Psychiatrists, offers pictorial representations of various scenarios (epilepsy, bereavement, depression and growing up, among others), allowing shared exploration of a topic, either using words or without the use of language. Cognitive-behaviour therapy has been used with some success in people with learning disability, although it requires a degree of understanding that may be difficult for people with significant intellectual deficit.\footnote{119}

Other members of the multidisciplinary team have very important roles to play.

Community nurses will be involved in various activities, including advice around medication, specialist training (e.g. use of rectal diazepam in status epilepticus), monitoring and administering intramuscular injections (contraception and antipsychotics), liaising with GPs, running healthy eating groups, and monitoring and maintaining health action plans in conjunction with GPs.

Social services can assist with benefits, accommodation and day activities. Help is unlikely to be delivered by a social worker, except through duty contact. Instead, an assessment of needs will be followed up by recommendations and, if eligible, the purchase of a care package. This might involve a second agency being contracted to provide care. They may be paid to visit the individual on a daily basis for a few hours to assist with shopping, budgeting, cooking and promoting social contact, this last factor being potentially very important. The current fashion for supported living and supported tenancies has resulted in many people with learning disability now living on their own. When this is coupled with the relatively small realistic peer group available to these people, without sufficient and imaginative support long-term isolation may result in depression and be a significant factor in a psychiatric presentation.

Occupational therapy approaches may assist the individual in finding the confidence to travel independently, seek employment or improve their general abilities in activities of daily living. Success in any of these spheres may well improve self-esteem and reduce depressive feelings. Where problems in communication appear to be important in maintaining anxiety or depression, speech and language therapists may be able to help with aids that allow pictorial representations of spoken words. Books can be produced with photos of various foods, favourite places to visit, rooms (e.g. the toilet, bedroom, bathroom) and pain, among other things. These can then be used by the person with limited vocal communication skills to make their needs known to others.

In conclusion, successful psychiatric treatment of people with learning disability is likely to be multifactorial and involve the input of different professionals, including social services. The prescription of medication will often be an important factor in such treatment.

**OFFENDERS WITH LEARNING DISABILITY**

It would be very unusual in the UK to find someone in prison who also has a significant learning disability, IQ has been studied in remand prisoners in Scotland and found to
be average although associated with low educational achievement. This is probably quite right, but what is the response of society to those people who appear to have a significant learning disability and who offend? It might be hoped that people with learning disability will not offend, which may well be the case in respect of crimes such as armed robbery and fraud. However, persistent physical assaults on others, arson and exposure in public certainly occur and require a response. For more extreme and dangerous crimes, a hospital disposal is a possible outcome, while for less serious offences, increased community supervision may be provided, in both instances along with therapeutic endeavours including drug treatment, talking therapies and other treatment options.

The 1983 Mental Health Act describes two grounds for detention under the Act that apply only to people with learning disability, namely mental impairment and severe mental impairment. These are considered, along with mental illness and psychopathic disorder, to constitute ‘mental disorder’, which may be grounds for involuntary treatment. Both mental impairment and severe mental impairment require that the person has ‘arrested or incomplete development of mind’, with significant or severe impairment of intelligence and social functioning along with ‘abnormally aggressive or seriously irresponsible conduct’.

Thus, a person with a learning disability who has been charged with a crime may be involuntarily detained for hospital treatment on the grounds of mental disorder. This may be after an assault felt to be secondary to a persecutory delusions (a mental illness), or when no obvious mental illness seems to be present, under mental impairment or severe mental impairment, by virtue of the learning disability and behaviour associated with the crime. The Act allows the possibility of providing secure forms of treatment to this group of people as an alternative to prison, usually in a hospital setting.

Since criminal behaviour is not obviously a psychiatric illness, it may be difficult for psychiatrists to treat more persistent offenders, and long admission periods become a possibility. Admissions may take place on general NHS learning disability wards, on forensic units or, more commonly, in private sector provision. Following a crime, ‘diversion’ of a person with learning disability from the criminal justice system to health and social services may occur at different stages. On many occasions after, for example, an assault on staff by a ward inpatient, the police are not called. If they are called, then it is not uncommon for the police to advise that there is little they can do and for the individual to remain within health and social services provision and treatment. If the alleged offence is more serious, then a hospital disposal under the Mental Health Act (Sections 2 and 3) may be sought, without attempting to charge the individual. If the person is successfully charged with an offence, then an alternative to prison might be the use of a forensic section of the Mental Health Act, for example Section 37, which in the most severe cases could have a Home Office restriction order also applied (Section 41), making ultimate decisions of discharge more complicated and not at the sole discretion of the responsible medical officer.

If a person with an apparent learning disability is to be interviewed by the police, the person should have access to an appropriate adult, whose role is to advise the individual and actively observe the interview process (Police and Criminal Evidence Act, 1984), hopefully safeguarding against issues such as a desire to please, suggestibility and poor understanding, which may result in incorrect and untrue confessions being made.

It may be felt that an apparent offender appearing at court with a learning disability is unfit to plead, meaning that they are unable to put forward a proper defence, challenge a juror, give instructions to their lawyer, and follow the evidence. If this is found to be the case, then a new jury will hear a trial of the facts, a guilty verdict at this stage leading to various possible disposals, including hospital treatment.

Risk assessments have become increasingly part of the remit of psychiatric teams, and attempt to bring some science to the prediction and possibly prevention of undesired future events. In forensic learning disability services, they might, for example, look at the risk of repeated arson.

Recidivism is usually most highly correlated to future risk. Other factors can be important; for example, in a non-learning disabled population, violence and being associated with previous violence were also found to be related to substance abuse, lack of empathy and stress. Risk assessments include personal factors, factors related to the illness, and factors related to the mental state and may be helpful in promoting consideration of issues that might be missed during a normal multidisciplinary case conference. The Historical, Clinical, Risk Management 20 (HCR 20) is one such tool and considers issues such as previous violence, relationship instability, employment problems, insight, attitudes, drug and alcohol use, personal support availability and compliance. Attempts have been made to validate these assessments, and reports exist indicating some success in this respect. Other authors have been more critical of their accuracy and usefulness. Even if risk assessments can be made to be more accurate, there remains the difficulty of what should be done when high levels of risk are predicted. Are we prepared to remove a person’s freedom for prolonged periods of time based on uncertain assessment tools predicting possible future events? Perhaps their main value is in assisting the research and development of effective treatments for these various undesirable behaviours.

Finally, court reports may be requested at times from psychiatrists working with people with learning disability. Information contained should include some note of the qualifications and experience of the doctor making the report, information made available to the doctor, a full
history, the circumstances of the offence, a mental state assessment, and diagnosis and formulation. Other considerations include fitness to plead, risk assessment and recommendations for disposal.

MENTAL CAPACITY AND CONSENT

Some people with learning disability and their carers are periodically faced with issues around consent. In health, a common example might concern an operation and the consent required of the individual before this can be carried out. (In the UK no one can consent for medical treatment on behalf of another adult.) A person with a severe learning disability will not understand the nature of the operation, the purpose of the operation, the possible risks involved, the risks of doing nothing, and the treatment alternatives (if available), the factors associated with the ability to give valid consent.

If doing nothing is likely to lead to a serious or potentially fatal outcome, then there is not usually any great problem, an example being the surgical treatment of acute bowel perforation. Here, ‘consent’ may be sought of the nearest relatives or main carers; provided the treatment is in line with what would be considered good medical practice, treatment without proper consent is accepted.

The situation is rather different for procedures that are not life-saving, the most notorious in the learning disability field being sterilization. Almost invariably in situations such as this, involvement of the legal profession and courts will be required.129

Lesser situations arise on a daily basis. Blood tests may be requested by a GP. People without learning disability can appreciate the potential value of the test, and know that it will not be particularly painful and that it is very low risk. A person without this understanding will, understandably, actively resist the procedure and may well require restraint if the blood is to be taken. If this is the case, then it is important for the doctor and carers to assess the potential importance of the test. Our feeling is that a blood test would not be justified as a routine check but might be justified where a treatable diagnosable condition is suspected, for example thyroid disorder or diabetes.

Drug treatment may be suggested for a person with a significant learning disability who is unable to understand the possible risks and benefits of the medicine. At times, the ingestion of the drug may be actively resisted. In some situations, this behaviour will be interpreted as refusing consent, and where the necessity of giving the medicine is in doubt the drug may be stopped. This might not be an acceptable outcome if the medicine involved is a powerful anti-epileptic and non-compliance is known to result in multiple seizures or status epilepticus, or the medicine is thyroid replacement treatment with refusal causing life-threatening myxoedema. If the person is felt to have capacity for their refusal, then even life-saving treatment cannot be given; however, in the case of significant learning disability, where capacity is in doubt, treatment may be insisted on, following multidisciplinary discussion and consent from relevant family and carers. Actually delivering this treatment may be easier said than done.

A similar situation occurs on a daily basis in many learning disability homes throughout the UK, where locked doors are used to protect vulnerable individuals from the dangers of the outside world, while at the same time clearly restricting their human rights.

The Mental Capacity Act, 2005, has considered these various issues. Under this Act people are assumed to have capacity for the decisions they make. This can be tested on each individual issue by assessing whether the person is able to understand the information relevant to the decision, is able to retain the information, can use the information in making a decision, and is able to communicate the decision (not necessarily verbally). If the person is felt to lack capacity, then any ‘act done or decision made under this Act on behalf of a person who lacks capacity must be done, or made, in his best interests’. It is also noted in the Act that ‘a person is not to be treated as unable to make a decision merely because he makes an unwise decision’.130

Generally speaking, if it is felt that an individual lacks capacity for a decision, then decisions made on the person’s behalf should be documented, in their best interest, in line with current practice, and should follow discussion with family, carers and other involved professionals.

CONCLUSION

Learning disability psychiatry is a fascinating field that touches all aspects of medicine. Forty years ago the majority of statutory care was provided in big institutions geographically removed from the rest of society. Now people with learning disability live in towns and cities with everyone else, with ever-increasing rights and some additional responsibilities. In the vast majority of cases, these changes have improved the quality of life for this group of people.

Providing good healthcare in these changing circumstances has proved challenging, but most GPs now have a list of learning disability patients and are becoming increasingly confident in treating this patient group. In general hospitals liaison work can still be of crucial importance when a patient with a learning disability is admitted for an illness or operation.

When considering behavioural change, physical causes should always be considered. It is important to remember that genuine psychiatric illness may present in atypical ways. Issues around consent, capacity and compliance may all contribute to important challenges in any aspect of treatment. The possibilities for research that could have implications for everyone exist, excellent examples being the association between the additional genetic material in
Down syndrome and presenile dementia, and obesity and Prader–Willi syndrome. There are, however, considerable challenges in carrying out research on people with learning disability, the inability to gain valid consent underlying many of these difficulties.

The role of traditional health services has changed considerably over the past few decades, and social services now head combined learning disability teams. In addition, mainstream medical professionals, particularly GPs but also general psychiatrists, are becoming increasingly involved in learning disability health and psychiatric services. The future of specialist learning disability psychiatry is therefore as a lead profession in the multidisciplinary team. The primary focus will be community work along with advice to other professionals, the development of specialist community teams (challenging behaviour, admission avoidance, autism), research, and an important role in limited admission services and traditional hospital-based care.

REFERENCES

INTRODUCTION

The population of elderly adults is rising in the western world. There will be a significant increase in the total number of people with dementias and functional illnesses in this age group. The psychiatry of old age is likely to become an increasingly important area of specialism over the coming years.

DEMENTIA

Dementia is a clinical syndrome characterized by multiple cognitive deficits. Behavioural, psychological symptoms and neurological difficulties may also be present. The deficits result in impairments in the ability to function at work and socially and to manage activities of daily living. Dementia is an acquired disorder that most commonly develops in late life and does not usually cause impairment in the level of consciousness.

Epidemiology

The number of cases of dementia (all subtypes) in the UK was estimated to be about 700,000 in 2007. This is a prevalence of about 1.1 per cent (1 in 88 of the population). Worldwide, in 2007 nearly 18 million people were thought to have dementia. The prevalence of dementia increases with age, doubling with every 5-year increase across the entire age range, from 30 years to 95 years and over. The number of people with dementia in the UK and the rest of the world is forecast to increase considerably over the next few decades.¹

Aetiology

The most common cause of dementia in elderly people is Alzheimer’s disease (AD), followed by dementia with Lewy bodies (LBD) and Vascular dementia (VaD). Potentially reversible aetiologies include normal-pressure hydrocephalus (NPH), subdural haematoma, metabolic and endocrine causes, and vitamin deficiencies.

The various causes of dementia are listed in Table 72.1.

Clinical features

A number of cognitive deficits occur in dementia. Memory impairment (amnesia) is a prominent symptom, especially in dementia of the Alzheimer’s type. Language difficulties (aphasia) may occur. This may present as a decrease in the quality of speech, and there may be difficulties understanding written and spoken language. In the late stages of dementia, the speech may be incomprehensible or the patient may be mute. Difficulties carrying out coordinated motor tasks are another symptom. This occurs despite intact motor and sensory functions and comprehension of the task (apraxia). Problems such as difficulties with dressing or using cutlery may be the result. There may be difficulties recognizing objects or familiar people, with no impairment in visual function (agnosia). The ability to plan activities and think abstractly (executive functioning) is often impaired. Executive functioning is particularly impaired in dementia of the frontal lobe type.
Behavioural and psychological symptoms of dementia (BPSD) are common in dementia. Depression occurs frequently. A variety of psychotic symptoms may occur, including paranoid ideation, delusions and hallucinations. Behavioural difficulties such as aggression, wandering, changes in sleep and changes in eating patterns are also common. Changes in personality can be distressing to relatives and are a prominent feature of frontal lobe dementias.

Neurological features may be present early in the course of the disease, depending on the type of dementia. Some common examples are parkinsonism in LBD, focal neurological signs in vascular dementia, and primitive reflexes in the frontotemporal dementias. Rarer dementias may have characteristic neurological features. Myoclonus occurs in Creutzfeldt–Jakob disease and choreathetoid movement in Huntington’s disease. All dementias involve a progressive loss of motor function in the end stages.

Dementia causes impairments in all domains of functioning. Difficulties in work may be noticed. Mild degrees of cognitive impairment may impair the individual’s ability to perform complex jobs but not less demanding jobs. Social functioning is frequently affected. The person may not remember appointments and may find it hard to remember the names of friends and relatives. With continued deterioration, it may no longer be possible to join friends in activities that are intellectually demanding. The person may lose interest in friends and family as a result of apathy, which is a common symptom of dementia. Neglect of household tasks may become apparent. There is often impairment in the activities of daily living (ADLs). ADLs refer to basic self-care tasks and the skills required to live independently in the community, such as washing, dressing, eating, personal hygiene and toilet activities. A decline in the standard of personal cleanliness may be noticed. Self-neglect of the diet can lead to weight loss. In the late stages of dementia, the ability to eat, use the toilet and dress may become severely affected.

**Assessment**

The diagnostic process involves identifying a dementia syndrome, determining the likely aetiology, and ruling out other causes of a similar clinical picture.

**History**

The history is probably the most important component of diagnosing dementia. History must be obtained both from the patient and from appropriate informants, including family members, friends and any professionals involved. Details of cognitive deficits and behavioural and psychological difficulties should be noted. It is essential to note the effect of the cognitive deficits on the patient’s functioning. The chronology of the symptoms, including the onset, rate of progression and any fluctuations in the symptoms, is especially important when it comes to elucidating the likely aetiology. A detailed medical history, including risk factors for vascular disease such as diabetes, hyperlipidaemia, hypertension and cardiac arrhythmias, and a history of cigarette use is needed. In addition, an alcohol history and a family history of dementias are also of aetiological significance.

**Mental state examination**

Mental state examination may reveal inappropriate clothing or reduced hygiene. The patient may be disoriented or disorganized. There may be signs of depression, such as psychomotor retardation or agitation. Speech in dementia is often fluent, but with a paucity of content. There may be word-finding difficulties and perseveration; as the dementia progresses, speech may get more sparse. In the terminal stages, speech output may be reduced to incoherent sounds or mutism. Thought content is often reduced. There may be evidence of psychosis or depression. Hallucinations may be present. Visual hallucinations must raise the suspicion of a delirium or an LBD. Cognitive assessment is a crucial part of the mental state. The patient interview when obtaining the history will give some indication of any cognitive difficulties. However, more formal tests are usually done. The Mini-Mental State Examination (MMSE) and the Abbreviated Mental Test Score (AMTS) are the most commonly used initial screening tests. The patient’s level of insight into the cognitive and other symptoms will vary. A degree of awareness may be present. Often, the patient may not be aware of the cognitive difficulties or may minimize their significance.

**Physical examination**

A complete physical examination must be done. A cardiovascular and neurological examination are of particular importance. An elevated blood pressure or an irregular pulse may have aetiological significance. A neurological examination may show focal neurological deficits, parkinsonism or primitive reflexes. The presence of difficulties in sight or hearing must be noted as these can contribute to cognitive problems.

**Investigations**

A number of standard blood tests are usually done in order to identify any treatable causes or co-morbid conditions in a dementia. The National Institute for Health and Clinical Excellence (NICE) guidelines in the UK recommend routine haematology, biochemistry including electrolytes, calcium, glucose, kidney and liver function, thyroid function and vitamin B12 and folate levels. Although a syphilis screen was routine in the past, the latest guidelines suggest doing this only if the history or clinical picture is of relevance. A chest X-ray or electrocardiogram (ECG) may be considered, depending on the history. A number of experts recommend doing an ECG routinely before starting cholinesterase inhibitor treatment.

Structural scanning (computed tomography (CT), magnetic resonance imaging (MRI)) is done to exclude pathology, such as a brain tumour, cerebral bleeding or hydrocephalus, which are potentially reversible. Scanning
is also helpful in diagnosing the dementia subtype, for example generalized atrophy in AD or evidence of ischaemic changes in vascular dementia. However, specialist interpretation is required, and a number of different pathologies may coexist.

CT screening is the radiological investigation of choice to exclude intracranial lesions, with MRI indicated for a more detailed assessment of cerebral structure.

Single photon emission computed tomography (SPECT) is a functional scan and measures blood flow. It can be of help in differentiating AD and a frontal lobe dementia. Dopamine transporter scans (DATScans) may be helpful in the diagnosis of LBD.

Electroencephalography (EEG) can detect the generalized slowing of brain electrical activity associated with a dementia. The EEG is not used routinely in dementia diagnosis but may help in cases of diagnostic uncertainty. It is certainly useful in Creutzfeld–Jakob disease or if an associated seizure disorder is suspected.

Rating scales
A number of scales may be used in the assessment and monitoring of dementia. The most commonly used is the MMSE. The MMSE is used as a screening test for dementia and can be helpful in the diagnosis and monitoring of the course of the disease. The test takes about 10 min but will not detect subtle memory difficulties, especially in well-educated people. The MMSE provides measures of orientation, registration (immediate memory), short-term memory (but not long-term memory) and language functioning. A score of 26 or less may indicate significant cognitive impairment. The AMTS is often used in the acute medical setting as a quick screening test for cognitive difficulties; it includes a list of ten items – a score of 6 or less is considered significant. The AMTS is rarely used by psychiatrists, however.

The clock-drawing test is often used, especially in general practice, to screen for dementia. It is easy to administer and is non-threatening. The Alzheimer’s Disease Assessment Scale is a more detailed cognitive test commonly used in research. The Clinical Dementia Rating Scale gives an overall severity rating. Neuropsychological symptoms can be monitored using the Neuropsychiatric Inventory (NPI); the NPI also records the distress caused by the symptoms in the carers. Scales for rating ADLs, such as the Bristol Activities of Daily Living Scale, may be used.

Diagnosis
The Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) definition of dementia involves multiple cognitive deficits with memory as a required criterion. There should be at least one other cognitive deficit, which must be aphasia, apraxia, agnosia or disturbances in executive functioning. The cognitive deficits must be severe enough to cause significant impairment in social or occupational functioning and must represent a decline from a previous level of functioning.

The International Classification of Diseases, 10th revision (ICD-10) requires a decline in memory and thinking sufficient to impair activities of daily living. However, certain dementias such as the frontotemporal lobe type may not have the cognitive deficits required to fulfil the present ICD-10 and DSM-IV criteria in the early stages of the disease.

Some experts feel that the emphasis on memory impairment as an absolute requirement for the diagnosis of a dementia is inappropriate in the non-Alzheimer’s dementias.

Differential diagnosis
A number of conditions can mimic dementia and must be considered in the diagnostic process. These include:

- delirium;
- depression;
- drugs;
- normal age-associated memory decline;
- mild cognitive impairment (MCI);
- chronic schizophrenia.

Differential diagnosis

Delirium is usually an acute disturbance (over days) with marked fluctuations in the clinical picture, whereas dementia generally has a relatively stable picture. Cognitive deficits that persist for an extended period (months) suggest a dementia. A LBD may, however, have a similar clinical presentation to a delirium, with fluctuations in the level of consciousness and cognition. People with dementia are at an increased risk of developing a delirium, and the possibility of these two conditions coexisting must be borne in mind.

Depression may present with symptoms similar to those of dementia. However, there are features that are helpful in differentiating between these conditions. In depression the patient may complain of memory loss, whereas in dementia it is often the relatives who notice the patient’s memory loss. Affective changes are more common in depression than in dementia. Negative thoughts, including low self-esteem, guilt, hopelessness and thoughts about death, should suggest a depressive disorder. Patients with depression tend to give ‘don’t know’ answers, whereas incorrect answers are more likely in dementia.

A number of drugs can cause symptoms of dementia. Medications with anticholinergic side effects are a particular culprit. A detailed drug history is therefore essential during the assessment process of a dementia.

It is normal for memory to decline with the age. In MCI, there are cognitive difficulties greater than what one would expect to be related to age, but there is no impairment in social and occupational functioning and ADLs, unlike the situation in dementia (see below).

Chronic schizophrenia may be associated with a number of cognitive impairments. However, these are often stable through middle life. The time course of symptoms will help to differentiate this from a dementia. A proportion of
patients may show further cognitive decline in old age. Mechanistic explanations may be schizophrenia-related neurodegeneration or a superimposed dementia.13

Management

The general principles of dementia management are described here. Specific treatment of issues of the dementia subtypes are described in the relevant sections below.

Dementia management requires a multidisciplinary approach. There may be the need for functional and social support, psychological assistance for both the patient and the carer, and drug treatment. Drug treatment is aimed at cognitive enhancement and the behavioural and psychiatric symptoms.

The needs of the patient and the carer should be assessed when a diagnosis of dementia is made. This may involve a social worker and an occupational therapy assessment. For patients living at home, help may be needed with shopping, cleaning, daytime activities and cooking. Risks at home, such as from fires, intruders and wandering, must be taken into account. Help with the management of financial issues and legal matters (e.g. wills, enduring power of attorney) is often required. If the patient is a driver, the Driver and Vehicle Licensing Agency (DVLA) must be informed. Support for carers, including sit-in services, respite admissions and day-centre placements, is often needed as the dementia progresses.

A number of psychological approaches targeted at the patient and the carer have been shown to be helpful. Reality orientation and verbal or visual cues are used to orient the person to themselves, the time and their environment. Validation therapy focuses on the emotional content of the cognitively impaired person rather than on the factual content.14 Behavioural analyses using an ABC (antecedent, behaviour, consequence) are helpful in the understanding and management of difficult behaviours. Supportive psychotherapy that uses techniques of reassurance, explanation and education may be beneficial.15

Intense individual psychotherapy is often unsuitable in dementia due to the patient’s cognitive difficulties. However, some of these techniques may be useful in the early stages of the disease.

Cognition, especially in Alzheimer’s dementia, may benefit from the use of the cholinesterase inhibitors or memantine (see Alzheimer’s disease, below).

Management of behavioural and psychiatric symptoms of dementia

The first step is to get an accurate assessment of the difficulties from the history and observation. The impact on both the patient and the carer should be noted. Standardized rating scales such as the NPI may be used. A behavioural analysis as described above should be considered.

When drug treatment is considered for agitation and psychosis, antipsychotics are often used. These have been shown to be effective, but there are a number of adverse effects, including increased mortality, risk of strokes, falls and drowsiness, worsening cognitive decline and Parkinsonism. There is evidence that the cholinesterase inhibitors are effective in the treatment of agitation and psychosis, and these are increasingly being used as alternatives to antipsychotics. Although the current evidence base is limited, clomethiazole or anti-epileptics are sometimes considered. Antidepressants should be considered for depression. In the UK, Kings College in collaboration with the Alzheimer’s Society is conducting a study looking at the effectiveness of the antidepressants setraline and mirtazapine in people with dementia and depression. The study is being carried out at a number of centres nationally and was still in progress at the time of writing (http://www.iop.kcl.ac.uk/projects/?id=10179). The judicious use of hypnotics for insomnia and the use of benzodiazepines for agitation may be options in some cases. The risk of falls and drug dependence must be borne in mind.

Non-pharmacological treatments for agitation, including aromatherapy16 and bright-light therapy,17 have some evidence of efficacy.

Mild cognitive impairment

MCI refers to a state of cognitive difficulties beyond that of normal age associated decline but not sufficient to meet the criteria for a dementia. Although MCI may involve any cognitive domain, memory impairment is most commonly involved. People with MCI progress to AD at a greater rate than would be expected for healthy individuals of the same age.

There are no consensus criteria for MCI. However, the following criteria formalized by Peterson and colleagues are frequently used:18

- Cognitive complaint, usually memory
- Normal general cognitive function (i.e. cognitive screening test) in normal range for age (e.g. MMSE)
- 1.5 standard deviations (SD) below age-appropriate norms on memory tests or memory component of other cognitive tests (tests determined by clinician’s judgement)
- ADLs not affected significantly
- Not meeting DSM dementia criteria (i.e. impairments not sufficient to impair professional and social activities).

Vascular cognitive impairment is MCI related to a vascular cause; however, the term is also used in the literature as an umbrella term to cover the entire range of cognitive impairment due to vascular causes, ranging from vascular MCI to vascular dementia. There is some evidence that cholinesterase inhibitors have symptomatic benefit in MCI, but it is unclear whether cognitive decline is prevented by their use.19
Alzheimer’s disease

Alzheimer’s disease was first described by Alois Alzheimer in 1907. It is the most common type of dementia, accounting for 50–70 per cent of cases. The number of people in the UK with AD in 2007 was estimated at 417 000.1 One in eight people over the age of 65 years has AD, and nearly half of people over the age of 85 years have AD.

Clinical features

The onset of the disease is insidious. Memory loss is the characteristic early symptom of AD. Although memory for recent events is lost first, as the disease progresses long-term memory is affected as well. Disorientation to time is common, and the patient may get lost in unfamiliar places. In the early stages of the disease, the standards of self-care may deteriorate. Language is commonly affected early in the disease. Word-finding difficulty (nominal dysphasia) is the most common language difficulty. Patients may describe the function of an object without being able to recall the name – for example, saying ‘a thing you write with’ instead of ‘pen.’ Fluent dysphasia – fluent speech but with a paucity of understandable content – is the second most common language problem. The other cognitive, behavioural and psychiatric features of dementia as described above also develop. Impairment of judgement is an important symptom that may put the patient at risk and cause concern to their family.

Pathophysiology

A characteristic feature of the brain of a person with AD is generalized atrophy of the cerebral hemispheres, in particular the medial temporal lobes, hippocampus and amygdala. The microscopic hallmark is the extracellular neuritic plaque and the intracellular neurofibrillary tangle. The plaques are composed of an amyloid core surrounded by neuritic processes. The amyloid core consists primarily of a small peptide known as Aβ, which is derived from the larger amyloid precursor protein (APP).

Neurofibrillary tangles are intracellular structures associated with hyperphosphorylated tau. The neurochemical basis of AD is thought to be a cholinergic deficit, and this forms the basis of the cholinergic hypothesis of AD. Other neurotransmitters such as γ-aminobutyric acid (GABA) may also be involved.

Diagnosis

The gold standard for the diagnosis of AD is the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS)–Alzheimer’s Disease and Related Disorders Association (ADRDA) criteria (Box 72.1).2

Management

Drug treatment has been available for AD since the 1990s. The drugs used are the cholinesterase inhibitors and memantine. There are currently three cholinesterase inhibitors licensed for the treatment of mild to moderate AD in the UK – donepezil, galantamine and rivastigmine. Memantine is licensed for the treatment of severe AD. Of these, donepezil is the most widely prescribed.3 These medications inhibit the enzyme acetylcholinesterase, which results in an increase in the amount of acetylcholine available for neurotransmission. Memantine blocks glutamate-mediated cell damage by binding to the N-methyl-D-aspartate (NMDA) receptors.

Cholinesterase inhibitors have been shown to slow down the rate of cognitive and functional decline. They are also beneficial in the treatment of neuropsychiatric symptoms and behavioural difficulties. Studies have shown that caregivers of patients on treatment may have reduced emotional distress. The benefits may last up to 3 years.4 In severe dementia, behavioural rather than cognitive benefits tend to be the goal. Memantine has similar benefits to the cholinesterase inhibitors. The most common side effects of the cholinesterase inhibitors are gastrointestinal – nausea, vomiting and anorexia. Caution in the case of a history of cardiac and respiratory disease, peptic ulcer disease or gastrointestinal bleeding is advisable. Memantine tends to be tolerated better.

In the UK, NICE introduced controversial guidelines in 2006 recommending that the cholinesterase inhibitors should be used only in moderate dementia. NICE does not recommend the use of memantine.5 These decisions were based on cost–benefit analyses and have been challenged. A subsequent court case resulted in NICE having to make it explicit that it would be based on the judgement of the clinician.

Prognosis

AD is a progressive disease and the life expectancy is shortened. A figure of 8 years is often quoted. There is however considerable variation in between individuals and people
may survive between 5 and 20 years after the onset of symptoms. The cause of death is often a medical condition such as a chest infection.

**Vascular dementia**

Vascular dementia occurs as a result of impairment in the vascular supply of the brain. This impairment can have many causes, but atherosclerotic changes are the most common. Vascular dementia is the third most common type of dementia after AD and LBD.

**Clinical features**

The classical history for vascular dementia described in textbooks is acute or subacute cognitive impairment after an acute neurological event, with a stepwise progression. However, the onset may be more gradual, especially if it is due to lacunar infarcts or white matter ischaemia. There may be neurological signs such as hemiparesis, sensory change, dysphasia or visual disturbances. Mood disturbances, including mood lability, depression and anxiety, are more common than in AD and may predate the cognitive impairments, especially if the onset is gradual. Headache, dizziness, tinnitus, syncope and other non-specific features may be early features that present before the cognitive or neuropsychiatric complaints. Neuropsychological testing in vascular dementia typically shows patchy deficits, whereas AD shows global impairment with memory difficulties prominent early in the disease.

**Diagnosis**

There are a number of criteria used in the diagnosis of vascular dementia. Hachinski and colleagues devised a list of criteria in the 1970s to differentiate vascular dementia and AD (Box 72.2). Based on the number of criteria present, a score below 4 was said to be AD and a score of 7 or above a vascular dementia. Patients scoring between 4 and 7 were thought to have a mixed picture. These criteria are rarely used nowadays because they do not take into account neuroradiological findings and are not as useful if the vascular dementia has a more gradual onset.

The DSM-IV criteria include focal neurological signs and symptoms or laboratory evidence of cerebrovascular disease (radiological evidence) that are judged to be aetiologically related to the dementia. This is sensitive but not very specific for vascular dementia. The National Institute of Neurological Disorders and Stroke (NINDS)–Association Internationale pour la Recherche et l’Enseignement en Neurosciences (AIREN) criteria are the most specific of all the available criteria and are used most commonly in research. These criteria provide three levels of certainty: definite, probable and possible (Box 72.3).

**Pathology**

There may be a number of different types of pathological change. Large single infarctions can affect the cerebral cortex and underlying white matter, usually in watershed areas (parts of the brain at the ends of the distribution areas of the cerebral arteries). Multiple cortical infarcts can occur. There may be lacunar infarcts (deep small infarcts < 1.5 cm in diameter). White-matter changes (leucoariosis), best seen on MRI as areas of hyperintensity, are believed to be caused by ischaemia as a result of small-vessel disease and are increasingly recognized as a cause of dementia, especially if the changes are in the periventricular area. If the white-matter changes are diffuse and widespread, then the resulting dementia is termed ‘Binswanger’s disease’. There may be a combination of the various pathologies.

---

**Box 72.2 Modified Hachinski score**

Score < 4: suggests a primary dementia e.g. Alzheimer’s disease  
Score 4–7: indeterminate  
Score > 7: suggests a vascular dementia.

1. Abrupt onset of symptoms  
2. Stepwise deterioration  
3. Fluctuating course  
4. Nocturnal confusion  
5. Personality relatively preserved  
6. Depression  
7. Somatic complaints  
8. Emotional lability  
9. History or presence of hypertension  
10. History of stroke  
11. Evidence of co-existing atherosclerosis  
12. Focal neurological symptoms  
13. Focal neurological signs

**Box 72.3 NINDS – AIREN criteria for vascular dementia (summarized)**

1. Probable vascular dementia: Dementia defined by a decline in memory and two or more other cognitive domains. There should be focal neurological signs consistent with a stroke and evidence of cerebrovascular disease by brain imaging. The dementia should arise within 3 months of the stroke or there should be an abrupt decline in cognitive functioning or a fluctuating, stepwise course.
2. Possible vascular dementia: Dementia with focal neurological signs in the absence of brain imaging studies.
3. Definite vascular dementia: Probable vascular dementia together with histopathological evidence.

Management
There is no treatment currently available to reverse the brain damage caused by cerebrovascular disease. The management of vascular dementia involves monitoring and treating the risk factors in an attempt to reduce the risk of further deterioration. This includes administering antiplatelet drugs and controlling major vascular risk factors (e.g. hypertension, hypercholesterolaemia, smoking, diabetes mellitus). There is some evidence that the drug pentoxifylline, which increases blood flow, improves cognition in vascular dementia.24 There is evidence that treatment with cholinesterase inhibitors may be of benefit; however, these drugs are not currently approved for this indication in the UK or the USA.

Prognosis
The course is extremely variable. The underlying vascular risk factors may lead to a stroke or a myocardial infarction; this may result in a pneumonia leading to death.

Dementia with Lewy bodies
Dementia with Lewy bodies and dementia in Parkinson’s disease are often described as distinct entities determined by the relationship between the onset of motor symptoms and dementia. However, it is unclear whether they are the same or different disorders.

Epidemiology
Although older textbooks state that vascular dementia follows AD in prevalence, many experts now believe that LBD is the second most common type of dementia.25 The prevalence in the community is between 0.1 per cent and 5 per cent. LBD accounts for about 22 per cent of all cases of dementia.26–28 LBD is more common in men than in women.

Clinical features
The age of onset is 50–83 years. Fluctuations in the cognitive performance are a characteristic feature. Alterations in the level of consciousness and visual hallucinations may occur, as in delirium.29 The visual hallucinations tend to be complex and are often of people or animals. The complexity of the visual hallucinations is thought to decrease with the progression of the dementia. Hallucinations may also occur in other modalities, and delusions may be present. Symptoms of depression are common: studies show its presence in between one-third and one-half of patients.29,30 Parkinsonism is present in up to 70 per cent of patients. Recurrent falls and syncope are common. Neuroleptic sensitivity may occur in a third of cases and may involve worsening parkinsonism, impaired consciousness and autonomic disturbances.31 Sleep disturbances are an important feature in LBD and include rapid-eye-movement sleep behaviour disorder (RBD), excessive daytime sleepiness, insomnia, sleep apnoea and restless legs syndrome.32,33

The differentiation from AD can be difficult in practice; however, patients with LBD tend to have more visuospatial impairment and less memory impairment in the early stages than patients with AD. Thus, memory changes on the MMSE may be more prominent with AD, whereas difficulties in clock-drawing or figure-copying may be more indicative of LBD.34

Diagnostic criteria
The consensus criteria by McKeith and colleagues are shown in Box 72.4.

Pathology
Lewy bodies are intracytoplasmic inclusion bodies and are found in LBD and Parkinson’s disease. They consist of abnormally phosphorylated neurofilament proteins aggregated with ubiquitin and alpha synuclein. The Lewy bodies are present in the brainstem or limbic areas, or they may have a diffuse distribution. Alzheimer’s-type plaques are present in a similar density and distribution to that seen in Alzheimer’s disease, but neurofibrillary tangles are less common.36 Evidence suggests that the clinical presentation is driven by AD pathology and not Lewy body distribution.37

Management
The treatment of hallucinations and delusions is challenging in LBD because of the symptom severity, the patient’s sensitivity to treatment and the high stress levels of the patient’s carers. If the symptoms are mild, no medication treatment may be needed. Cholinesterase inhibitors are

</table>
often used as first-line treatment for troublesome symptoms. A multicentre trial has shown behavioural and cognitive benefits when rivastigmine is used in LBD. At the time of writing, rivastigmine was the only one of the cholinesterase inhibitors licensed for the treatment of dementia in Parkinson’s disease and so it is often used for LBD. A more recent trial has shown that all three currently available cholinesterase inhibitors – rivastigmine, galantamine and donepezil – are of benefit, in terms of both neuropsychiatric symptoms and cognition. Cholinesterase inhibitors may worsen tremor; however, this worsening is usually very mild and not too troublesome clinically. Cholinesterase inhibitors are not routinely prescribed solely for the cognitive difficulties seen in LBD, unlike in AD. There is evidence of cognitive benefit, but the slowing of cognitive decline is harder to establish in LBD and has not been adequately demonstrated. The early symptomatology of LBD tends to be dominated by behavioural and psychiatric issues.

Antipsychotics can be effective for the treatment of psychosis in DLB, but there is a risk of neuroleptic sensitivity with both typical and atypical antipsychotics. There are also other risks associated with the use of antipsychotics in dementia, including increased mortality and cognitive decline. If an antipsychotic is considered, atypical antipsychotics, particularly quetiapine, may be preferred. A study by Roger and colleagues showed that quetiapine did not worsen parkinsonism; however, other studies have not shown this. The NICE guidelines for dementia in the UK allow severe behavioural symptoms in LBD to be treated with antipsychotics, but they advocate monitoring for worsening parkinsonism and acute physical deterioration. There is no evidence to suggest that depression should be treated any differently from usual. RBD may be treated with clonazepam. Other treatments include antidepressants and melatonin.

Parkinsonism may sometimes be helped with medications such as levodopa. However, there is the risk of worsening confusion and psychotic symptoms, and the effect on the movement disorder is probably less than that in Parkinson’s disease.

**Prognosis**

The rate of progress in LBD is similar to that of AD, although some authors believe that the course is shorter in LBD. The functional impairment may be greater and quality of life may be more impaired than in AD.

**Frontotemporal dementia**

Frontotemporal dementia (FTD) is a group of disorders that primarily affect the frontal and temporal lobes of the brain.

**Epidemiology**

Frontotemporal dementia is the second commonest cause of early onset dementia (<65 years) after AD. Although some studies had suggested that FTD occurred more frequently in men than in women, the most recent evidence shows an equal prevalence in both sexes.

**Pathology**

There are three types of histopathological finding in FTD. The first type, which is the most common, shows neuronal loss, spongiform change and minimal gliosis. The second type (Pick type) includes argyrophilic inclusions, with neuronal loss and abundant gliosis. The third type involves either of the first two patterns plus evidence of motor neuron disease in the anterior horn cells of the brainstem and spinal cord.

**Clinical features**

The clinical features include personality changes, behavioural changes, language problems and, as the disease progresses, neurological signs. Memory and other cognitive functions tend to be affected less severely in the early stages of the disease.

A key feature is a decline in social conduct. This might include socially inappropriate behaviours such as stealing, sexually inappropriate behaviour, disinhibition and tactlessness. The patient may become apathetic, with a loss of drive, or may be overactive. There may be decreased emotional expression than was the case premorbidly. A lack of awareness of the behavioural problems and the difficulties they cause commonly occurs.

Compulsive or repetitive behaviour such as foot-tapping, collecting things or hand-washing is another feature. An increase in appetite and a preference for sweet foods, leading to weight gain, is a symptom. Loss of speech and language, and various verbal stereotypes, may be present. There may be a decreased response to painful stimuli.

As the disease progresses, parkinsonian symptoms may develop.

There are two related disorders with similar histological characteristics. The clinical presentation depends on the topography of the disease and not on the pathology. Semantic dementia involves the temporal lobes bilaterally and results in a loss of ability to understand the meaning of words and objects. Progressive non-fluent aphasia is associated with the Sylvian fissure in the left hemisphere and involves language difficulties.

**Diagnostic criteria**

The Lund Manchester criteria are given in Box 72.5.

**Investigations**

Although the history is the most important component in the diagnosis, neuropsychological testing including frontal lobe tests may be of benefit. The tests may often be normal. CT or MRI scanning may reveal frontotemporal lobe shrinkage. SPECT scanning may be helpful in differentiating this disorder from AD. The EEG is usually normal.
Management
A multidisciplinary approach involving the family and other caregivers is needed in view of the frequent difficulties in managing these patients. The patients are relatively young and physically well, can demonstrate a number of behavioural difficulties and have limited insight.

There is currently no treatment that helps to prevent the progression of FTD. Symptomatic drug treatment for the behavioural problems may be considered. Antipsychotics may be of benefit for aggression and if there are psychotic features. Selective serotonin reuptake inhibitors (SSRIs) have been shown to be of benefit for compulsions, disinhibition and overeating. Caregivers may need assistance from support groups and planned respite admission; 24-h care may be needed.

Prognosis
The disease progresses over 2–10 years before resulting in death.

Mixed dementias
AD pathology often coexists with vascular pathology, and this is sometimes referred to as 'mixed dementia'. Although both DSM-IV and ICD-10 include a category of mixed dementia, there are no consensus criteria. ‘Pure’ AD or vascular dementia may not be as common as previously thought. About 40 per cent of patients in the community with dementia have been found to have mixed pathology. The diagnosis during life may be based on clinical and imaging factors. In clinical practice, the results of neuroimaging are probably the most common reason for changing an initial clinical diagnosis of AD to that of a mixed dementia. Treatment involves cholinesterase inhibitors or memantine and the management of vascular risk factors.

DELIRIUM
Delirium, or acute confusional state, is a state of cerebral dysfunction. It usually has an acute onset and fluctuates over the course of the day. It is characterized by a disturbance of consciousness, which manifests as impaired attention. The patient’s attention wanders and they may be distracted by irrelevant stimuli. There are cognitive difficulties, particularly with short-term memory, and disorientation to time or place. Speech may be rambling and incoherent. Perceptual disturbances including distortions, illusions and hallucinations, especially in the visual mode, are common. The patient may be overactive and restless, or lethargic and drowsy; sleep patterns are frequently affected. Mood may be one of perplexity, euphoria or apathy and may shift rapidly and unpredictably.

Delirium is a medical emergency and has a high mortality and morbidity rate in elderly people. In elderly patients, delirium is associated with increased length of hospital stay and a higher rate of entry into nursing homes. Risk factors for delirium include cognitive and sensory impairment, use of restraints, malnutrition, the use of more than three medications, bladder catheterization, and increasing number of iatrogenic events. Common precipitants for delirium in elderly patients include infections, constipation, medications and electrolyte abnormalities. Delirium is common after surgery.

As for younger people, the treatment involves identifying the cause and offering supportive measures.

LATE-ONSET SCHIZOPHRENIA
The classification of schizophrenic illnesses starting late in life has been contentious. A number of different terminologies and cut-off age limits have been used in the literature. The term ‘late paraphrenia’ was used by some authors to describe paranoid delusions and hallucinations in older people. Other authors prefer the term ‘late-onset schizo-
phrenia’ (LOS) because of a number of similarities to early-onset disease. The DSM-IV and ICD-10 classifications do not include a separate category for late-onset psychotic illnesses; however, schizophrenia may be diagnosed at any age.

The Late Onset Schizophrenia Group, which comprised 17 international representatives of basic science and clinical schizophrenia research and academic and clinical geriatric psychiatry centres, issued a consensus statement in 2000 that divided schizophrenia into three groups based on age. The early-onset group is said to have an age of onset below 40 years, the late-onset group between ages 40 years and 60 years, and the very late schizophrenia-like group at an age above 60 years.68

Epidemiology

The epidemiology for new-onset schizophrenia has not been established clearly; however, the proportion of patients with schizophrenia whose illness first emerged after the age of 40 years was estimated to be 23.5 per cent in one study.59 An incidence rate of 12.6 per 100 000 population per year has been calculated using the age of onset of 45 years. The 1-year prevalence rate of schizophrenia in individuals aged 45–64 years was shown to be 0.6 per cent.60 The prevalence of schizophrenia in older adults in the community is less than 0.5 per cent.61,62 The risk for females is higher than that for males in late life.

Clinical features

LOS is frequently characterized by persecutory delusions, which may relate to the patient’s neighbours. Partition delusions – usually relating to some material or radiation passing through the patient’s walls or ceilings from a neighbour’s house – may occur in two-thirds of patients with very-late-onset schizophrenia-like illness. Auditory hallucinations are the second most common psychotic symptom. The auditory hallucinations may range from a hum to those of a Schneiderian first-rank symptom nature. Visual, tactile and olfactory hallucinations are not uncommon. Thought disorder, negative symptoms and catatonia are rare, especially after the age of 60 years.

Aetiology

Structural imaging is similar to that of early-onset cases, with higher ventricular to brain ratio versus age-matched controls and focal abnormalities such as reduction in the volume of the left temporal lobe.63

Some studies reported an increase in infarcts or white-matter hyperintensities in very-late-onset cases.64 However, when patients with focal neurological abnormalities and dementia were excluded, there was no demonstrable excess of these changes.65

It is possible that an increase in the number of D4 receptors plays a role in the development of LOS.

There are often lifelong paranoid and schizoid traits in people who develop LOS. However, there is probably less psychosocial, educational and occupational dysfunction than in people with early-onset disease.66

There is an association between sensory deficits, especially deafness and visual impairment, and late-life schizophrenia. However, causation has not been established.

Management

Elderly patients who develop schizophrenic symptoms frequently have poor insight into their experiences. Often they manage in the community for long periods until their behaviour becomes a significant risk to themselves or others, when they are brought to the attention of the mental health team. They may resist investigations and treatment. Many will agree to take medications for symptomatic relief while not accepting the medical opinion regarding the diagnosis. Antipsychotic agents continue to be the first-line treatment for late-onset psychosis, despite the lack of robust randomized clinical trials in this population. Clinical experience, however, suggests that these drugs are of benefit. It is important to select patients appropriately and to carefully weigh the benefits and risks when initiating these agents. Dosages of one-quarter to one-half of those used in early-onset cases are often sufficient. Elderly people starting antipsychotics are at an increased risk of having side effects compared with working-age adults. The risk of developing tardive dyskinesia may be three to five times greater in elderly patients than in younger adults.67 Psychosocial interventions may be helpful in helping the patient and their family to cope with the symptoms. There is very little published evidence on specific psychotherapies in schizophrenia with first onset in old age.

Prognosis

Fully developed symptoms rarely go away completely; however, their intensity and the disruption they cause will fluctuate over time. One small study suggested a link with AD.48 However, other evidence indicates that patients with very-late schizophrenia-like disorder present with stable cognitive and everyday functioning, compared with chronically institutionalized elderly patients with schizophrenia.69

Older people with chronic schizophrenia

People who have had a diagnosis of schizophrenia from an early age and have grown old with the disease are sometimes referred to as ‘graduates’, especially in the UK literature. This term has been used since the early 1970s and predominantly describes people with schizophrenia; however, other enduring mental illnesses such as mood disorders are also included. People are thought of as ‘graduating’
from services designed for the needs of adults of working age to those designed for older people.

**Epidemiology**

The number of older people with chronic schizophrenia is not known. This is due partly to the variety of settings in which these individuals are now based. It is estimated that people who develop schizophrenia before the age of 45 years, and who age with it, represent about 85 per cent of all people with schizophrenia. In the UK, the number of elderly people with chronic psychoses in the 1980s was estimated at around 30 per 100 000 of the population.

**Clinical issues**

Older people with chronic schizophrenia have complex mental and physical health difficulties and social needs. Hallucinations and delusions tend to become less severe with time, but negative symptoms tend to worsen. Some studies have shown evidence of continued cognitive decline in elderly people with chronic schizophrenia. Cognitive deficits are associated with poor social and community functioning.

Elderly people with chronic schizophrenia may be at risk of having unrecognized physical health problems and poor management of illnesses. This may be for a number of reasons, including poor insight and poor medication compliance. The rates of cardiovascular diseases and diabetes in people with schizophrenia have been reported to be increased above those in people without the disease.

Elderly people with chronic schizophrenia tend to have varying degrees of social impairment, but their general coping skills may improve. Social impairment is associated with impaired cognition, negative symptoms and parkinsonism. There may also be issues of stigma due to the long history of mental health difficulties and the side effects of antipsychotic medications.

**Management**

Elderly people with chronic schizophrenia are managed by adult, old-age or rehabilitation psychiatry. The Royal College of Psychiatrists in the UK produced a report in 2002 to highlight the needs of ‘graduates’. This report recommended that health and social services identify these needs and draw up individual care plans to meet these needs, taking into account the available resources.

Older people with schizophrenia may be on high doses of medications started when they were young. With the pharmacokinetic and pharmacodynamic changes of the ageing process, lower doses may be more suitable in older people. Cognitive-behavioural therapy (CBT) has been shown to be helpful in treating persistent symptoms in younger patients. In older people, a cognitive-behavioural approach may also be of benefit, particularly for improving social functioning. Social care needs may be complex and should be addressed on an individual basis.

---

**AFFECTIVE DISORDERS IN ELDERLY PEOPLE**

**Depression**

**Epidemiology**

Depression is the most common psychiatric illness in elderly people. The prevalence of major and minor depression in elderly people living in the community is 10–15 per cent. About 2 per cent of these people meet the criteria for a major depressive disorder. A number of people have subthreshold depression – symptoms of depression that do not fulfil the standard criteria for a depressive disorder but that still cause suffering and are treatable.

**Clinical presentation**

It may be more appropriate to think of depression as a spectrum ranging from subthreshold symptoms to a major depressive disorder. Sticking rigidly to the categories in ICD-10 and DSM-IV may be less appropriate in elderly people, due to the variety of clinical presentations.

The diagnostic criteria for depression do not take age into account; however, there may be some differences in presentation in elderly people compared with in younger adults. Low mood or sadness may not be reported in elderly people, while anxiety, feelings of not being able to cope, and irritability may be more frequent. Memory may be impaired and can present with a dementia-like picture. Somatic and hypochondriacal symptoms may occur in elderly people, making the differentiation from physical disorders difficult. Depression may present with behavioural changes such as refusing care, aggression and new-onset alcohol dependence. Physical symptoms such as low energy, anorexia and weight loss may be difficult to interpret due to co-morbid physical disorders.

There is evidence for a subtype of depression (vascular depression) that arises primarily in later life and is associated with cerebrovascular disease. Distinct clinical features may include reduced depressive ideation (e.g. guilt), greater cognitive impairment, particularly including executive functioning, and psychomotor retardation. An association has been reported between deep white-matter changes, especially in the frontal lobe and basal ganglia, and depression on MRI scanning. These changes may reflect small-vessel ischaemia. The concept of vascular depression is not without its critiques, however, and there are no consensus criteria at present.

**Management**

Antidepressants are effective in elderly people, with tricyclic antidepressants and SSRIs having equal efficacy in this age group. The altered pharmacokinetics and pharmacodynamics of elderly people make it essential to use antidepressants with caution. The SSRIs are often preferred because of the anticholinergic side effects of tricyclic antidepressants. The SSRIs are also safer in an overdose.
However, there is an increased risk of gastrointestinal bleeding with SSRIs: it is advisable to use caution if there is a history of gastrointestinal bleeding or if the patient is on aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), and concomitant use of a proton-pump inhibitor may be an option worth considering in some cases. There is also the risk of hyponatraemia in elderly people as a result of the syndrome of inappropriate antidiuretic hormone secretion (SIADH), particularly with the SSRIs; monitoring of serum electrolytes is therefore advisable. Venlafaxine and mirtazapine have also been shown to be effective in elderly people. Medical co-morbidity is associated with a decreased tolerability of, and a poorer response to, antidepressants.

Electroconvulsive therapy (ECT) is a safe and effective treatment in major depression in old age, with a recovery rate of 70–80 per cent of patients. ECT is generally used for severe depression when other treatment options have failed and when there is a threat to life from poor dietary intake or suicidal ideation. There is evidence that it is particularly effective in psychotic depression. The current NICE guidelines recommend ECT only for short-term treatment and not for maintenance treatment. Patients should have ongoing cognitive checks due to the risk of post-ECT memory impairment.

CBT is increasingly used in the treatment of mild and moderate depression and is recommended by NICE in the UK. CBT is at least as good for treating depression in older people as it is for younger adults.

Interpersonal therapy is effective in preventing relapse. Cognitive therapy may, however, be better than interpersonal therapy in more severe depression. Cognitive analytical therapy may be considered particularly if unresolved issues from the patient’s past form a significant part of the clinical picture. In more severe depression, a combination of psychotherapy and medications may be the most effective option.

Prognosis
The recovery rates of depression in elderly people are lower than those in younger adults. If confounders such as physical illness are taken into account, the rates in late life are little different from those in midlife, but relapse rates appear higher. A number of patients develop chronic symptoms.

Late-life depression may increase the risk of mortality. A study in 2008 showed that increasing depression severity corresponds to a greater mortality risk, with elderly men on antidepressants being at a particularly high risk. The risk was thought not to be pharmacological but to be related to the depression. The mortality is due in part to cardiac causes.

Bipolar affective disorder
Although bipolar affective disorder is relatively uncommon in elderly people, it can be a diagnostic and management challenge. Mania in older people can either be in the context of a patient with a previous diagnosis of a bipolar disorder or have its first onset in old age.

Epidemiology
The prevalence of mania in the community decreases with age, from 1.4 per cent in younger adults to 0.1 per cent in people over 65 years. However, first admission rates increase with age, perhaps relating to an increased need for inpatient treatment. Twelve per cent of all affective disorders treated on specialized geriatric psychiatry units are due to mania.

Clinical presentation
The clinical features of older people with mania are similar to those seen in younger adults with mania. The former may have a less severe form of the illness and less sexual preoccupation. A late-onset mania is more likely to be associated with organic mental illness, although one study showed that overall there was only a slight increase in the association with organic pathology in late-onset versus early-onset bipolar disorder.

Management
A thorough physical examination and appropriate investigations have to be carried out in late-onset mania in order to rule out an organic cause. Neuroleptics, lithium and anti-convulsants are used as for younger people, but in lower doses and at a slower titration. Social and psychological support is important to consider.

Prognosis
Although not supported by all studies, there may be a poorer prognosis in elderly people with bipolar affective disorder compared with those with unipolar depression. A risk of increased risk of mortality was found in the former by Shulman and colleagues. Late-life bipolar disorders are associated with cognitive impairments. It is unclear whether there is an increased risk of dementia.

ANXIETY DISORDERS

Epidemiology
The prevalence of anxiety disorders has been estimated at 1–10 per cent of the elderly population. Up to one in seven adults may have appreciable levels of anxiety if life-disrupting subsyndromal anxiety is included. There is an excess of females for most disorders. The prevalence and incidence tend to fall with age.

Clinical presentation
The full range of anxiety disorders seen in younger people may occur in elderly people. A relatively common type of
phobia in elderly people called ‘space phobia’ has been described. This involves a fear of falling in open spaces and may lead to confinement at home.107

Abnormal illness behaviour, including somatization and hypochondriasis, may develop. In the majority of patients, these behaviours have their onset in early life. First presentations in old age are usually secondary to depression or an anxiety disorder. Obsessional disorders rarely appear for the first time in old age. The possibility of focal or generalized organic causes must be considered.

Assessment

Detection of anxiety symptoms in elderly people is complicated by a number of factors, including physical illnesses, multiple medications, the difficulty of differentiating anxiety from depression, and the tendency of some older adults to resist psychiatric evaluation.108 The anxiety may be dismissed by health professionals as being ‘understandable’ given the life situation.

Symptoms starting for the first time in elderly patients require thorough investigation. Due to the range and overlap of anxiety symptoms and co-morbidity with medical illnesses, some authors have suggested that a dimensional rather than a categorical approach may be more useful in the evaluation of these symptoms.109

Management

Medication treatment is as for younger people. However, the side effects of medications and the effects of ageing need to be taken into account. Antidepressants may be considered, especially if there are symptoms of depression. SSRIs are usually the preferred choice, but the risks of gastrointestinal bleeding and hyponatraemia must be borne in mind. Short-term use of benzodiazepines for relief from troublesome symptoms may be an option. The possibility of dependence, memory impairment, risks of falls and delirium in elderly people should be taken into consideration.

Psychological therapies have been shown to be of benefit in treating anxiety disorders in younger adults. Trials in older people are also supportive of the use of psychological approaches. Research conducted to date suggests that CBT produces significant improvement in anxiety symptoms among elderly patients. However, there is some concern that CBT does not benefit elderly patients with anxiety as much as it does younger patients with anxiety. Methods of augmenting or supplementing CBT are being developed to make it more suitable for older adults.110

Smit and colleagues identified risk factors for developing anxiety in late life, which include depression, two or more chronic illnesses, poor sense of mastery, poor self-rated health and low educational level. The authors suggested that this may offer opportunities for prevention.111

LEGAL ISSUES

Mental capacity

Mental capacity refers to a person’s ability to make a decision regarding an action. This is of particular relevance in old-age psychiatry and is often an issue when making decisions regarding medical treatment, place of residence, finances and care arrangements.

Mental Capacity Act

The Mental Capacity Act 2005 came into force in England and Wales in October 2007. It is a statutory framework that enables decision-making on behalf of adults aged 16 years and over who lack capacity to make decisions on their own behalf.

The Act sets out a clear test for a person who lacks capacity. This involves the inability to:

● understand the information relevant to the decision;
● retain that information;
● use or weigh that information as part of the process of making the decision; or
● communicate the decision.

The test of capacity is decision-specific, for example a decision regarding a particular treatment, and is not a global characteristic of the person concerned. People are presumed to have capacity unless it is proved otherwise. The Act also states that the ability of a person to make a decision must be maximized before a conclusion about the lack of capacity can be made; this might include writing things down or using a translator. People are allowed to make ‘unwise’ decisions.

When a person lacks capacity, decisions must be taken based on the person’s best interests. The Act provides a checklist for determining best interests; these include taking into account the person’s past and present wishes (in particular, any relevant written statements made by the person when capacity was present), the person’s beliefs and values, and the views of anyone involved in the care of the person and any donee of a lasting power of attorney.

The Act has introduced a number of new powers and bodies. The Lasting Powers of Attorney (LPA) allows individuals to appoint another person (an attorney) to look after their property and financial affairs and to make health and personal welfare decisions when they lack the capacity to make these decisions themselves in the future. The attorney(s) can use the LPA only after it has been registered with the Office of the Public Guardian. The Act creates a new Court of Protection, which is ultimately responsible for the proper functioning of the legislation. Independent mental capacity advocates (IMCAs) have been introduced by the Act. The role of the IMCAs is to assist incapacitated adults who do not have anyone else to help them in the decision-making process for serious medical treatment or place of residence.112
Living wills and advance directives (decisions)

Any person with capacity has the right to accept or refuse medical treatment. Living wills are statements made about accepting or refusing medical treatment at a future date when capacity is not present. Living wills are not legally binding but should be taken into account when treatment is being considered in an incapacitated person. Advance directives are a type of living will concerned specifically with decisions made in advance about the refusal of treatment when it is being considered and capacity is not present. Advance directives have a legal basis in the Mental Capacity Act and must be respected; however, there are circumstances when an advance directive might not be acted upon, such as when the person has acted in a manner inconsistent with the decision (e.g. a change of religious faith) or an unanticipated change in circumstances (e.g. treatment advances that change the prognosis of the condition).112

Testamentary capacity

This refers to the ability of a person to make a will. The criteria for testamentary capacity are based on the case of Banks versus Goodfellow (1870) and involve the following. The person making a will (testator) must:

- understand the nature of a will;
- have knowledge of the nature and extent of their assets;
- be able to recall and understand the claims of potential heirs;
- be free of delusions or hallucinations that influence their testamentary decisions.

Understanding the nature of a will refers to understanding that the will deals with the distribution of the testator’s property to the named person or people after the testator’s death.

The testator need not have a detailed knowledge of their property, but they do need to have a reasonable idea of what their property constitutes. A psychiatrist may be asked to assess a person’s testamentary capacity in difficult cases. They may also be asked to give evidence if the will is contested after the testator’s death on issues of capacity and undue influence.

Driving

Driving is a complex activity and requires the integration of perception, motor function and cognition. Ageing is associated with slower cognitive functioning and reduced musculoskeletal strength and flexibility. There is a slight increase in the crash risk in people over 70 years (the highest risk is in males aged 16–24 years). Practical steps to continue safe driving include driving for shorter periods, taking frequent breaks, driving during only daylight hours, and maintaining longer stopping distances.

In the UK, the DVLA is responsible for issuing driving licences. The law governing the issue of driving licences is contained in the Road Traffic Act 1988 and the Motor Vehicles (Driving Licences) Regulations 1999. Age is not a bar to having a UK licence. However, at the age of 70 years, the DVLA requires confirmation that there is no medical disability; thereafter, the licence is reviewed every 3 years.

A diagnosis of a dementia has consequences for driving. As the disease progresses, the ability to drive is usually lost. Over the course of the disease, evidence suggests that the risk of a crash is increased significantly. As a general rule, however, the risk seems to remain acceptably low for up to 3 years after the onset of dementia, by which time most patients have stopped driving.111

The DVLA acknowledges that it is extremely difficult to assess the driving ability in people with dementia and that the presentations and rates of progression are variable. In early dementia, when sufficient skills are retained and progression is slow, a licence for group 1 vehicles (cars, motorcycles) may be issued, subject to annual review. A formal driving assessment may be necessary. The licence for group 2 vehicles (vehicles over 3.5 tonnes, including lorries and buses) will be revoked on the basis of a diagnosis of a dementia in view of the increased risks relating to the size of the vehicle and the time spent in occupational driving.

Notifying the DVLA of a medical condition that affects driving is the responsibility of the licence holder. It is the duty of the doctor to inform patients of this responsibility. Failure to notify the DVLA is a criminal offence. There is also a duty to inform the insurance company. The DVLA may require a medical report and a driving assessment.

The General Medical Council (GMC) advises doctors that, in some circumstances, it may be necessary for them to break confidentiality and contact the DVLA if the patient continues to drive when they may not be fit to do so.

The psychological and practical negative consequences of revoking a licence must be borne in mind. It is an independent risk factor for entry into a nursing home.114

OLD-AGE PSYCHIATRY SERVICES

Older people have often been overlooked when it comes to the planning of services. As the population ages and the number of older people with mental illnesses rises, it is important that planned and funded services exist to address the need. The cut-off age for entry into services is usually 65 years. There have been discussions as to whether separate services should exist for elderly people, since this has implications of ageism. However, older people do have unique requirements, such as physical co-morbidity, increased incidence of cognitive difficulties and frailty. A continued separate service with the required expertise is probably the most useful way of addressing the needs of these people.
Community mental health teams
Mental health services in the UK are provided through specialist community mental health teams (CMHT). The role of the team is to provide assessment and treatment of the mental health of older people with complex needs. The team consists of members from a variety of professional backgrounds who work in a concerted manner. The National Service Framework for Older People in the UK recommended that the core members of the team should include a consultant psychogeriatrician, community mental health nurses, a clinical psychologist, a social worker and an occupational therapist.\(^{115}\) There should be referral arrangements with other professionals, including physiotherapists, speech and language therapists and dieticians.

The role of the community nurse may include monitoring the mental health of the patients and providing advice and support to the carers. The nurse can alert the general practitioner (GP) or psychiatrist if the patient’s condition worsens and needs further medical input. Nurses in the UK have the opportunity to become supplementary prescribers and can do this as part of an agreed care plan.

Psychologists play a vital role in neuropsychological assessments of people with cognitive impairments. Specific psychological treatment may also be offered, depending on the local arrangements.

Occupational therapists are needed to assess patients’ skills for independent living; this is particularly relevant in dementia. They may help in setting up adjustments to the patient’s home in order to enable the patient to continue to function well in that environment.

A CMHT social worker helps in coordinating care arrangements in the community and in organizing 24-h residential or nursing placements. An approved mental health worker (most often a social worker with specialized training) in the UK also has the role of assessing the needs of people being considered for detention under the Mental Health Act.

Day hospitals
Day hospitals form an important part of the psychiatric services for older people in the UK, with more than 90 per cent of teams in the UK having access to places.\(^{116}\) However, a number of Mental Health Trusts have recently been reviewing the need for Day Hospital access.

The roles and benefits of day hospitals include the following:

- Assessment of patients to help with diagnostic clarification and for observation of behavioural difficulties in dementia
- May be an alternative to more expensive in-patient admission in some cases
- May help in the transition from in-patient settings to the community and reduce the length of in-patient admission
- Rehabilitation of patients with dementia
- Psychotherapeutic interventions for behavioural difficulties
- Respite for carers
- Longer-term support for those with relapsing illness or poor response to treatment.

Day hospitals are distinct from day centres.

In-patient care
Elderly people frequently have considerable physical health needs and may be frail. They are best managed in wards for older people and not together with working-age adults.\(^{117}\) In-patient settings around the UK vary as to whether they have separate units for people with organic and functional disorders or whether such patients are admitted together. This may depend on local resources and practicalities such as the number of patients. Patients with dementia may have a number of behavioural difficulties, and it is advantageous to manage them separately, as this will require specific staff expertise and ward environment. Old-age psychiatric units are best located in or close to general hospitals, where there is access to geriatric or general medical expertise and laboratory and radiological resources.

Memory clinics
Memory clinics are specialized clinics that aim to diagnose and treat people with memory problems. The staff must consist of a psychiatrist, nurses and a neuropsychologist. The role of the doctor is to help with the diagnosis of dementia and to assess co-morbid psychiatric and medical conditions, which may contribute to the memory problems. Some memory clinic teams are nurse-led. The nurses may be involved in the initial diagnostic process and help in the monitoring of treatment. A psychologist must carry out comprehensive cognitive assessments, especially in cases of diagnostic difficulty. The clinic may advise the patient and their carers on issues to do with driving and social care. Longer-term issues such as financial arrangements, living wills and advance directives may also be addressed. There is evidence to suggest that memory clinics provide better-quality assessment, care-planning and follow-up than do traditional old-age psychiatry home assessment visits for people with memory disorders.\(^{118}\)

Liaison service
There is a very high prevalence of mental health disorder among older people within the general hospital setting. Delirium in elderly people is common, with a prevalence of up to 20 per cent on medical wards and even higher in surgical wards.\(^{119}\) Dementia is found in up to 30 per cent of elderly in-patients.\(^{120}\) The rates of depression vary between studies but may be as high as 40 per cent.\(^{121}\) These illnesses are often underdiagnosed and undertreated, with resulting increased morbidity.

Despite this, liaison psychiatry for older people is gener-
ally a poorly resourced part of the psychiatric service. In the UK, the service is generally on an ad hoc consultation basis, usually by a psychiatrist. A liaison model may be more suitable. One option is to have a multidisciplinary team, including psychiatrists, social workers, occupational therapists, psychologists and psychiatric nurses. In addition to helping with the diagnosis and management of mental illness, the role of the team would be to provide training to the general hospital staff. The liaison model would facilitate easier access to psychiatric advice, help with ongoing management difficulties and may help to improve clinical outcomes.122

KEY POINTS

- Dementia is a clinical syndrome of a number of cognitive deficits along with behavioural, psychological and neurological symptoms; it causes significant morbidity in older people and has an impact on the patient’s family, health and social services, and the economics of a country. The prevalence is expected to increase considerably over the next few decades.
- The commonest cause of dementia is Alzheimer’s disease. Early memory loss is a characteristic feature of Alzheimer’s disease; however all cognitive domains are affected over time. A cholinergic deficit is thought to be an important cause of the symptomatology, and treatment with acetylcholinesterases such as Aricept can slow down the course of the disease.
- The second most common cause of dementia is Lewy body disease. Marked fluctuations in cognition and level of consciousness, parkinsonism, visual hallucinations and neuroleptic sensitivity frequently occur. Lewy body disease may cause more severe functional impairment than Alzheimer’s disease. Treatment of the visual hallucinations can be problematic; cholinesterase inhibitors are a useful option.
- Vascular dementia has a variety of presentations, ranging from the classical stepwise progression to a slow and gradual course. Neurological symptoms and psychological symptoms are commoner than in Alzheimer’s disease, and the cognitive deficits are patchier with early memory loss being a less prominent symptom. There is no specific treatment; however the vascular risk factors need to be monitored closely to reduce the risk of further brain damage. Vascular dementia may coexist with Alzheimer’s disease.
- Frontotemporal dementia is common in people under the age of 65. Behavioural and personality changes are the presenting symptoms. There is no treatment at present which affects the course of the disease.
- A delirium is an acute confusional state with fluctuations in consciousness and perceptual disturbances. It may coexist with a dementia and requires urgent medical attention.
- Cases of schizophrenia in old age may refer to those with chronic disease – ‘graduates’ – who have aged, or to those whose first episode of illness starts late in life. There are differences in symptoms, with the latter having less thought disorder and reduced treatment requirements.
- Depression is the most common mental illness in older adults and there are a greater variety of presentations than in younger people. Memory may be impaired and it is a differential diagnosis when a dementia is suspected. Antidepressants are effective; however lower doses are used in view of the altered pharmacokinetics and risk of side effects in older people.
- The assessment of mental capacity is important when it comes to deciding on treatment, competence to manage financial affairs and writing wills. The Mental Capacity Act in England and Wales provides a statutory basis for this.
- Services for older adults with mental health problems vary across the UK; however they are usually based primarily in the community and have a multidisciplinary team approach.

WHAT IS REHABILITATION PSYCHIATRY?

The development of rehabilitation psychiatry

Rehabilitation psychiatrists in the UK date the origins of their trade to the opening in 1796 of the Retreat in York by the Quaker merchant William Tuke. This institution pioneered what came to be known as ‘moral treatment’ for, as Tuke described the client group, ‘people deprived of their reason’. The Retreat offered humane care in an environment that resembled a family, with a strong emphasis on encouraging people to be active and to take responsibility for themselves, while at the same time managing risk. The Retreat became the model for the Asylum, in the early nineteenth century a cutting-edge and evidence-based technology for promoting the recovery of people experiencing episodes of what we now term ‘severe mental illness’. Discharge rates from the early asylums were impressive, although by the latter part of the nineteenth century the asylums had entered their ‘long sleep’, losing their initial impetus for recovery and discharge.

The best asylums always retained some focus on recovery. Organized aftercare for people discharged from a mental hospital dates back to the foundation of the Mental After Care Association in 1869 ‘to facilitate the readmission of the poor friendless convalescent from Lunatic Asylums into social life’. The potential importance of work as a stimulus to rehabilitation (as opposed to something necessary for the economical running of the asylum) was recognized in the UK in the 1930s and became a major theme in the 1950s and 1960s, with the development of industrial therapy workshops both for in-patients and for people who had been discharged from hospital.

Throughout the Western world the large mental hospitals have been closing, to be replaced by systems of community care: mental hospital bed numbers peaked in the UK and the USA in 1954. An ‘open door’ movement both literally opened the previously locked doors within the mental hospital and metaphorically led to hospitals admitting and discharging many more people. During this process, the term ‘rehabilitation’ became synonymous with ‘resettlement’ – in other words, discharging long-stay patients from hospital.

Careful evaluation of hospital closure programmes, notably in the large-scale Team for the Assessment of Psychiatric Services (TAPS) study into the closure of Friern Hospital in North London, led by Julian Leff, has confirmed that people do well with adequate support, even if discharged after decades of living in a hospital.

In the USA, psychiatric rehabilitation is seen as having emerged in the 1970s as a consequence of deinstitutionalization, the large-scale, rapid closure of state mental hospitals that occurred in the 1960s and 1970s. This challenged community mental health services to address the needs of people with severe mental illnesses. The challenge was not generally taken up with enthusiasm, and as a consequence specialist psychosocial rehabilitation services emerged.

The situation was different in the UK, where deinstitutionalization was a slower process and the evolving community mental health services always focused on those most in need. In the UK psychiatric rehabilitation has continued to serve a small minority of people with the most severe illnesses, most commonly schizophrenia, who required longer-term hospital treatment and intensive community support.

Social inclusion

People with severe mental illness are among the most marginalized members of our society, commonly experiencing poverty, educational failure, unemployment, lack of access to leisure and recreation, and poor housing. On average, their social networks are smaller and less reciprocal compared with the general population, and in relationships they are more likely to give than to take. They are less likely to be married or cohabiting than their peers. They are more likely to be the victims of crime than the general population, and they are more likely to end up in prison having committed a crime. Severe mental illness is associated with increased physical morbidity and consequent decreased life expectancy. Mental illness carries with it a burden of stigma and discrimination that no longer applies to physical illness or disability. The experience of someone with a mental illness is therefore commonly, although not inevitably, one of social exclusion. The corollary of exclusion is inclusion, and a major aim of contemporary mental health services is to foster social inclusion.
Recovery

Contemporary mental health policy emphasizes the importance of ‘recovery’ within mental health services. The term ‘recovery’ has additional meanings to the ordinary concept of becoming free of symptoms and disability, although the starting point for the movement was the observation that the inevitability of continuing disability inherent in the Kraepelinian concept of schizophrenia was wrong. A substantial proportion of people who have psychotic episodes do get better.

Equally salient is the concept of recovery while living with a mental illness, or, as Patricia Deegan put it, ‘recovery as a journey of the heart’. Here, the focus is on user-defined outcomes, quality of life, empowerment, the installation of hope, facilitating self-management and helping people to find personal meaning in life. A narrative approach – listening to people’s stories of living with and recovering from severe mental illness – informs the contemporary recovery movement (Box 73.1). The aim of recovery-oriented services is to enable people to ‘live well despite any limitations caused by the disability or illness’.

Understanding mental illness

According to the vulnerability–stress–coping–competence model, biological vulnerabilities (which can themselves be the result of environmental factors) predispose to mental illness and interact with multiple factors, which include psychosocial stressors and the social environment, to determine outcome.

Interventions can:

- alleviate predisposing factors;
- mitigate triggering and maintaining factors;
- improve coping skills;
- increase personal resilience in the face of adversity.

Institutionalization

In his powerful book Asylums, the sociologist Erving Goffman described the phenomenon of institutionalization. He described the ways in which the behaviours of patients could be understood as a response to the bureaucratic and dehumanizing processes of the mental hospital. A sociologically informed study by John Wing (a psychiatrist) and George Brown (a sociologist) on patients with schizophrenia living in three mental hospitals in England carefully teased out the effect of the social environment of the wards on the patients. They showed that the negative symptoms that patients demonstrated were related, in part, to the impoverishment of the wards and in particular to the amount of time patients were left doing nothing at all.

Understanding disability

The concepts of social inclusion and recovery are fashionable. Less fashionable are concepts relating to the disabilities that are associated with severe mental illness. According to John Wing, the effects of mental illness on an individual are can be understood in terms of the following:

- Impairments: the direct effects of illness, e.g. positive and negative symptoms, cognitive impairment, lack of drive and motivation.
- Disabilities: the difficulties the person experiences in carrying out day-to-day tasks.
- Social handicaps: the effects of impairments and disabilities on performing social roles and living a good life.
- Personal reactions to illness: the person’s responses to the illness experience, and that of their immediate social network.
- Stigma and discrimination: the effects of societal views towards mental illness.

Impairments, disabilities and handicaps are influenced by psychological and social factors, which include the person’s reaction to the illness experience, the stigma associated with mental illness, and other aspects of the social environment.

These concepts lie behind the definition of rehabilitation adopted by the World Health Organization, ‘reducing the impact of disabling and handicapping conditions and enabling disabled people to achieve social integration’.
There are two elements to this definition:

- It is an active process for the individual in acquiring attitudes and skills that allow the person to overcome the effects of an illness or disorder.
- It can involve changing the environment in order to decrease the impact of illness at both the individual and the societal level.

**Psychiatric rehabilitation: a contemporary definition**

A whole system approach to recovery from mental illness which maximizes an individual’s quality of life and social inclusion by encouraging their skills, promoting independence and autonomy in order to give them hope for the future and which leads to successful community living through appropriate support.3

This is an inclusive and person-centred definition. It focuses both on a desired end – successful community living – and on the aims that people have for themselves. These aims tend to include both everyday concerns, such as improving one’s financial situation, social relationships and physical health, and improving cognitive capacities and symptoms, particularly symptoms of depression and anxiety. The quality of life literature confirms that people experiencing severe mental illness are concerned about the same issues as the general population, such as housing, finances, relationships, safety, health and occupation, although people living impoverished lives tend to lower their expectations and aspirations. The core skills of the rehabilitation practitioner are to encourage people who may lack motivation and have often lost hope to identify achievable goals for change and then support them in achieving these goals.

**What’s different about rehabilitation psychiatry?**

Rehabilitation psychiatry is now recognized as a specialty in its own right, becoming one of the faculties of the Royal College of Psychiatrists in 2004. It differs from traditional psychiatric practice in a number of ways (Box 73.2). The rehabilitation psychiatrist’s primary focus is on functioning and quality of life. However, the rehabilitation psychiatrist will always be seeking optimal management of symptoms for a patient group that has, by definition, responded poorly to standard treatments.17 Given that all forms of mental disorder affect functioning and result in social exclusion, rehabilitation skills and attitudes are clearly relevant to all psychiatrists.

**ASSESSMENT**

People who come to a rehabilitation service need to be assessed in a responsive and adaptable fashion, as they may not be able to tolerate a more formal approach. The assessment process needs to be truly person-centred if it is to be effective, and it should as far as possible be a collaboration between the service user, carers and staff members. The focus should be on the strengths of the individual, without ignoring or glossing over areas that require support. A good starting point is to get the person to tell their life story, putting the illness and its treatment as far as possible to one side. This should be supplemented by a through review of available case records, which will document the person’s ‘illness career’.

Thorough assessment of needs is core to the process of rehabilitation. People who come under the remit of rehabilitation services often have needs that have previously not been properly recognized or met, for example co-morbid mental disorders. Unrecognized or unmet needs can often lead to recurrent hospital admissions, further decline in function and a loss of hope for all concerned. In-depth assessment requires a multidisciplinary approach and should be a continuing process. Key assessment domains are discussed below.

**Mental health**

Assessment of mental (ill-)health should include an accurate primary diagnosis and identification of co-morbidities. A thorough understanding of past and current symptomatology is required. Co-morbidity may include substance misuse/dependence, personality disorder, learning disability, mood and anxiety disorder, and autism-spectrum disorder. It is important to have a clear understanding of the user’s perception of their illness. Assessment will lead to a treatment plan that works towards symptom control and risk reduction and encourages self-management.

**Physical health**

Severe mental illness is associated with markedly increased physical morbidity. Risk of ill-health is exacerbated by social exclusion, poverty and underactivity. There is an increased prevalence of obesity, smoking is common with
all the associated increases in physical health problems, and the metabolic abnormalities that can arise with psychotropic medication may lead to cardiovascular risk factors such as hyperlipidaemia, glucose intolerance or frank diabetes mellitus. Service users can be particularly reluctant to engage in screening programmes such as cervical smears. Rehabilitation services will work closely with primary healthcare in addressing these issues.

**Family and personal relationships**

Forming and maintaining relationships is core to quality of life and as such any existing relationships should be supported. There are often conflicts and unresolved issues that may impact negatively on both the service user and significant others, and these should be identified.

The lack of meaningful relationships in a user’s life can also be starkly apparent; support towards positive change in this area is possible.

**Daytime activities**

How we spend our days impacts hugely on our mood and self-esteem. Finding out what the user is able to engage in regularly can be used as a starting point to set goals for future activities. Gross underactivity is an indication of severe social impairment.

**Housing**

The person’s current housing situation, with an indication of whether there are any issues in this setting, should be clarified. A full accommodation history with the support received in each placement, and any clear reasons for a breakdown of a placement, should be explored. This can aid planning for future placement and support requirements.

**Occupation and education, including functional skills**

Activities of daily living such as self-care, care of the user’s living space, and ability to shop, cook, launder, use public transport safely and manage finances should be looked at in depth so that a plan for support and work towards improvement in any relevant areas can be formulated.

**Finances and welfare benefits**

How much money is received in benefits or otherwise, and how the user manages their money, is an important practical concern. In cases where there are serious concerns about an inability to self-manage funds – for example, running up large debts, falling into arrears with rent, or running out of money for food and essential items before the next amount of money arrives – appointeeship may be considered. Another suitable adult such as a relative or the local social services can take on this responsibility to support the user and ensure all bills and expenses are dealt with and then pass on the remainder of the funds to the user at agreed regular time intervals. Budgeting skills can be an area for support to work towards, whenever possible, a return to independent management by the user.

**Risk issues**

Risk assessment is part of standard psychiatric practice. It is important to consider risks around self-neglect, vulnerability, fire-setting and other challenging behaviours that are more common in this population. By identifying and appropriately managing the risks they present, the user can be supported to take positive risks. When considering placement, adequate support and contingency plans can be put into place, thus maximizing the likelihood that the placement will be a successful one.

Many users will have a forensic history: this should be seen in context. Is the offending secondary to times of deterioration in mental health, linked to substance misuse, or simply criminality in its own right? Some understanding of the context within which risk behaviours occurred will enable the service user and the team to move forwards and the current risks to be assessed and managed appropriately, alongside other agencies when appropriate, such as the probation service and the local police-led multi-agency public protection arrangements (MAPPA).

**Substance misuse**

It is important to identify co-morbid substance misuse, which is common, and to develop an understanding of the user’s recognition of this as an issue and willingness (or otherwise) to address it. (The issues surrounding dual diagnosis for rehabilitation services are very complex and not amenable to simple solutions, but the fact of co-morbid substance misuse cannot be a reason for exclusion from contemporary rehabilitation services.)

**Medication, including side effects**

Many users who come to rehabilitation services continue to experience positive and negative psychotic symptoms, depression, anxiety and obsessional symptoms, despite vigorous pharmacological management. A full review should be undertaken of the user’s illness history, including their medication history, noting which medication was prescribed, at which dose and for what period of time, and the compliance of the user with it (including blood levels of medication where available). Periods of relative stability and best function should be correlated with medication regimes at the time, as well as social factors. It is important to hear the user’s and their carers’ views on which regimes may have worked best, or not, for them in the past, and to take side effects seriously. One should ensure that the diagnosis is
correct, that co-morbidity has been accounted for, and that other primary diagnoses such as organic mental disorder have not been missed.

**Early warning signs, relapse indicators and contingency plans**

Discussion of past episodes of acute illness can tap into the user's and carers' current understanding of the illness and their coping strategies. A discussion with the user of what they have and have not found a helpful response from services also can be enlightening.

Assessment should also include a number of other areas. The psychological approach of the individual incorporates information about their early life experiences, triggers for relapse, core beliefs, coping strategies, emotional and behavioural consequences of the illness, relapse indicators and support networks. Cognitive function, particularly memory and executive functioning, is often severely impaired in the rehabilitation client group and can be a specific target for rehabilitation interventions. Unfortunately formal cognitive assessment is uncommon in current clinical practice. Were it to be assessed routinely, then treatment and management plans could be informed by an understanding of any specific deficits that the individual experienced. Structured assessment of quality of life may be revealing: this will include consideration of the person’s religious, spiritual and cultural needs. These issues are often neglected, and addressing them can lead to both a greater understanding of the person and reconnection with potentially powerful sources of social support, for example through faith communities. Identification of recovery factors enables an understanding of the individual’s motivation for self-management, goals, roles, strengths and illness understanding.

**Carers’ assessment**

Most National Health Service (NHS) mental health trusts have a standardized format for assessing and making a care plan around the needs of the patient’s carers. The role of carer can impose a huge burden on individuals and families, and the importance of supporting carers cannot be overemphasized. When carers do not receive adequate support, the result may be their disengagement from the user because of an inability to cope, which is clearly an enormous potential loss for the user. Rehabilitation services may need to rebuild shattered relationships between the service user and their carers.

**Assessment tools**

A standardized approach to assessment is important to ensure an adequate assessment in these complex individuals. There are many tools that can be used in routine clinical practice, a number of which deserve specific mention. The Camberwell Assessment of Need – Clinical Version covers 22 life domains and can incorporate the views of the assessor, user and carer. It identifies serious need and also incorporates the view of the user as to what they would find useful support. The Social Functioning Questionnaire is composed of five eight-item scales that assess a person’s level of competence in an area of social functioning. The areas are self-care, domestic skills, community skills, social skills and responsibility. The Health of the Nation Outcome Scale is a summary outcome measure that focuses mainly on symptoms. The Manchester Short Assessment of Quality of Life provides a useful brief assessment of quality of life in a number of domains.

Symptom questionnaires for psychotic, mood or anxiety symptoms also can be used, tailored to each individual’s needs. These instruments can be used at the beginning of a user’s time with the service, and then at relevant intervals, but they should certainly be rated again at the end of a period of intervention and treatment – for example, at the end of a stay on a rehabilitation unit. This can provide evidence of outcomes as a result of specific interventions and overall change from receiving rehabilitation.

Other important outcomes to measure include whether the user moves on to a more or less independent living situation following time in receipt of rehabilitation services, and the number and length of admissions to an acute hospital setting before and after rehabilitation. Improvements to social networks can also be measured.

**Formulation**

An overall formulation of the user once these assessments are complete can provide insight into why the individual is in the current situation at this point in time and can be used to forge a way forward collaboratively with them and their carers.

**INTERVENTIONS**

**Pharmacological treatments**

It is beyond the scope of this chapter to discuss in detail issues of pharmacological management in the rehabilitation population, many of whom have treatment-resistant psychosis. Clozapine is the drug of choice in this situation. Its use is described at length in the Maudsley Prescribing Guidelines. The key to successful use of clozapine is management of its many side effects. Augmentation strategies can be adopted when clozapine, along with psychological and social interventions, fails to provide adequate symptom control. If clozapine cannot be tolerated, adherence is a major problem or symptomatic improvement is not adequate after a good trial other regimes may be tried. When prescribing in this situation, where the evidence base is limited, it is wise to seek a second opinion wherever possible and certainly to employ routine outcome measures.
Psychological treatments

A wide range of psychological interventions have been shown to be effective in the treatment of psychotic illnesses. These include cognitive-behavioural therapy (CBT) and family therapy,26–28 cognitive remediation therapy19,29 behavioural therapy based on operant conditioning paradigms30,31 and psychoeducation.32 Psychodynamic understanding can also be useful in complex cases, particularly for the staff team in helping them to understand the patient and their reactions to him or her.13

The psychoeducational component of treatment should incorporate collaborative and wherever possible user-led plans of how to stay well by, for example, using the Wellness Recovery Action Plan, which is described below.14 The trick here is to work out with the user an agreed treatment plan that enables the user to work towards their goals more effectively.

Skills training

People referred to rehabilitation services tend to have deficits in functional and social skills. A key task of rehabilitation practitioners is to help the user to improve these skills. Formal, manualized social skills training is much favoured in the USA.35 A meta-analytical review of controlled trials showed no clear evidence of efficacy in terms of relapse rate, social functioning, quality of life or treatment adherence.36 The problem appears to be with the generalization of skills outside the artificial treatment setting. In vivo interaction with staff (primarily occupational therapists, nurses and support time and recovery (STR) workers, whose role is described in more detail below) and peers is likely to be more effective than artificial programmes, and that is what good rehabilitation services offer.

Rehabilitation services also provide environments that have positive expectations on service users in terms of interpersonal behaviour and functioning. The Three Hospitals Study demonstrated the powerful effect that the social environment has on the functioning of people with schizophrenia.13 Encouraging people to structure their time is particularly important in maintaining social functioning, an insight that was well understood by the pioneers of the Asylum 200 years ago.

RECOVERY AND REHABILITATION IN THE COMMUNITY

The aim of rehabilitation is for people experiencing severe mental illness to live successful and fulfilled lives. This requires a range of therapeutic interventions that have already been described and a set of supporting services – hence the need for a whole-system approach. 4

In England, mental health services are coordinated under the overarching umbrella of the Care Programme Approach (CPA).17 Its central principles are quite simple:

- Assessment of health and social care needs, including housing and employment (described in some detail above)
- Assessment of risk issues, including risks to self and others
- Development of a written care plan to address needs and risks
- Identification of contingency, crisis and relapse plans
- Regular review of the plan by all those involved in the plan
- Identification of a care coordinator who brings people together
- Full involvement of the service user and carers in care-planning
- Interprofessional collaboration and cooperation.

These principles are fully consistent with rehabilitation practice. However, there is a clear potential tension between the essentially user-defined concept of ‘recovery as a journey of the heart’ and the necessarily reductive and professionally led process of elaborating a CPA care plan within a formal meeting. Self-management strategies have an important potential role here, and the Wellness Recovery Action Plan is an influential and popular tool.13 This involves the service user identifying actions, thoughts and behaviours that are associated with staying well and then developing a written plan of action, warning signs and a crisis plan: crucially, the process is patient-led rather than professionally driven.

Community support services

Most people in the UK living with severe and disabling mental illness are treated by their general practitioner (GP) or a community mental health team (CMHT). Their community support will come from family, friends, informal agencies such as places of worship, and, for those in contact with a CMHT, a package of care overseen by the care coordinator under the CPA.

In England, mental health services employ STR workers, who are:

people who come from different walks of life with different backgrounds including volunteers and existing and former service users ... to help service users to have an ordinary life assisting them with their everyday, practical needs in whatever setting they find themselves to facilitate recovery.38

This includes, for example, helping people to manage their finances and address their housing needs. The STR role is intended to complement that of the care coordinator and is oriented towards rehabilitation and recovery.

Stein and Test published a landmark controlled study into what became known as ‘assertive community treatment’ (ACT).39 ACT is a form of intensive community support designed specifically to help people at risk of admission because of their severe mental illness to live successfully outside hospital. The service was designed around what they
felt to be the requirements for successful community tenure (Box 73.3). These requirements reflect concern with the individual’s basic needs (including treatment needs) but also attention to the person’s motivation, morale and social environment. The ACT model emphasizes staff offering support in vivo, in the person’s own environment, in contrast to standard care in the USA, which remains clinic-based.

**Box 73.3 Requirements for community tenure of people at risk of hospital admission**

- **Material resources**: e.g. food, shelter, clothing, medical care
- **Coping skills**: e.g. budgeting, cooking, using public transport in vivo
- **Motivation**: e.g. systems of support to help people cope with stress
- **Freedom from dependent relationships**: aiming to break the cycle of dependency
- **Support and education of community members**: to help community members to interact appropriately with the patient
- **Assertive support system**: to preclude the tendency to drop out of care.

Adapted from Stein and Test.39

ACT, or assertive outreach (AO), as it is known in the UK, has become the standard method of supporting people who disengage from treatment and are recurrently admitted to hospital. Success in maintaining people in the community seems to be related to adherence to a specific service model that involves a team-based approach to care and in vivo treatment.40 ACT has been significantly less effective in UK studies than in those carried out in the USA, but undoubtedly AO teams can keep marginalized patients in contact with services more successfully than can generic CMHTs. This may be because of the recovery-oriented practices that successful AO teams adopt, which foster engagement with the treatment team.40

Early intervention in psychosis (EIP) teams provide intensive community support to people who newly present with psychotic illnesses. EIP teams follow the principles of ACT, but in addition provide phase-specific interventions that are age-appropriate and take into account the needs of patients and carers who are new to the mental health system. EIP is an extremely promising approach, although to date the proposition that EIP improves long-term outcomes is unproven.41

All mental health services in England are required to provide AO and EIP services. The community rehabilitation team (CRT), designed to offer intensive community support to a minority of patients with the most severe disabilities, predates this requirement.4 Increasingly, specialist CRTs focus on working with individuals placed in high-support residential and nursing care.

**Box 73.4 Work options for people with a mental illness**

- Maintaining pre-illness employment
- Voluntary work
- Sheltered employment

- Mainstream employment.

Work, daycare and education

Work plays an important part in most people’s lives. This goes beyond the obvious financial rewards to include opportunities for social relationships and offering meaning and structure to daily life. Being unemployed has very well-documented bad effects on both physical and mental health. Work is a powerful aid to social inclusion and the majority of people with mental illness want to be occupied and to work.62 However, the employment prospects of people with schizophrenia in the UK have worsened markedly over the past 50 years,43 and until recently interest in providing work opportunities for people with a mental illness had been waning.

There are a wide range of work options for people with a mental illness (Box 73.4). By far the most preferable is remaining in employment following the onset of the illness, something that EIP services prioritize, or rapid return to the workforce following an episode of illness. Some people lack basic skills and will benefit from re-entry into education before seeking employment. For others, a period of voluntary work acts as a stepping stone into open employment. The welfare benefits system is very complex and can act as a disincentive to people to seek a return to work, although part-time employment can be undertaken without loss of benefit if it is an element of a rehabilitation programme.
Recovery and rehabilitation in the community

mental illness, with the aim of recruiting current and former service users to work as paid members of staff, on the grounds that they have a particular and valuable perspective to offer.

Not everyone wants or can achieve paid employment. Many find voluntary work both rewarding in itself and a potentially valuable stepping stone into open employment. Daycare may provide similar psychological benefits to work. Informal projects that offer a drop-in function may offer a safe place for people to go to. Projects may specifically promote people’s creative skills or engage them in sporting activities that encourage active lifestyles. Further education may give people life skills that they lack and offers an excellent venue for developing social skills in a mainstream environment.

**Housing**

Most people with severe mental illness live in their own homes or with family members. A minority live in one of the many forms of supported housing that are available (Table 73.1). These include family placement schemes (where the person lives with a paid carer), supported lodging schemes (where a carer oversees the person but does not live with them), housing with peripatetic support (which can be in individual units or in shared housing – what used to be called ‘group homes’) and staffed housing.

There is an extremely wide range of staffed housing available, from services that have a few hours a day of support worker time, through services that provide a member of staff available on a sleep-in basis at night to 24-h staffed units, which offer residential and nursing care. Most forms of supported housing rely on staff who do not have professional qualifications, although nursing homes are required to have minimum numbers of nursing staff. Supported housing can be oriented towards ‘rehabilitation’ in the sense of helping the person to become more independent or merely offer a form of continuing care, which, at its worst, can foster institutionalization and undermine people’s autonomy and practical skills. Some services specialize in particular client groups, for example forensic patients or people with co-morbid learning disability and mental illness.

A key skill in rehabilitation practice is to identify the appropriate form of housing for an individual given their current level of functioning and the clinical problems that they present. Placement is no easy task and requires complex negotiations between the patient, their carers, potential care providers and funding authorities. Once the person is placed, the CRT may work with the individual and their

Adapted from Ramsay and Holloway.46
placment provider to ensure that realistic rehabilitation and recovery goals are being pursued.

Funding for housing and supports to live independently comes from a range of sources: people’s earned income or savings, housing benefit, ‘supporting people’ monies (a funding stream developed to encourage vulnerable people from a range of client groups to live as independently as possible), social services authorities and health authorities.

Current policy is aimed at decreasing the numbers of people living in residential care and nursing homes in favour of packages of care that allow people to live in their own homes. These packages may provide practical support with tasks of daily living and prompts to take medication. The policy reflects the aims and aspirations of service users, who, unless they have been living in the system for many years, rarely opt for some form of communal living, whatever their assessed disabilities.

Limits of community care

Experience of the hospital closure programme, notably the TAPS study, has confirmed that even former long-stay inpatients can live successfully in ordinary housing with the support of non-professional care staff, although a minority require initial placement in specialized hospital-based facilities. Contemporary rehabilitation in-patient services aim to work intensively with people for a year or less before discharging them to independent living (relatively uncommon) or some form of supported or staffed housing, although a small proportion have to move on to continuing care units.

A small group of patients exhibit ‘challenging behaviours’. No generally agreed service model has yet emerged in the era of deinstitutionalization for this patient group, which is diagnostically heterogeneous but characterized by non-compliance with treatment, absconding, violence, disturbance at night and bizarre behaviour. Some of these patients will improve after intensive rehabilitation and active pharmacological management over a period of years. When behavioural disturbance, risk or offending behaviour is extreme, patients may be treated in a special hospital or medium secure unit, although the latter were not designed or resourced to provide long-term care. More recently, long-term low secure units have opened to provide continuing care, institutionally based care and treatment for people who present with challenging behaviours.

A significant proportion of people requiring longer-term high-support care cannot be cared for locally and are placed as out-of-area treatments (OATs). Until recently very little was known about the numbers and characteristics of OATs: however, the client group is known to be very heterogeneous, with, in general, little systematic attempt being made by the placing services to review the users’ needs and to facilitate return to their local area.

Good-quality local mental health services follow up OATs very carefully and are constantly seeking to help people to return to life in community settings.

REHABILITATION: ETHICAL ASPECTS

Coercion versus empowerment

Mental health services are often experienced as coercive. When the individual’s views of what is and is not acceptable differ too greatly from the treatment team conflict and coercion can result. The simple process of supporting a user’s rehabilitation may be seen as coercive, for example taking control over someone’s financial affairs or strongly prompting them to attend to their activities of daily living.

Empowering people to manage their own illness as far as possible rather than fostering a paternal approach to care produces rewards for the individual and the team supporting them. Putting the user at the centre of the care and involving them and their carers in a meaningful and informed way is the best approach to achieving empowerment. Access to advocacy can support this, and advance directives can be useful. The service user agrees at a time when they have capacity what they would and would not find useful or agree to should their condition deteriorate. Jointly formulated crisis plans may lead to a decrease in compulsory admissions.

There does come a point when, usually for reasons of risk to self or others or in the face of marked self-neglect, the locus of control passes to the mental health staff supporting the user, who will need to act in the best interests of the user and others. This can clearly be perceived as coercive. It is important that decision-making and control are handed back as soon as is practicable. Actions by staff and lay carers need to be undertaken in the light of relevant legislation – in England and Wales, the Mental Health Act and the Mental Capacity Act – which requires decisions surrounding treatment and care to be taken in the best interests of the patient or service user.

Confidentiality

Confidentiality and joint working is another contentious area. There is guidance about confidentiality from regulatory bodies such as the General Medical Council (GMC), but this can be difficult to reconcile at times with day-to-day practice. For example, there is the need to share information with the criminal justice system for the purposes of public protection or in the best interests of the patient when they may not have consented to such information-sharing (the GMC test for this being extremely high). CPA policies may state that information must be shared between relevant others – both professionals and carers. What approach should be taken when service users emphatically do not wish information about their care to be shared with carers from whom they may nonetheless derive a great deal of support and who may be at risk? How can carers support a care plan of which they have no knowledge? These are extremely sensitive issues for which there is no easy answer.
**Acknowledging ethical dilemmas**

Ethical issues need to be recognized and debated at team and service level, taking into account the legislative framework, advice from professional codes of conduct and the growing ethical literature. In this way, an appropriate way forward may be found for each individual.

**SERVICE DEVELOPMENT AND EVALUATION IN REHABILITATION**

Successful practice in rehabilitation requires a whole-system approach, which implies working with multiple actors and agencies (e.g., the patient, lay and paid carers, the care team, independent sector providers, funders of care packages, commissioners of services). Given that there is a stark gap between what is available and what we believe to be the ideal provision, the effective rehabilitation psychiatrist will inevitably become involved in service development. This requires complex managerial skills that can only be acquired in practice, albeit supplemented by relevant courses and texts (e.g., Bhugra et al.). Useful practical experiences include working closely with voluntary-sector organizations, including joining management committees, and helping to develop business plans for service innovations.

Promoting service development rests on three core issues: What is the need? What is the policy? What is the potential funding? Currently, funding streams for service development rely on responding to policy initiatives or identifying activities that will lead to immediate cost savings (e.g., by decreasing expenditure on residential care by improving the available community support). Rehabilitation psychiatrists require advanced skills in population needs assessment. This demands a grasp of epidemiological principles (relating to the incidence and prevalence of disabling severe mental illnesses) and the ability to undertake or support local evaluation of the needs for high-support care.

Evaluation of rehabilitation services is challenging. Seven stages of evaluation in a rehabilitation service have been identified (Table 73.2). There are complexities surrounding the desired outcomes of rehabilitation (e.g., bed use, costs, personal satisfaction, symptomatology, social functioning) and the definitions of the interventions provided by rehabilitation services. In comparison with other countries the hospital closure programme in the UK was well evaluated, providing data that remain relevant to contemporary rehabilitation services. Locally, rehabilitation services should audit their activities by measuring patient outcomes, patient and carer views of services, lengths of inpatient stay and other service use data, and the overall costs, which is where any evaluation programme should start.

**SPECIALIST REHABILITATION SERVICES**

**Forensic rehabilitation**

As the large mental hospitals closed and the traditional high secure hospitals (e.g., Broadmoor) downsized, inpatient provision for offender-patients in medium secure and low secure units expanded very rapidly. A new specialism of Forensic Rehabilitation, devoted to reintegrating offender-patients with significant social disabilities into the community, was born. Balancing ongoing risk management with rehabilitation and reintegration into the community lies at the core of Forensic Rehabilitation. The recognition that for each user there may be a level of support that to go below would be unsafe is an important part of the management of forensic patients. It is also key not to forget risk at any time, however long the user may have been stable. Long-term support and monitoring are vital, particularly in less supported placements, as the re-emergence of risk may occur at any time as destabilizing factors come into play for the user, such as substance misuse and relapse of psychosis.

The forensic population tends to be complex, with the majority being co-morbid for any or all of the following: low intellectual function, substance misuse, personality disorder and physical problems. For effective management, this co-morbidity must be identified and addressed appropriately.

**Rehabilitation and learning disability**

Service users who have both significant learning disability and co-morbid mental illness with rehabilitation needs are often not cared for at a local level. They are commonly
placed in very costly OAT settings within the independent sector, which may offer continuing care rather than rehabilitation.

The key points for assessment, treatment and management of this group of individuals are that a flexible, user-centred approach needs to be adopted. A highly skilled staff group with expertise in the concepts of learning disability, rehabilitation, care-planning and the ability to liaise across relevant services and with the service user’s family and carers with adequate resources is also central to success. The strengths of the individual should be recognized and sufficient onus placed on quality of life.

Impairments, disabilities, handicaps and stigma need to be taken into account, and where possible the root causes of behavioural problems need to be identified and addressed. This can prove challenging in service users who have limited ability to communicate. Adequate risk assessment can also prove to be a challenge, and this in turn impacts on the user’s management and progress. If triggers for risk behaviour cannot be identified or communicated, then the individual may remain in a more restrictive setting for extended periods of time.

**Acquired brain injury**

The common causes of brain injury include anoxia, hypoglycaemia, trauma, subarachnoid haemorrhage, infectious causes such as meningitis, and alcohol use. The main psychiatric symptoms that develop are psychosis, depression, anxiety disorders and aggression. Aggression has a number of causes, for example being secondary to disinhibition as a consequence of frontal lobe damage, seizure activity or psychotic symptoms. Assessing the underlying cause is essential if aggression is to be treated appropriately and effectively.

Pre-existing psychiatric conditions may have given rise to the head injury, for example following a suicide attempt or as a result of risky behaviour in a patient with attention deficit hyperactivity disorder (ADHD). Patients with both a severe mental illness and an acquired brain injury are most likely to present to psychiatric rehabilitation services because of the increased likelihood of them developing a chronic disability.

It is important to have an understanding of the type and severity of the head injury in order to provide appropriate input for each individual. Care must be taken with treatment of psychiatric symptoms post-head injury because, although the symptoms can generally be treated using the relevant medication for a particular diagnosis (e.g. antipsychotics for psychosis, antidepressants for depression), some caveats exist. Anticholinergic side effects of medication can worsen confusion in this patient group. Generally there is an increased sensitivity to side effects. Starting at a low dose initially with gradual increases and avoiding drugs that may have central nervous system side effects is advisable.

When the brain injury is severe and obvious rehabilitation is undertaken in a neuropsychiatric brain injury unit, with the possibility of move-on to a community-based service. The rehabilitation programme is dictated by each individual’s pattern of enduring disability: the keys to success are detailed understanding of the cognitive deficits and the elaboration of an individualized and highly structured programme.

For patients with moderate to severe impairments, cognitive rehabilitation focuses on improving independence in specific areas of function, such as being able to cook a simple meal and goal-planning. Staff, who will often be clinical psychologists or occupational therapists, provide an individualized programme of activities to address the person’s needs that is undertaken in a graduated and carefully evaluated manner. Memory impairment may be assisted by the use of electronic devices such as a watch with an alarm that sounds at times when medication must be taken.

Behaviour modification is another useful intervention that can reinforce wanted behaviour and reduce unwanted behaviour. A functional analysis of unwanted behaviour should be carried out before formulating the plan in order to understand the triggers and potential gains from such behaviour (a similar approach to that adopted in the management of challenging behaviours in psychiatric rehabilitation settings). A consistent approach is imperative for all staff involved in a person’s care in order for behaviour modification to be implemented successfully.

**THE FUTURE OF REHABILITATION AND RECOVERY IN PSYCHIATRIC PRACTICE**

Potential users of rehabilitation and recovery services are characterised not only by particular diagnostic labels (notably schizophrenia) and the consequent stigma, but also by multiple indices of social exclusion: they tend to be poor, socially isolated, inadequately housed, unemployed and at risk of victimisation.

The UK currently has no clear government policy relating to specialist recovery and rehabilitation services. Given that potential users are those with a mental illness who are in most need, are most socially excluded and take up a large proportion of the currently available resources (e.g. through recurrent acute hospital admissions, long-term daycare, residential care and high-cost placements), this is a puzzling anomaly. The Rehabilitation and Social Psychiatry Faculty of the Royal College of Psychiatrists has sought to remedy this policy gap and the Irish College of Psychiatrists has published detailed guidance on establishing rehabilitation and recovery services.

In addition to the elaboration of a coherent policy for recovery and rehabilitation services, there are a number of
areas where further development is clearly required. Of prime importance is for services to move towards a more user-led pattern of care, with a much greater emphasis on a truly collaborative approach between staff, user and carers than currently occurs in many care settings. Supporting users to make informed choices both empowers them and will, in the long term, lead to better outcomes. In many services, this will require a change in culture.

We need to take much more seriously the positive impact on people of returning to meaningful activity: this includes improving opportunities for work and education. Effective reintegration of people who are experiencing severe mental illness also requires efforts to tackle the barriers that perpetuate stigma and discrimination and is an ongoing but important part of the task of rehabilitation services in collaboration with users. Enabling a devalued group to participate on equal terms can reduce prejudice.3,51

Traditionally there were barriers to accessing recovery and rehabilitation services for people with a history of offending, who were experiencing co-morbid substance misuse, or who had functional disabilities occurring in the context of a personality disorder. These barriers will fall. As an example, a significant minority of people with severe personality disorders are found in expensive placements. By developing local strategies for joint working with specialist psychotherapy services, these individuals can be supported in moving to progressively less dependent settings.

There is an increasing need for rehabilitation services to prove their worth by ensuring that the work they undertake is measured appropriately and reported to commissioners. This requires services to embrace routine measurement of patient outcomes, including feedback from users and carers, together with regular reviews of the service that ensure that treatment and care are evidence-based and that provision is relevant to the needs of the local population, responsive and of a high quality.

KEY POINTS

- Rehabilitation and recovery concepts and attitudes are relevant to all areas of psychiatric practice.
- The assessment process must be thorough and identify all areas of need, as this patient group often experiences unidentified and unmet needs.
- Rehabilitation focuses on the individual’s skills and abilities as well as on symptoms and disabilities.
- Many rehabilitation clients suffer from treatment-resistant psychoses for which evidence-based treatment is available.
- There is a focus on the working alliance between patients/service users and carers.
- Rehabilitation services have as explicit aims fostering hope, social inclusion and individual recovery in the face of continuing illness and disability.

PART 7

Mental health service provision
INTRODUCTION

We live in times of great scientific and medical inventions. Psychiatry has undergone one of the most dynamic developments over the past 50 years. The fast-developing pharmaceutical industry has armoured us with a range of effective psychotropic medication, which has greatly affected the way our services are now organized. In recent years, we have seen specialist community mental health teams established across the country, offering home treatment, early intervention and intensive support for people with complex needs. The National Service Framework (NSF) for Mental Health, published in 1999, is a strategic document for the development of adult mental health services in the National Health Service (NHS). The NHS Plan, which followed the NSF in July 2000, promotes new models of care and contains key targets and core standards for the health and social care sectors, based on the NSF. This ambitious and far-reaching plan requires strong clinical leadership and managerial skills for its successful implementation.

Doctors constantly strive to improve services and have learned to adjust to service changes. As front-line clinicians, we are best placed to understand and deal with intricate clinical issues and help organize and develop services that will suit our patients.

Clinical involvement in such innovative service developments is crucial, but this can only be achieved in a meaningful and constructive manner if clinicians have a good understanding of the issues involved in such service change. Service change and development is linked closely with service improvement, but our training, which is largely clinical, hardly deals with the complexities involved in effecting such changes.

Our aim in this chapter is to provide an overview of the intricate logistics of organizing, leading and developing a new psychiatric service or change of service while ensuring the delivery of a high standard of care.

Staff members are sometimes resistant to change. This may be due to several reasons, such as a lack of understanding of the issues involved, feeling threatened because of the changes, or a fundamental disagreement with the proposal. Such resistance may also present in different forms, ranging from open hostility and refusal to cooperate to indifference and covert sabotage. Management of these issues can be both difficult and sensitive and requires considerable skill, understanding and maturity. As clinicians, we receive no training in any of these core management skills.

We discuss various aspects of management, including communication, difficult colleagues, resistance and the principles of project management.

EFFECTIVE MEDICAL MANAGEMENT

Who is an effective medical manager? What are the specifications required to be an effective medical manager? The job is unique, in that it requires an excellent grasp of not only clinical but also managerial issues. The need to work effectively with both managers and clinicians, without compromising credibility, honesty and transparency, is not an easy task and requires good management skills. The key attributes necessary to be an effective medical manager can be conveniently listed under two main headings: personal characteristics and core skills.

Personal characteristics

The medical manager leads, plans, organizes, completes and evaluates. Effective leadership requires as a minimum good skilful management of multidisciplinary teams. To achieve this, one needs to have the respect of the team members. Respect is earned and never automatic by virtue of one’s position. To gain respect, the leader must work tirelessly and demonstrate competency to lead the team in an appropriate and constructive manner that encourages collaboration and maximum team cooperation. Unlike multidisciplinary clinical teams, where clinical knowledge is usually the central focus, service development and project teams have a wider remit with not only clinical but also financial and political dimensions. A good medical manager is flexible and remains receptive to the views and opinions of other team members, who may not have a clin-
ical background. Clearly, the leader of such a team has the knowledge and interpersonal skills to gain the trust and confidence of others within the team. Individual differences may exist within team members, borne out of certain beliefs and convictions, and these should be recognized and acknowledged. A medical leader should not be seen as driving a medical model, giving no consideration to the disparate views of other professionals in the team. Instead, the leader should be open, honest, fair and transparent and should adopt an inclusive approach. These are the essential ingredients to gain trust, credibility and, above all, respect.

When working with colleagues, one could come across the difficult ones, ranging from the aggressive and manipulative to the incompetent. An accomplished leader will have clear strategies to diagnose and manage such diverse personalities and get the best out of them. Similarly, when team functioning is affected, it is necessary to identify the possible causes and to take early remedial action. The common causes of team dysfunction include poor leadership, lack of role clarity and perceived inequalities.

Probity and integrity are of paramount importance, not only in one’s personal life but also in one’s professional dealings. These are linked closely but not exclusively with financial and commercial issues and include matters such as ethical provision of information, writing reports, giving evidence and dealing with pharmaceutical companies and other commercial organizations.

A good leader is able to devise good plans that are achievable and takes into account the diverse views and opinions of others. The best of plans could go wrong and, therefore, one must have subsidiary plans to deal with such eventualities. All plans must have clear and unambiguous objectives, with a well-defined pathway to reach the endpoint. Both the endpoint and the pathway may require change, depending on circumstances, and a competent leader will adjust accordingly.

No plan will be successful if it is not linked to conscientious and meticulous organization. This involves attention to detail, careful coordination and accurate analysis with methodical administration.

A leader must be a completer, and no amount of planning or organization would help if one does not have the skills and qualities necessary to complete. A medical leader should relentlessly pursue the aims and objectives outlined in the service change, showing great courage and resilience in the face of repeated obstacles and resistance. This is possible only if the change is driven by a firm belief and conviction that such change is necessary for the benefit of all users of the service, staff and the organization.

Once implementation is complete, attention moves to consolidation and evaluation of the change, first to determine the effectiveness, both clinical and financial, of the change, and second to replicate such change in other appropriate clinical settings.

**Core skills**

Leadership and management require not only personality characteristics but also a number of core skills, explained in the sections below.

**Communication skills**

Communication skills are central to effective leadership and require the highest priority. Faulty and ineffective communication is the root cause of many problems within teams. Change and communication are inextricably linked, and an effective medical leader requires excellent communication skills, including the ability to listen, assimilate and synthesize information, consider the range of views expressed, and communicate in a clear, precise and unambiguous manner. Communication is a two-way process – top-down and vice versa – with a beginning but no end. Middle managers are a useful source for developing good communication with front-line staff and must be utilized fully throughout the process. Honesty, appropriate challenges and clarity are the hallmarks of good communication.

**Chairing meetings**

This requires specific skill and experience that one would expect in effective leadership. A quality chairperson commands the respect of the team, is able to adhere to time limits, has control of the meeting, is unfailingly courteous and listens to all views expressed. The chair of a committee can have personal opinions, but these must not be allowed to dominate the meeting. A good chair will encourage others to express their views, allocate adequate time for debate on different issues, lead the group towards decisive action and, above all, maintain a good sense of humour at all times.

**Setting clear objectives**

In any form of service change, it is important to define the aims and objectives as clearly as possible. In a health organization, the objectives are usually driven by health or financial priorities. Aims must be clear, precise, achievable and preferably measurable against established targets. In service development, it is often necessary to differentiate between immediate objectives and outcome measures. Thus, for example, in the development of a home treatment service, the immediate aim is to establish the service in both structural and functional terms (see below). However, the outcome measures and targets are different and will be in relation to user satisfaction, reduced hospital admissions, and so on.

**Developing a project plan**

Once the objectives have been defined clearly, the next step is to develop a project plan that outlines the actions and activities necessary towards implementation. At the outset, a project team should be constituted. This will consist of staff with varying skills and different professional backgrounds, who are capable and motivated and also share a firm belief
in the need for change. The project plan will consist of a series of operational measures that are set out in chronological order, with one activity leading to another, until eventually the endpoint is reached. The leader will delegate authority and responsibility to individual members of the project committee, for each of the action points, which may be divided into several components, if necessary.

Delegating
Appropriate delegation demands a good understanding of the knowledge, skills and ability of each individual in the team. Every individual will have some special aptitude or talent, and a good clinical leader will mobilize and channel such skills effectively. Past performance is often a useful guide in such situations.

Timescales
Good project management involves establishing achievable timescales, with a defined completion date for each activity. This should take into account both expected and unexpected events such as annual leave and sick leave, the competency of the individuals, and resource and capacity issues. The timescales must be realistic and, to some extent, flexible.

Resistance
No project runs entirely to plan. In the process of implementation, one often encounters obstacles and difficulties. These may arise from external or internal sources. The cardinal rule is to be one step ahead and to anticipate such issues. At the very outset, it is necessary to have some understanding of the possible sources of resistance within the service and, as far as possible, to take action to deal with them. Unexpected complications could also arise that may hinder progress. In all such situations, a good clinical leader will retain the support, loyalty and cooperation of the team, so that working together such issues are overcome and dealt with appropriately. It is the responsibility of the leader to encourage, facilitate, persevere and respond adequately, ensuring at all times that morale is maintained and the project remains on course. Feedback to project members must be realistic, positive and encouraging.

IMPLEMENTATION OF A SERVICE CHANGE

Having discussed the personality and core characteristics of an effective medical manager, the rest of this chapter deals with the process involved in effecting a service change.

Setting the scene
What is the proposed change? This can vary from a minor change in existing clinical practice to more significant and substantial changes in the development and delivery of a new service.

Is the change really necessary? This is not an easy question to answer, particularly when changes are imposed from the department or the strategic health authority. In such cases, it is good practice to carefully assess the issues involved and, if necessary, to seek clarification from higher authorities.

It may be necessary to research the proposal, taking into consideration the current practice, including its strengths and weaknesses; the likely benefits from the change, which may be clinical, organizational or financial; the effects on staff and service users; the impact on other clinical services; and the views of the stakeholders, including voluntary organizations, and if available, the experience of other organizations that have implemented such change. Careful consideration and wide-ranging discussions and consultations may be necessary before a final decision is made regarding the need for change. This is a critical decision that requires considerable thought, since it will form the basis for all other actions. It is vital that the person leading the change should be convinced firmly of the need for such change.

The next step is formation of a project team. Careful consideration must be given to the composition of the project team, in terms of numbers, professional representation and the skill mix required.

Action plan
Once the project team is in place, a project plan including operational action points and dates for future meetings should be developed. This will form the working document for the future.

The action plan is essentially a pathway that leads to the implementation of the project. This will have, as outlined above, several action points, some of which may be broken down into several components. The action plan also defines responsibility and specific timescales.

Implementation
This is the hub of the service change. This process can take from a few weeks to several months, depending on the proposed change. The implementation of the action plan can be considered under two broad components:

- **Structure**: what is the structure of a service? This comprises the buildings and service facilities that are necessary. Depending on the nature of the proposed service, accessibility to users and carers, soundproof interview rooms, conference rooms, storage space and security are some of the provisions that need consideration. Structure must also deal with staff composition, skill mix and staff members’ professional needs such as computers, telephones, fax machines, and the general working environment.

- **Function**: The functional component relates to the development of appropriate operational policies and guide-
lines. This will vary from one service to another, taking into account the roles of different professional groups, job descriptions and service requirements.

The functional part of the service has to be developed carefully and built around the agreed aims and objectives of the service. The operational policy, the job descriptions of the different professionals, guidelines on staff training, and clinical/managerial supervision are important components that must relate to the aims and objectives of the service. This is not an easy task, and it is essential that, throughout this phase, one remains focused on the key objectives.

Both structural and functional changes will require wide-ranging discussion with all members of the project team, as well as stakeholders from within and outside the organization. Effective communication processes must be established across different staff groups, community teams, in-patient services, medical staff committee, staff unions, general practitioners (GPs), commissioners and other stakeholders. Throughout the entire process, it is essential to monitor the financial impact and to ensure that the project remains within the allocated budget. The potential for further development of the project and possible expansion into future markets, both locally and outside the region, must be borne in mind.

At this stage, the project team may wish to break down the action plan into manageable components, with appropriate delegation and agreed timescales, based on skill and expertise.

The implementation phase, which includes structural and functional development, is the body of the service change and will take a considerable amount of time and effort. It is during this stage of project management that resistance will emerge. Such resistance can take many forms, ranging from passive expressions of discontent to open hostility, anger and even sabotage. Different forms of resistance need to be handled differently, based on the probable cause. Throughout this process, and despite the numerous distractions, the project team has to maintain focus and a grip on the task at hand. Tact, patience and diplomacy are useful, as is emotion in some situations, but these must never lead to poor judgement or indecisiveness.

Consolidation and review

Once a service is established and fully operational, it must be accepted and embedded within the organization. Staff and users who are involved with the service need to recognize its value and benefits as well as its deficiencies. This will facilitate regular reviews and changes within the service in order to meet the varying demands of the users and the organization. The establishment of a new service is not the end but rather the beginning of further changes, which will be driven by surveys, audits and other outcome measures.

Evaluation of a new service is a continuous process and has different dimensions, which may be clinical, financial or operational. More often than not, it is a combination of all three. The central role of the customer is paramount throughout the process of evaluation. The customer is the service user, who is not only the patient but also others such as the carers, community and in-patient teams, professionals, outside stakeholders and commissioners.

CONCLUSION

Service development and delivery will continue to remain at the forefront of NHS reforms for many future years. If such change and development are to have meaningful clinical engagement, it is necessary for clinicians to provide strong, effective clinical leadership. In this chapter, we have outlined the main personal characteristics and core skills that are needed for such a role. Essentially, these are the qualities of leadership, which make one credible, trustworthy and dependable. Individuals who are genuinely interested in medical management acquire these features over a period of time through experience, training and apprenticeship. A young doctor requires multiple skills along clinical, academic, research and management lines. Irrespective of one’s main interest, knowledge of the basic principles of medical management is essential for the delivery of a good-quality service.

The second part of this chapter deals with the processes involved in implementing a major service change. This is about higher-level medical management and will be beneficial mainly to those who aspire to develop a career in management. However, all clinicians, both medical and non-medical, would benefit from a knowledge of the fundamentals involved in the process of implementing a service change.

KEY POINTS

- The health service is changing and evolving constantly. It is crucial that there is strong clinical involvement and engagement with such changes.
- The medical manager leads, plans, organizes, completes and evaluates.
- The personal characteristics of an effective medical manager include sound knowledge, interpersonal and communication skills, flexibility, adaptability and transparency, fairness and credibility.
- The core skills of a medical manager include an ability to communicate effectively, chair meetings, set clear objectives, delegate and deal with resistance.
- The process involved in effecting a service change includes development of a project plan, identification of a project team, establishing realistic timescales, implementation, consolidation and review.
- The implementation can be considered under two broad components – structure and function.
In the consolidation phase, the new service must be accepted and embedded within the organization.

The evaluation phase has different dimensions, which may be clinical, financial or operational.

**FURTHER READING**

INTRODUCTION

Psychiatric problems are commonplace throughout clinical medicine. It follows that no clinical service in secondary or tertiary care hospitals can function adequately without access to psychiatric advice on diagnosis and management, although the frequency with which this advice is sought varies across the specialties. In recognition of this need, liaison psychiatry has developed as a subspecialty within psychiatry, and many hospital trusts now have established liaison psychiatry services. The number of consultant posts has expanded from a small base in the 1980s, but not as rapidly as the Royal College of Psychiatrists has recommended. Clinical expansion has been accompanied by increased professional recognition, liaison psychiatry now having faculty status within the College.

Following the purchaser/provider separation introduced into the UK National Health Service (NHS), the commissioning of secondary care is in the hands of primary care trusts. Services in acute general hospitals are commissioned according to the perceived needs of the community that the hospital serves. The provision of psychiatric services to special medical services is complicated by the fact that mental health services are commissioned separately and are provided by distinct mental health trusts. Liaison psychiatry services are usually managed by mental health trusts, even though the patients that these services treat are fundamentally looked after by acute hospital trusts. There needs to be close collaboration between commissioners, acute trusts and mental health trusts if good psychiatric care is to be delivered within general hospitals.

But the provision of services is extremely variable within the UK. This chapter reviews the need for services and makes recommendations for their development. Whenever possible, reference is made to recommendations from official bodies such as medical royal colleges, the Department of Health and the National Institute for Health and Clinical Excellence (NICE), bearing in mind that these recommendations aspire to a standard of clinical practice that is seldom, if ever, achieved.

Joint reports from the Royal College of Physicians (RCP) and the Royal College of Psychiatrists (RCPsych) have drawn attention to the high prevalence of psychiatric problems in emergency departments and acute wards and have called for an expansion of services so that a liaison psychiatry service is established in every general hospital. These recommendations have been echoed by a report from the Academy of Medical Royal Colleges, which has pointed out that there has been no incentive to commission or develop services as they are not a priority for mental health or acute trusts. The Academy’s report emphasized that there is an urgent need to develop national standards that inform the commissioning services, thus ensuring that patients in need receive prompt assessment and management by appropriately trained professionals. The guiding principles of an ideal service were as follows:

- The quality of care given to people with mental health problems should be the same as the care given to people with physical health problems.
- The quality of care should be the same, regardless of the patient’s racial, religious or cultural background.
- Particular attention should be given to people with learning difficulties.
- Emergency department staff should be trained to carry out initial mental health and risk assessments.
- Emergency departments should receive timely support from mental health services, led and coordinated by liaison psychiatry teams.
- Patients in acute hospitals should have similar access to the opinion of a consultant psychiatrist as they would to a consultant in physical health problems.
- There should be good referral pathways and communications with primary care.

There should be access to more specialized services for children and older people and a brief intervention service for patients with alcohol-related problems. Rapid access to effective interpreting services must also be available.

EMERGENCY DEPARTMENT

The emergency department holds a key position at the interface between acute medical and mental health services. The prevalence of psychiatric illness is high among attendees, and in many trusts the emergency department is the
agreed place of safety for patients to be assessed if they have been detained by the police under the Mental Health Act. This arrangement is advantageous in that it allows physical and psychiatric examination to be conducted in the same place, but the emergency department does not often provide a suitably calm environment for a detailed mental state assessment. It is important that the place of safety for a particular catchment area is agreed by clinicians and managers from acute and mental health trusts and by the local police service.

The profile of patients attending with psychiatric problems has been described in several studies. Salkovskis et al. showed that approximately one-third of attendees at an emergency department had scores on a self-report questionnaire indicative of psychiatric disorder. Many patients have deliberately harmed themselves by drug overdose or injury, and there is a high prevalence of drug and alcohol problems. Attendance outside normal working hours is common, this factor probably contributing to many patients leaving the department before being assessed adequately. Up to a third of patients attending inner-city hospitals live outside the catchment area of the local mental health service. For patients in many districts, the emergency department is a major point of entry to the mental health service. A survey in Manchester found that 16 per cent of patients newly admitted to the mental health service made their first contact via the emergency department. The Department of Health has advised that in England and Wales no patient should wait in the emergency department for more than 4 h from the time of arrival to the time of admission, transfer or discharge. This target time cannot always be achieved, and patients with psychiatric problems form a high proportion of those whose stay exceeds the 4-h target. Delays occur due to lack of available staff, particularly approved doctors and social workers, and difficulties in finding beds for patients who need admission.

Psychiatric services to emergency departments vary widely with regard to their configuration and available clinical staff. Problems of contacting psychiatric staff are particularly common where the mental health trust has no presence in the acute hospital and where no liaison psychiatry service has been developed. These deficiencies need to be addressed, and a joint report from the Royal College of Psychiatrists and the British Association for Accident and Emergency Medicine has made several recommendations to improve the standard of psychiatric care:11

- Local policies should be agreed on the management of common clinical problems.
- There should be agreement on the responsibility for managing children, adolescents and older people.
- Rapid access to patient information (e.g. databases, care plans) should be available.
- Staff should be aware of customs and beliefs of patients from ethnic minorities. Access to interpreters should be available.
- Emergency department personnel should have knowledge of mental health issues sufficient to make an initial assessment. Mental health training needs to be part of the education of emergency department staff.
- A consultant psychiatrist needs to be identified as the senior member of mental health staff responsible for liaising with the emergency department.
- The first point of contact from the mental health service may be with an experienced mental health nurse or a junior doctor.
- There should be locally agreed standards regarding attendance times of mental health staff. Suggested times for first-line attendance were 30 min from being called in urban areas and 90 min in rural areas. For an approved doctor’s attendance, the times were 60 min in urban areas and 120 min in rural areas.
- There should be unambiguous arrangements regarding the attendance of social workers in emergency departments.
- Interview rooms should allow for privacy but should also include standard safety features.
- Staff should be trained in safety techniques.

These recommendations are most likely to be achieved if there is a 24-h liaison service to the emergency department; the case for such a service is particularly strong for inner-city departments.12

**Deliberate self-harm**

Deliberate self-harm (DSH) is such a common problem that it warrants special consideration. It was the only area of liaison psychiatry discussed in the National Service Framework (NSF) for mental health in England. It has been estimated that there are over 150 000 admissions annually to hospitals in the UK following DSH. Most of these come through the emergency department and are initially assessed there or in adjacent observation wards, sometimes known as clinical decision units. Although evidence for its effectiveness is not convincing, it is generally agreed that all patients should undergo a specialist psychosocial assessment. There is an increasing trend for this to be carried out by a suitably trained mental health nurse, preferably someone who is a member of a liaison psychiatry team. The topics to be covered in the assessment are well-established:

- Events leading up to DSH
- Suicidal intent at the time of the episode
- Current and ongoing psychosocial difficulties
- History of previous psychiatric treatment
- Previous episodes of DSH
- Family and personal history
- Personality traits
- Misuse of alcohol and other drugs
- Evidence of current mental illness
- Current suicidal intent
• Coping strategies and external support
• Patient’s willingness to engage in aftercare.

It is essential for the nurse or doctor who completes this assessment to have good rapport with community mental health teams so that appropriate aftercare can be arranged. In some cases the general practitioner (GP) will be the most suitable person to provide further treatment, but in any case the GP should be informed of the episode of DSH as soon as possible. Unfortunately, the evidence base for the effectiveness of treatment to prevent repetition is very weak.14 Most services aim to identify people at high risk of repetition and to focus treatment on this group. These people have usually developed a severe depressive illness or schizophrenia or have evidence of a borderline personality disorder. Medication will be appropriate for those with an identifiable illness; psychotherapy is more suitable for personality disorders.

Some patients refuse to cooperate with psychiatric assessment or may refuse treatment for the physical complications of the self-harm. In such circumstances it is important for emergency department and mental health staff to be familiar with the concept of mental capacity and to be able to assess whether or not the patient lacks capacity to make decisions concerning refusal of treatment. It is unlikely that the Mental Capacity Act can be used in acute decision-making. If there are grounds for believing the patient lacks capacity, common law can be applied to detain the patient in the department and to administer whatever medical treatment is thought to be in the patient’s best interest. If a patient is detained under common law, arrangement should be made for an urgent psychiatric evaluation by an approved doctor and social worker to determine whether hospital admission under the Mental Health Act is required. Non-psychiatric staff in the emergency department need to know their responsibilities under common law with regard to detaining and treating a patient who lacks capacity.

Royal College of Psychiatrists guidelines recommend that all patients over the age of 65 years who harm themselves should be referred to an old-age psychiatry team.15 The prevalence of psychiatric illness is high in this age group, as is the risk of subsequent suicide. Similarly, children and adolescents should be referred to a child and adolescent service.16 It is usually appropriate to admit children to a paediatric ward following an episode of DSH so that a full evaluation of the family background can be undertaken.

MEDICAL DEPARTMENTS

The high prevalence of psychiatric illness among medical patients is due to several factors, which often interact with one another:

• Pre-existing psychiatric illness contributing to development of physical illness
• Psychological reaction to physical illness, e.g. anxiety, depression, acute psychosis
• Organic effects of illness on mental function, e.g. delirium, dementia
• Influence of medically prescribed drugs on mental function and behaviour
• Medically unexplained symptoms that mask underlying psychiatric illness
• Alcohol and drug misuse.

Psychiatric illness adds to the distress experienced by medically ill patients and complicates their management. Almost certainly it prolongs their hospital admission. Most in-patient referrals to liaison psychiatry services come from medical specialties, particularly neurology, oncology and gastroenterology. Much depends on the ability of medical and nursing staff to identify their patients’ psychiatric problems. Psychiatrists have a responsibility to educate these professionals by enhancing their communication skills and their psychiatric diagnostic acumen. They should indicate which patients are most likely to benefit from psychiatric referral and treatment. The choice of psychotropic drug, if required, has to be made with attention to side effects complicating the medical condition and to interactions with drugs already prescribed. Protocols are required to advise on the general management and pharmacological treatment of acutely disturbed patients.

Patients who attend hospital frequently but whose symptoms cannot be explained adequately in terms of physical pathology constitute a troublesome group who use up considerable resources in terms of medical time and expensive investigations. Many have an underlying psychiatric disorder, most often a depressive illness, anxiety disorder or panic attacks. Referral for psychiatric assessment should be encouraged at an early stage if the presenting symptoms do not conform to a recognized pattern of illness or if routine investigations prove to be negative. Psychiatric treatment is more likely to be effective if it can be started before a pattern of chronic invalidism is established.

Psychiatric input may be required by specific units that wish direct access to a particular psychiatrist.17 Such arrangements work well but must not be allowed to develop at the expense of other departments of the hospital. Funding must be arranged to allow clinical sessions to be devoted to whichever specialty requires them. Examples where special links have been developed include pain clinics, palliative care services and neurology. Indeed, some psychiatrists have specialized in providing a service solely to neurology patients, and a subspecialty of neuropsychiatry has emerged.

Alcohol misuse

Increasing consumption of alcohol, particularly among young adults, is responsible for a growth in alcohol-related medical admissions and in mortality related to alcohol, for example from cirrhosis.18 The prevalence of problem
drinkers among medical in-patients varies from one hospital to another and between medical specialties. However, among male in-patients, prevalence rates of 25 per cent have often been reported. Alcohol-related problems are also common in emergency departments.\textsuperscript{19}

Different degrees of problem drinking have been described. Harmful drinking is defined as drinking that has led to demonstrable physical damage or dependence. Hazardous drinking describes a level of consumption that increases the risk of harm. It is equivalent to ‘at risk’ drinking and is usually defined as an average daily consumption of over 5 units of alcohol for men and 2.5 units for women. Conditions that are directly related to alcohol include alcoholic liver disease, acute alcoholic poisoning and withdrawal fits. In other conditions alcohol is a contributory factor; these include hypertension, cardiac arrhythmias, self-poisoning, fractures, tuberculosis and various types of cancer. Detection of harmful and hazardous drinking is essential if further harm is to be prevented. Clinicians must be able to take a drinking history, with particular reference to the quantity of consumption, usually expressed in units of alcohol per week, the pattern of drinking, evidence of dependence and alcohol-related harm. Laboratory tests are useful corroborators of high consumption. They are sometimes the first indicators of problem drinking. Various questionnaires are also available as screening instruments. A report from the RCP recommended that hospitals should develop a defined strategy for managing patients with alcohol problems.\textsuperscript{20} This strategy should include:

- screening for early detection of harmful and hazardous drinkers;
- early assessment of severity of dependence;
- protocols for pharmacological treatment of detoxification;
- good links with liaison psychiatry or specialist alcohol service for management of patients with complex withdrawal;
- assessment of need for referral to specialist service;
- brief intervention for coincidental hazardous drinkers;
- provision of general staff education and support;
- good links with the GP after the patient’s discharge;
- occupational policy for alcohol for all hospital healthcare workers.

With regard to staffing implications, the report advised that senior members of the medical and nursing staff should be identified to act as a focus for the alcohol strategy and to provide support for junior staff. A senior psychiatrist with an interest in alcohol misuse should act as a link between the acute hospital and mental health trusts, and one or more dedicated alcohol health workers should be employed to coordinate strategies, provide brief intervention (in the form of counselling) and have sufficient knowledge of local services to refer on for more specialized treatment.

**Drug misuse**

Similar comments apply to drug misuse. Although not as prevalent as alcohol misuse, drug-related problems can create substantial difficulties in clinical management. A survey by Canning \textit{et al.} found that, of the 6 per cent of medical in-patients identified as dependent on illicit drugs, the great majority were taking cannabis.\textsuperscript{21} In most cases cannabis causes few problems in medical management; acute psychotic reactions can occur but are uncommon. More difficult problems are associated with opiates, ecstasy, amphetamines and sedatives. Hospital trusts need to develop protocols for the management of patients with acute intoxication and withdrawal states. Pregnant users need to be encouraged to withdraw from drugs in early pregnancy. Withdrawal is best undertaken as an in-patient. It should be conducted gradually to avoid precipitating premature labour and causing fetal distress. Few acute hospitals need a specialized drug treatment service, but there is much to be said for incorporating this responsibility into the work of the alcohol treatment service.

**Sexual dysfunction**

A decision needs to be taken on whether to establish a sexual dysfunction service to help people with sexual problems attending medical, surgical and gynaecological clinics. Some trusts in the UK have special sexual dysfunction clinics; others employ sexual counsellors attached specifically to one service, usually gynaecology. Much depends on the identified need and the ability to persuade commissioners to fund the service. If a clinic of this nature is established, then it will almost inevitably attract referrals from GPs.

**SURGICAL DEPARTMENTS**

Surgeons refer fewer patients for psychiatric assessment than do their physician colleagues. In general surgical practice, most referrals request help in the management of postoperative delirium. Advice on managing behavioural problems following head injury is sometimes requested by neurosurgeons and orthopaedic surgeons. More chronic psychological problems occur in the aftermath of major surgery such as mastectomy for breast cancer, colectomy followed by colostomy for bowel disease, and limb amputation for trauma, malignancy or vascular disease. Disfigurement from trauma, malignancy and burns is also a major source of distress. Depression is a well-recognized problem and results from body-image disturbance and its effects on morale and relationships. Surgical departments now employ clinical nurse specialists to help patients adjust to postoperative problems. Breast-care and stoma nurses acquire considerable expertise in providing emotional and practical support. Close links between nurse specialists and liaison departments should be encouraged and can be facilitated by regular clinical meetings.
Victims of road traffic accidents, assault and other forms of trauma are at risk of developing post-traumatic stress disorder during the weeks following the trauma and should be asked about relevant symptoms at follow-up appointments.

Preoperative psychiatric assessment may be requested if there is doubt about a patient’s capacity to consent to surgery. Although in principle all registered doctors are entitled to make a judgement concerning capacity, in practice surgeons may prefer the opinion of a psychiatrist, especially where there is evidence of previous psychiatric illness affecting judgement. Preoperative assessment is also requested for some patients who seek plastic surgery for cosmetic reasons, a rapidly growing population in the USA and the UK. The most frequent operations requested are breast enlargement or reduction, rhinoplasty and pin- 

- Mania, schizophrenia and severe depression, when judgement about the effects of surgery is likely to be impaired
- Eating disorders, when abdominoplasty is desired as a weight-reduction procedure
- Body dysmorphic disorder, which is characterized by a preoccupation with an imagined defect in appearance or excessive concern with a slight physical abnormality. The underlying concern is often unchanged or made worse by surgery.

It is important that the surgeon asks screening questions at the initial consultation to uncover an underlying psychiatric disorder and seeks specialist advice if there is any doubt about the indication for surgery. Very rarely, a patient may request amputation of a perfectly healthy digit or limb. This is a manifestation of a condition known as amputee identity disorder. The outcome of surgery and the long-term prognosis of this condition are unknown.

MATURETITY SERVICES

The association between childbirth and psychiatric illness is well established. Postnatal depression develops in 10–15 per cent of women in the months following childbirth. A more serious psychotic disorder occurs in two women for every 1000 live births. Predisposing factors include a previous or family history of psychiatric illness and a complicated delivery. There is also some evidence that pregnancy itself is a vulnerable period as far as psychological symptoms are concerned. Women with pre-existing psychiatric illness may be at risk of an exacerbation of symptoms, not least because many women stop psychotropic medication abruptly once they discover they are pregnant. For these reasons, attention has been given to providing better care for women during the antenatal and postnatal periods.

The NICE guidelines recommend the establishment of a network of perinatal mental health services managed by a coordinating board of healthcare professionals, commissioners, managers, service users and carers. There should be a multidisciplinary perinatal service in each district; in areas of high morbidity, these services may be provided by a separate specialist perinatal mental health team. Each network should have access to a designated specialist inpatient service, providing facilities for the admission of mothers and babies, but a decision for joint admission must be taken only after a very careful appraisal of risk to the baby. Admission is usually needed for managing the small number of women who develop a postnatal psychosis or who have a poorly controlled pre-existing psychotic illness.

Identification of vulnerable women begins at the time of the first antenatal booking appointment by asking screening questions concerning past or previous mental illness, previous treatment by a psychiatrist and a family history of mental illness. Specific questions should also be asked about current or previous use of illicit drugs. A midwife is well placed to conduct this screening. Some clinics like to supplement this with self-report questionnaires. A written care plan should be developed for women at risk. If a possible mental health problem is identified, further assessment should be considered according to the severity of symptoms. When severe mental illness is suspected, referral should be made to a mental health service, including, if available, a specialist perinatal mental health service. Similar screening questions should be used to detect mental illness at the postnatal visit.

NICE guidelines recommend a stepped care approach to the treatment of postnatal depression. Much of this involves psychological therapy, and so it is important for a range of treatments to be accessible. Self-help strategies, non-directive counselling, brief cognitive-behaviour therapy and interpersonal psychotherapy all have their place for mild to moderate depression. Antidepressant medication is recommended only if psychological therapy is not available, is declined or does not work.

PLANNING FOR MAJOR DISASTERS

Every acute hospital has (or should have) a coordinated plan for dealing with unexpected major disasters such as train and plane crashes and the effects of terrorist activity. Most of the planning deals with the medical and surgical management of serious physical injuries, but in recent years many hospital plans have included advice for dealing with the psychosocial effects of disasters. Liaison psychiatrists should be involved closely with the development and implementation of these plans. Bisson et al. have provided useful advice. Planning for a psychosocial response should be a multidisciplinary exercise. It should be sufficiently flexible to cope with a range of situations and be capable of immediate response. A core multidisciplinary
ESTABLISHING A SERVICE

Where no specific liaison psychiatry service exists, it will be necessary to make a case for its establishment if the recommendations of the Academy of Medical Royal Colleges are to be fulfilled. This will involve persuading commissioners to fund an adequately staffed service and to agree its managerial arrangement. Psychiatrists may have to undertake some fairly basic educational work in this regard. Although physicians and surgeons are becoming increasingly aware of psychological factors in their clinical practice, commissioners may have little knowledge of liaison psychiatry and the diagnostic and therapeutic skills it has to offer. The NSF for mental health had little to say about liaison psychiatry, but the Scottish Executive specifically acknowledged the evidence supporting the effectiveness of liaison psychiatry and made a commitment to develop it further.\(^{27}\) Subsequent publications such as the NHS Cancer Plan\(^ {28}\) and the NSF for older people\(^ {29}\) have stressed the importance of access to psychological care and psychiatric services. Reference should also be made to government targets such as the waiting time initiative and the reduction of the national suicide rate. The effectiveness of treatment needs to be emphasized. Psychological therapies are of proven benefit in the management of chronic physical illness.\(^ {30}\) Psychotropic drugs have an established role in the treatment of co-morbid mental illnesses, but their use often has to be modified in order to avoid drug interactions and dangerous side effects.

Estimating the demand

A helpful guide has been provided by Morris, based on her own experience of establishing a service at Hull Royal Infirmary.\(^ {31}\) It is important to be familiar with research that demonstrates the high prevalence of psychiatric illness, but only a fraction of these patients will require a specialist opinion. Some idea of the likely demand can be gleaned partly by examining patterns of referral to a psychiatrist (if data exist) before developing a new service. However, this is likely to underestimate the demand because experience shows that a specific service is almost certain to increase the rate of referrals once it is established and accepted as part of the acute hospital.\(^ {32}\) More useful information can be obtained by looking at reported referral rates from other hospitals of a similar size and nature. Teaching hospitals tend to report higher rates than district general hospitals, as do hospitals with tertiary services such as neurology, oncology and transplantation.

Service profile

It is essential for liaison psychiatry to be located within the general hospital that it serves. This enables the service to be accepted as an integral part of the hospital and facilitates a prompt response to urgent referrals. It also helps to reduce the stigma that is still attached to psychiatry and psychiatric hospitals. The presence of the service can be enhanced if its clinicians participate in aspects of the hospital’s management and contribute to postgraduate teaching of nurses and junior doctors. Presenting cases at medical grand rounds further raises the profile.

Ideally, referrals should be accepted from all departments of the hospital, regardless of where the patient lives. Clinicians from other specialties often find it exasperating to be told a referral cannot be made to a particular psychiatrist because the patient does not reside at an appropriate address. This is clearly a denial of choice. There should also be agreement as to whether out-patients can be seen and whether referrals can be accepted from GPs as well as from hospital consultants. Some liaison psychiatrists have developed special skills in managing chronic somatizers who are often frequent attendees at GP surgeries, medical outpatient clinics and emergency departments and who make considerable demands on medical time and expensive investigations. Chronic fatigue is another condition for which expertise has been developed and for which patients could be referred by GPs.

If patients are seen in an out-patient clinic, they usually prefer this to be located on the same site as the clinics they attend for other medical reasons. It follows that adequate clinic rooms should be provided together with office space...
one secretary.
● one or two health psychologists/clinical psychologists;
● five liaison nurses;
● one trainee psychiatrist;
● one full-time consultant liaison psychiatrist;

The team should comprise:

- approximately 600 beds serving a population of 250,000,
- responsibility needs to be clarified and agreed with commissioners.

The level of staffing is difficult to define. It is likely that a liaison service will start with relatively few staff but will expand as it becomes established and demand increases. It is important that there should be an appropriate range of clinical skills within the team. The joint report from the RCP and RCPsych estimated that, for an acute hospital of approximately 600 beds serving a population of 250,000, the team should comprise:

- one full-time consultant liaison psychiatrist;
- one trainee psychiatrist;
- five liaison nurses;
- one or two health psychologists/clinical psychologists;
- one secretary.

A teaching hospital, serving an inner-city population with several tertiary specialist centres requires a larger service with at least two full-time consultant liaison psychiatrists. Most services operate predominantly on a consultation basis, patients being seen following a specific request by the referring team. The referral process should be uncomplicated and the response timely. During periods of heavy workload, the liaison service must be flexible and give priority to urgent referrals. There should be good channels of communication with medical, nursing and other professionals within the general hospital and with community psychiatric teams. A liaison, as opposed to a consultation model, should be developed with certain medical units if there is demand. Closer links can be forged through regular multidisciplinary meetings, which help to improve the detection and management of psychological problems; some psychiatrists seek referrals proactively in this manner.

The newly appointed consultant in liaison psychiatry is at some risk of professional isolation, given that most of the groundwork in establishing the service will involve working with clinicians and managers who are not concerned directly with mental health issues and persuading commissioners who may be sceptical about what liaison psychiatry has to offer. Psychiatric colleagues may be working elsewhere in mental health units or community clinics. Links with psychiatrists must be retained and developed by attendance at postgraduate case-conferences, lectures and committee meetings. Soon after appointment, the consultant should approach a mentor who is familiar with the acute hospital and nature of the clinical work. The mentor should agree to provide regular support and advice, thereby helping to alleviate the obstacles and frustrations that are inevitably experienced.

**Training**

Experience of managing mental health problems within a general hospital is a valuable part of training for junior psychiatrists. It is essential for those who wish to consider a career as a liaison psychiatrist. Each psychiatry training scheme should have at least one junior liaison training post and opportunities for further specialized experience towards the end of training, at which stage scope for research should also be available. Posts in liaison psychiatry should also be available during the first or second foundation years. The consultant’s job plan must recognize the training role so that adequate time is available for weekly supervision.

**Funding and management**

The joint RCP and RCPsych report advocated that a liaison service should be funded from within the acute trust’s budget and also managed within the acute trust, given that the patients treated are primarily the responsibility of staff employed by the acute trust. The more recent report from the Academy of Medical Royal Colleges also recommended that the liaison service should be commissioned via the acute trust. Local primary care trusts should therefore fund the acute trust accordingly. There must also be recognition of the demands made by patients attending the acute hospital from outside the immediate catchment area. Tertiary referral patients, for example, to neurology and oncology, have many psychological needs and make demands on the liaison service. Funding for tertiary care must provide for this clinical activity.

**SUMMARY**

The establishment of a liaison psychiatry service should be achieved in all acute general hospitals. It is warranted by the high prevalence of mental health problems and supported by medical royal colleges and official government documents. Commissioners must be actively engaged in providing this service through the acute trust.

Legal and ethical aspects of psychiatry
This page intentionally left blank
INTRODUCTION

Forensic psychiatry is the application of psychiatric knowledge to issues related to the courts and law. The principal work of forensic psychiatrists is the assessment of and preparation of psychiatric reports for the court on mentally abnormal offenders and their treatment. In practice, however, nearly all general psychiatrists will have to undertake such work on their own patients from time to time. In addition, forensic psychiatrists are also asked to provide advice on the management of aggressive and other severely behaviourally disturbed patients, who may not have been formally charged with offences or reached the courts, for example very aggressive in-patients in ordinary psychiatric hospitals.

Forensic psychiatrists in the UK are most often based in secure psychiatric hospitals such as medium secure units or special hospitals, for example Broadmoor in the UK, but they frequently undertake work in prisons to provide reports for the courts on people on remand in prison awaiting trial and to advise the prison medical service on the psychiatric management of particular inmates. Forensic psychiatrists have characteristically undertaken specialist forensic psychiatry training and are not formally legally trained. However, they are often more familiar than most lawyers with the legal issues surrounding the field of mentally abnormal offenders.

The term ‘forensic’ comes from the Roman forum, where offenders were tried. The Romans took the view that the ‘mad’ were punished enough by their madness and should not be additionally punished (*satis furore punitor*). The Bethlem Hospital in London, from where the term bedlam originated, was given cash from the early nineteenth century to take mentally disordered offenders, but due to the resulting stigma associated with such patients, which persists today, they were eventually placed in a new facility, the State Criminal Lunatic Asylum, which opened in 1863, following the Criminal Lunatics Asylums Act of 1860, and which was later renamed Broadmoor Hospital, the first of the special hospitals.

Special hospitals

In the UK, as constituted under the National Health Service Act of 1977 (Section 4), special hospitals are for individuals subject to detention who also require treatment under conditions of special (i.e. maximum) security on account of their ‘violent, dangerous or criminal propensities’. Such patients are considered an immediate and grave danger to others, either to the public or to staff and patients in hospital. The level of security in special hospitals is equivalent to that of a category B prison in terms of preventing a patient escaping, but not in terms of preventing people breaking in to obtain an individual’s release, as in category A prisons.

The three special hospitals in England are Broadmoor Hospital in Berkshire, Rampton Hospital in Nottinghamshire, and Ashworth Hospital in Liverpool. Rampton Hospital provides for all English female special hospital cases and is the national special hospital for those with learning disability and those with hearing problems. Rampton and Broadmoor hospitals also have dangerous and severe personality disorder (DSPD) units. These hospitals have the advantage of having large sites facilitating greater freedom and therapeutic activities compared with less secure units.

Most admissions to special hospitals in the UK come via the courts. Some patients are transferred from ordinary psychiatric hospitals, where they have behaved dangerously, but may not have been formally charged with offences. Others are transferred during custodial sentences from prison. Women are admitted at least five times less frequently than men and are more likely to be civilly detained, have personality disorder and be suicidal.

Special hospitals and their equivalents throughout the world have in the past been frequently criticized concerning their physical conditions, repressive regimes and the maltreatment of patients by staff. They have often tended to develop in isolation from the developments in practice in ordinary psychiatric facilities. A number of official inquiries have commented on the abuse of patients in such facilities, which have arisen due to the combination of poorly trained staff and a difficult to manage patient population, among other factors. In the UK, the Fallon Inquiry in 1999 severely criticized the lack of control in a special unit for people with personality disorder in Ashworth Special Hospital. Such hospitals have been described as being in a ‘no-win situation’, being criticized for keeping patients in too long, or letting the wrong ones out who, on occasions,
may kill or otherwise behave dangerously again, often many years later. However, the latter may have more to do with the patients’ subsequent situation or their psychiatric follow-up than with decisions made by the special hospitals. It can be difficult, in any case, to assess whether a patient will be dangerous in the community while he or she is still in a secure, single-sex ward without access to, for instance, alcohol, drugs or potential victims. The risk of re-offending is, however, long-term. Nonetheless, such hospitals clearly fulfil a need in many countries, with the demand for admissions often exceeding capacity. Of relevance is Penrose’s law, which was based on a 1936 study of different European countries and states that a higher national homicide rate correlates with a lower national number of psychiatric hospital beds.

Medium secure units

These were set up in England on a regional basis (hence, the previous term ‘regional secure units’) following the 1975 Butler and the 1974 Glancy reports in response to an unmet need for secure care. This arose from the open-door policy since the early 1950s of ordinary psychiatric hospitals, overcrowding in special hospitals, and increasing numbers of mentally abnormal offenders in prisons needing in-patient psychiatric treatment. Mentally abnormal offenders were sent by the courts to ordinary psychiatric hospitals after conviction; they would then abscond and re-offend, but not so dangerously as to require special hospital admission. They would end up in prison again, and the vicious cycle of admission and re-offending continued.

Medium secure units were set up for people whose severely disruptive or dangerous behaviour requires psychiatric treatment in conditions of medium security – that is, more than that available in ordinary hospitals but less than that in special hospitals – and who also have a prospect of responding to care within about 18 months. However, provisions for longer-stay patients in medium secure units have also now been developed. Many patients have committed dangerous offences such as homicide, rape or arson. The majority have severe (psychotic) mental illness, mainly schizophrenia. Aggressive psychopaths are not considered suitable for such units, as there is no definite evidence that they are amenable to treatment in such conditions within the original maximum recommended duration of admission. Severely mentally handicapped people are also excluded, as they can generally be managed within locked units of hospitals for mentally handicapped people.

In general, patients admitted to medium secure units are detained under the 1983 Mental Health Act. The largest number, at least 40 per cent, come via the courts, having dangerously offended. Most, up to 90 per cent, are male, but more recently women’s enhanced medium secure (WEMS) units have been developed – the term ‘enhanced’ referring to the therapeutic input rather than the level of security. Such units have allowed chronic behaviourally disturbed females to be transferred out of special hospitals.

Over a third of patients have been transferred to medium secure units from special hospitals as a graded step in their rehabilitation to conditions of less security and, ultimately, the community. Some patients are admitted from prison, either while on remand awaiting trial or after becoming mentally ill during a custodial sentence. Others are transferred from ordinary psychiatric hospital facilities. Most patients admitted to medium secure units are either discharged to the community, often to supervised hostels, or transferred to ordinary psychiatric facilities. A few require transfer to a special hospital.

The National Adolescent Forensic Network in the UK has developed medium secure units (five in number to date) for 12- to 18-year-olds with severe mental illness who have committed serious offences.

The number of places available in specialized secure psychiatric facilities is limited compared with the large number of mentally abnormal offenders. Thus, most mentally abnormal offenders continue to be dealt with by ordinary psychiatric hospitals as either in- or out-patients.

Low secure units often admit, under locked conditions, chronic behaviourally disturbed, sometimes violent, patients who have offended less seriously. Locked psychiatric intensive care units are usually for acute mentally ill individuals who are violent, destructive or suicidal, and length of admission is usually short (less than 2 months).

Community forensic psychiatry

Forensic psychiatry services have historically been institutionally based and for mentally disordered individuals who present a substantial or persistent risk to others. However, increasingly specific forensic psychiatry out-patient services are being developed, which should offer specialist skills not available to non-forensic teams, such as anger-management and specific brief treatments. These services may be either parallel to those of adult general psychiatry services or integrated with them, and they have had a duty to cooperate with multi-agency public protection arrangements (MAPPAs) since 2003.

CRIME AND PSYCHIATRY

Psychological motives for crime can be found in nearly all offenders, and this has led to psychiatric and, in particular, psychoanalytical interest since the time of Freud. The problem has been that this has not led to successful psychological treatments for offenders in general. Crime is now increasingly seen as a sociological phenomenon, better explained by sociological theories than by individual psychological theories. Psychiatric explanations for an offence, although providing understanding of the offender, do not necessarily provide an excuse for, or remove legal responsibility from, the offender, although this is often perceived by the public to be the case. Psychiatrists are trained to detect
the presence or absence of psychiatric disorder; they are not especially equipped to assess a defendant’s responsibility for his or her actions, which is a legal concept. It is a philosophical question as to whether an individual in fact has complete free will: our response to events is due to the combination of our genes, previous experience and the current stresses in our life. There is also a contrast between the legal system’s attempt to clarify whether an individual offender is either ‘mad’, and therefore in need of psychiatric treatment, or ‘bad’, and therefore in need of punishment, and the often multifactorial psychiatric explanations of behaviour. Offending is not a characteristic symptom of any mental disorder, and an offender’s behaviour may arise from a combination of mental illness, premorbid personality difficulties and background.

The courts are, in general, sympathetic to offers of psychiatric treatment as an alternative to other sentences, particularly custodial sentences, which are generally known to be ineffective, although guaranteeing that an individual will not offend for the period of sentence. Occasionally the court can be dismissive of psychiatric evidence, especially as this may be perceived as being based largely on the history obtained from the individual (e.g. whether or not the individual says they hear voices).

A psychiatric assessment is particularly likely to be requested if there is no apparent motive for an offence, if the offender is female rather than male, and in cases of sexual offending. Even where the psychiatrist does not consider that an individual has a specific mental disorder or is amenable to psychiatric treatment, the court may be assisted in sentencing by the psychological understanding provided by a psychiatric assessment.

For instance, although a theft may appear to be committed for financial gain, it will rarely be the entire explanation, and other motivations, such as excitement, may be important. People with personality difficulties, for example, may be unable to sustain relationships or work and may find life generally unrewarding and meaningless; they may obtain ‘kicks’ not only from alcohol and drug abuse but also from the excitement of offending. One reason burglars may urinate in the homes they enter is such excitement, sometimes compounded by alcohol abuse, which itself may have given them the courage to offend. Such behaviour may also be an act of defilement. Burglars may also find it exciting to creep around while the owners are at home and asleep and, on occasions, the excitement generated may lead to a serious offence such as rape. At a deeper unconscious psychological level, offenders may, for instance, be standing up to their parents or stealing to obtain symbolic affection.

Aspects of criminology

Crime is socially determined and varies between societies and over time. In the past in the UK, both suicide and certain homosexual acts were illegal; hence, the saying that ‘the major cause of crime is the law’. Studies indicate that almost everyone commits a crime at some time in their life. There is thus a less clear cut-off between offenders and non-offenders than is generally assumed. Most crime goes undetected, and crime statistics may merely reflect changes in detection rates, or a reduced tolerance of the public to a particular behaviour, or increased police recording of offending, rather than, for instance, a real increase in crime. Increasing police numbers is thus likely to increase the number of offences detected and recorded. Currently about 60 per cent of offending in the UK is related to motor vehicles. The British Crime Survey collects information independently from the police and suggests that nearly twice as much crime may be committed (over 10 million crimes per year) than is reported to the police (about 5 million crimes). The best deterrent appears to be the certainty of arrest rather than, for instance, the severity of punishment.

Although certain categories of crime may have increased over the past 25 years, it is likely that the public’s perception that we live in a less law-abiding society than formerly is misplaced. The term ‘hooligan’ may originate from the name of an Irish gang leader in Victorian London involved in what would now be termed ‘mugging’. Even in the early twentieth century in the UK, public-house brawls were common and sometimes observed by several hundred individuals at a time as entertainment. Industrial and political violence were also more common in the early part of the twentieth century than at present.

The peak age of offending in the UK is 14 years for girls and 17–18 years for boys (Figure 76.1). Studies in inner London have shown that up to one in five boys there have at least one conviction by the age of 21 years. Half the indictable crimes (more serious and eligible for trial by jury) are committed by people under the age of 21 years, and 30 per cent of males have been convicted of such an offence by the age of 30 years. Crime in general decreases with age as personality matures, except for a small peak for women aged 40–50 years, around the menopause. With the falling numbers of people aged 14–15 years in the UK (i.e. the peak age of committing crime), there has been a corresponding fall in the rates of certain offences.

![Figure 76.1](image-url)
Sexual differences in offending rates
In the UK, convicted males outnumber females by five to one, although this preponderance is only half of what it was 25 years ago. The excess may be due, among other factors, to the strength of males in general for repetitive violence (females tend to commit only isolated offences of violence), opportunity at work (e.g. fraud, although this is an area where females are also increasingly being convicted), the psychology of the male as ‘breadwinner’, and females being generally more conforming in behaviour. A female offender generally comes from a more damaged background and is otherwise more psychologically and behaviourally disturbed than a male who has committed the same offence. This in turn is reflected in the fact that females in prison tend to be more behaviourally and psychiatrically disturbed than their male counterparts. Females are also reported less frequently for crimes, particularly by male police officers, and yet are up to three times more likely to go to prison for their first offence than males in the UK.

In the past it was argued that the female equivalent to male delinquency was promiscuity, but evidence suggests that delinquent males are equally likely to be promiscuous. Some offences are, by definition, more common in women (e.g. those related to prostitution). Economic motives are commonly given as a rationalization for prostitution, although prostitutes as a group show an excess of mental disorder, self-harm, alcohol or drug abuse, physical disorders, personality disorders and bisexuality.

Premenstrual tension and crime
There is evidence that women are more likely to offend, be violent in an institution or harm themselves premenstrually than at other times during the menstrual cycle. Indeed, some women have successfully used premenstrual tension as a defence to a charge of homicide. It is most likely, however, that premenstrual tension is only an exacerbating factor in such individuals, and it does not imply that women in general are overall ‘less responsible’ at that time of the month.

JUVENILE DELINQUENCY
Delinquency is defined as law-breaking behaviour. Juvenile delinquency usually means such behaviour committed by 10- to 21-year-olds. The majority of boys under the age of 17 years may commit a delinquent act. Up to one in five males in London have a conviction by the age of 21 years, and half of all indictable crimes (the more serious offences eligible for trial by jury) are committed by individuals under the age of 21 years. Five males are convicted for every one female. Recidivism (chronic offending) is associated with an earlier age at first offence and with both loss of life experience and institutionalization due to repeated custodial sentences.

Aetiology
This is multifactorial and is not associated with an established psychiatric disorder. Some such individuals do have a personality disorder, but opportunity may be more important. For those with personality disorder, the aetiology of their offending is likely to be that of their personality disorder. There is evidence that adult criminality may have an inherited genetic predisposition, especially for acquisitive crime, but this is not definitely so for juvenile delinquency.

Sociological theories include delinquent subcultures and associated peer pressure, differential association15 and social protest theories16 of the ‘have-nots’. Differences in juvenile delinquency rates have also been related to residence in large towns and even particular bad schools. There is also evidence of labelling effects: those labelled as delinquent by conviction in court are more likely to continue with such behaviour than if they are not apprehended and convicted.

Individual developmental factors
Studies of children with conduct disorder show that 28 per cent grow up to be psychopathic adults, compared with 4 per cent of those with neurotic disorder and 2 per cent of controls.17 The factors summarized in Figure 76.2, if present, are associated with the development of delinquency.

If three of these five factors are present, then there is a 40 per cent chance of the individual showing delinquent behaviour during adolescence. Also, if troublesomeness at school is noted, then there is a 50 per cent chance of later showing delinquent behaviour.

Prevention and management
Many of the factors associated with juvenile delinquency are present before birth. It might therefore be countered, for instance, by reducing family size, increasing family income
to counter poverty, and countering low intelligence by special attention and remedial education. Individual counselling to improve self-esteem and counter feelings of resentment may help suitable individuals, particularly those who are of high intelligence and show good motivation, but a paternalistic, strict regime tends to be more helpful than a psychologically based regime for people who are immature and of low intelligence.

Juvenile delinquency may be ameliorated by a good relationship with one parent or, in its absence, a counsellor, by improved emotional harmony in the home and a good experience in school, together with a good peer group. Successful employment and a good relationship/marriage also improve the prognosis with regard to adult criminality.

Prognosis

By 19 years of age, half will have stopped their delinquent behaviour. The half who will continue are more likely to be abusing alcohol and drugs, and to gamble, to smoke and to be more sexually promiscuous. Delinquency in teenagers is also associated with criminality in adult life. The best predictor of future criminality remains the extent of previous delinquency, although offending usually ceases in the early twenties.

More recently, a 32-year follow-up of a birth cohort of 1000 New Zealanders has differentiated, apart from adult onset offenders and discontinuous offenders, life-course-persistent offenders and adolescence limited offenders and the implications for treatment (Box 76.1).19,20

**MENTALLY ABNORMAL OFFENDERS**

It has been variously estimated that 1–3 per cent of all offenders and up to one-third of those in prison have a mental abnormality. Other estimates are even higher. Most of these people have personality disorder/psychopathy or alcohol and drug dependency. Nevertheless, there is an over-representation in prison of people with learning disabilities, and people with both functional and organic mental illnesses. Imprisonment may precipitate mental illness. In the UK, men outnumber women in prison by 30 to 1, but female prisoners have more mental and physical disorders.

Mentally abnormal offenders have usually committed petty and minor offences. In fact, it is not certain that mentally disordered people break the law more often than nonmentally disordered people. Both mental illness and law-breaking are common. Up to 40 per cent of ordinary psychiatric hospital admissions may follow threatened or actual aggression, but in most of these cases it is usually considered pointless for such individuals to be charged with their offences. When assessing offenders, it is important to bear in mind that they may become mentally ill before or after an offence, due to being in custody or to fear of the likely consequences of their offending.

After committing an offence, a mentally abnormal individual may be arrested and detained in hospital under the civil provisions of a country’s mental health legislation, be cautioned by police or be charged. An individual must normally be charged within 3 days of arrest in the UK. If charged, the individual may be remanded on bail or in custody (e.g. in prison) until the court case is heard.
Box 76.2 Forensic psychiatric assessment

- Full history and mental state of patient, including fantasies and impulses to offend
- Objective account of offence, e.g. from arresting police officer or from statements (depositions) in Crown Court cases
- Objective accounts of past offences, if any, e.g. obtain list of previous convictions
- Additional information gathering, e.g. interviews with informants (e.g. relatives), reading a social enquiry report from a probation officer (if prepared)
- Review of previous psychiatric records, e.g. to ascertain relationship of mental disorder to previous behaviour and response to psychiatric treatment and need for security.

Forensic psychiatric assessments

Referrals to psychiatrists may be made by the court itself, the probation service or defence solicitors. Custom in England and Wales is that all individuals charged with murder have reports prepared on them by two psychiatrists. Psychiatrists are expected to assess whether an individual is fit to plead and stand trial, whether mental disorder is present, the individual’s level of mental responsibility, and detainability under the relevant Mental Health Act (e.g. Sections 37 and 41 of the Mental Health Act 1983 in England and Wales), and to arrange any treatment recommended, on either an in- or out-patient basis as required. Psychiatrists are also expected to give an opinion (make a risk assessment) as to the degree of dangerousness of an offender, as far as they are able.

Areas to be considered in a forensic psychiatric assessment are shown in Box 76.2.

To rely solely on an offender’s account may lead to an underestimate of the severity of the circumstances of the offence. For example, a paranoid psychotic patient may complain of being threatened by a victim of his violence when in fact the victim plausibly states that the offence was unprovoked. Also with incomplete information about previous convictions, a psychiatrist runs the risk of being discredited in court.

Box 76.3 outlines the areas to be covered in a clinical forensic psychiatric risk assessment and management plan.

Multifactorial nature of offending

When assessing an offender, it is important to bear in mind that no psychiatric disorder is specifically characterized by

Box 76.3 Clinical risk assessment and risk management planning

The aim is to get an understanding of the risk from a detailed historical longitudinal overview, obtaining information not only from the patient, who may minimize his or her past history, but also from informants. Ideally it should not be a one-off single interview assessment.

Reconstruct in detail what happened at the time of the offence or behaviour causing concern.

Independent information from statements of victims or witnesses or police records should be obtained where available. Do not rely on what the offender tells you or the legal offence category — for example, arson may be of a wastepaper bin in a busy ward or with intent to kill. Possession of an offensive weapon may have been prelude to homicide.

Offence = offender × victim × circumstances/environment

Risk factors associated with violence to be sought in a forensic assessment have been usefully summarized and are detailed later in this chapter.

Consider also protective factors:

Practical risk assessment (history × mental state × environment) can be supplemented by standardized instruments of risk, including actuarial risk instruments based on static risk factors, such as the Violence Risk Appraisal Guide (VRAG), and dynamic risk instruments, such as the Historical, Clinical, Risk-20 (HCR-20) based on factors that can change or be managed, for example symptoms of mental illness and non-compliance.

In conclusion:

- Aim to answer how serious the risk is (i.e. its nature and magnitude): is it specific or general, conditional or unconditional, immediate, long-term or volatile? Have the individuals or situational risk factors changed? Who might be at risk?
- From such a risk assessment, a risk-management plan should be developed to modify the risk factors and specify response triggers. This should ideally be agreed with the individual. Is there a need for more frequent follow-up appointments, an urgent care programme approach meeting or admission to hospital, detention under the Mental Health Act, physical security, observation or medication? If the optimum plan cannot be undertaken, then reasons for this should be documented and a back-up plan specified.
- Risk assessments and risk-management plans should be communicated to others on a ‘need to know’ basis. On occasions, patient confidentiality will need to be breached if there is immediate grave danger to others. The police can often do little unless there is a specific threat to an individual, whereupon they may warn or charge the subject. Very careful consideration needs to be given before informing potential victims to avoid their unnecessary anxiety. Their safety is often best ensured by management of those at risk.
offending, and it is important to see an offence as being due to a combination of the offender, the victim and the situation/environment.

The offender
For those with a psychiatric disorder, being young and male increases the chance of committing an offence. Overall, chronically mentally ill people are more likely to commit offences than those who are acutely ill. People whose mental illness has relapsed and who are not compliant with treatment are also more likely to commit offences. The motivation for crime may be the same as for those who are not mentally ill (e.g. as a reaction to rejection), but also it may be due to delusions or hallucinations, or as a result of a deterioration in social functioning and personality due to mental illness, so that such individuals are more impulsive and have a lower stress tolerance (e.g. in schizophrenia or depressive disorder).

People with paranoid schizophrenia may develop isolated paranoid delusions about particular individuals, which may go unrecognized, and they may otherwise appear to function adequately in daily life. They may plan attacks and are more effective in their execution compared with individuals with other types of schizophrenia. Specific parts of the body, e.g. the eyes, are more likely to be attacked by such patients.

The victim
This is most commonly a family member with whom the individual is in close proximity. This is true for victims of both mentally disordered people and ‘normal’ individuals. Most conflicts in any case occur within the family. Although it is important not to overrate the role of the victim, the victim can unintentionally provoke an offence, especially if they are physically or mentally ill themselves or have been abusing alcohol or drugs. The victim may also not appreciate the degree of stress that a potential assailant is under. Battered children are more likely to be temperamentally more difficult to manage.

The circumstances
These may also be important, for example in a pub, where victim and offender have both abused alcohol. Mentally ill individuals will tend to commit offences of criminal damage against public rather than private property, and in situations where they are likely to be apprehended. The availability of weapons is also important.

Outcomes of sentencing
Box 76.4 shows the outcomes of sentencing. In England and Wales, an individual charged with an imprisonable offence may be detained in a psychiatric hospital under Section 37 of the Mental Health Act 1983 (a 6-month renewable treatment order). A Section 41 Restriction Order may be added by a Crown Court. This requires Ministry of Justice authorization for leave, transfer or conditional or absolute discharge of the individual from hospital – that is, it removes the final decision from the patient’s consultant psychiatrist and responsible clinician. The order is made ‘to protect the public from serious harm’ and allows for conditional discharge subject to conditions such as place of residence and compliance with psychiatric treatment.

Under English law, a shoplifter with depression would be found guilty but might be placed on a community rehabilitation (previously, probation) order with a condition of psychiatric out-patient treatment. An individual with schizophrenia who smashed shop windows would be found guilty of criminal damage and might then be admitted to a psychiatric hospital under a hospital order (e.g. Section 37 of the Mental Health Act 1983 in England and Wales). See Figure 76.3 for an indication of the prevalence of community rehabilitation orders.

In countries other than the UK, mentally abnormal offenders are not considered legally guilty; they thus do not have a conviction recorded against them and are merely ordered to be detained in hospital for treatment. Under UK law, alcohol and drug dependence are not grounds for detention under the Mental Health Act, although again this does not always pertain in other countries.
The courts

Doctors, whatever their specialty, are likely to have to attend court at some time in their career, if only to give evidence to a coroner’s court or regarding personal injury cases.

Over 98 per cent of all criminal prosecutions in England and Wales are dealt with by magistrates’ courts. Three magistrates usually preside. A juvenile court is composed of a special panel of three magistrates, one of whom is usually a woman. It deals with offences committed by children and young people. In these courts, the defendant’s name must not be disclosed by newspapers and other media without the court’s permission.

The UK system of law is adversarial. If called to give evidence, for example by the defendant’s legal advisors, then a witness will initially undergo examination-in-chief by them, followed by cross-examination, in this case by the prosecution, and then a re-examination. It is important as a doctor not to overstate one’s professional views. One should indicate clearly the limits of opinion and in what areas one cannot comment.

In most cases it will be sufficient for a psychiatrist to give an opinion to the court in a report. Oral evidence is usually requested only when there is a dispute regarding the medical evidence, such as in cases of homicide where a disputed psychiatric defence has been put forward (such as diminished responsibility) in order to reduce the charge from murder to manslaughter, or where oral evidence is legally required, for example in supporting an individual being made subject to restrictions under Section 41 of the Mental Health Act 1983 of England and Wales.

ASSOCIATION OF PARTICULAR MENTAL DISORDERS WITH OFFENDING

Offending is not a primary characteristic of any mental disorder. When considering an offence, it is important to consider not only the offender but also the victim and the circumstances.

Organic mental disorders

The onset of minor offending such as shoplifting, minor sex offences and fraud at a late age may be due to dementia (e.g. Alzheimer’s disease) owing to its reduction of intellectual functioning, judgement and normal inhibitions in social behaviour. Elderly people in general often show coarsening of their personality characteristics and disinhibition with increasing age.

Brain damage from head injury, even in the absence of significant cognitive impairment, may produce a profound alteration in personality, resulting in excessive aggression, for example to a partner, who may then find it impossible to continue to live with the individual. Brain damage also reduces alcohol tolerance, which in turn may predispose to further head injuries.

Huntington’s disease may present in the early stages with psychopathic behaviour.22

The association of epilepsy with offending is discussed in detail later.

Schizophrenia and delusional disorders

Most individuals with schizophrenia do not commit criminal offences, but overall schizophrenia is overrepresented among offenders, particularly compared with affective psychoses. Most convictions are for minor offences and are secondary to the associated deterioration in the individual’s personality and social functioning, rather than arising from delusions and hallucinations. Schizophrenia, especially paranoid schizophrenia, can, on occasions, lead to dangerous offending and may result in planned assaults, including homicide, without apparent motive.

Antisocial behaviour is occasionally seen in the prodromal phase of schizophrenia, when the clinical picture may be referred to as ‘pseudo-psychopathic schizophrenia’. Schizophrenia may otherwise distort the perceptions, judgement and voluntary control of actions. Matricide (the killing of one’s mother) is frequently, but not invariably, associated with schizophrenia.

Morbid delusional sexual jealousy (Othello’s syndrome) does not infrequently lead to severe aggression towards, and the killing of, a sexual partner about whom delusions of sexual infidelity are held. This is discussed in detail later.

Querulous paranoia (litigious paranoia or morbid querulousness) leads to a profound sense of being wronged and a desire to seek redress through the courts.23

Mood (affective) disorders

Overall, people with mood disorders are underrepresented in forensic psychiatric populations. Depressive disorder is more generally associated with the risk of suicide, but it is an occasion associated with homicide, for example the ‘altruistic’ homicide of a family where the individual feels that the family may be better off out of this ‘wicked’ world. Homicides associated with depressive disorder are more likely to occur in the morning and usually involve family members. As will be discussed later, up to one-third of individuals suspected of committing homicide commit suicide, with up to one-half trying, although this predominantly reflects the psychological difficulty of living with having committed such an offence. Shoplifting may also be associated with depression, particularly in middle-aged females of previously good record who may shoplift as a cry for help to bring attention to their mental state.

Hypomania or manic episodes are often associated with disinhibited behaviour, irritability, intolerance and increased sexual drive. This may lead to convictions for breach of the peace, road-traffic offences, impulsive violence and sexual offending such as rape. Such patients spend money excessively, often due to their belief that they will soon make this up, but it can also lead to fraud.
Disorders of adult personality

These are common among offenders, but there is no clear cut-off between psychiatrically ‘normal’ individuals who offend and individuals with personality disorder. Some individuals are given a diagnosis of personality disorder on the basis of the circular argument that they have a personality disorder because they have offended. However, it is possible to contrast psychopathic offending, which is impulsive and unplanned, with more organized planned criminality with co-defendants. People with personality disorder who offend have frequently abused alcohol or drugs, or are dependent on them, and often have chronic neurotic and stress-related disorders as well.

Learning disabilities (mental retardation)

People with learning disabilities are three to four times overrepresented among offenders and even higher among violent offenders. This may be because they lack understanding of the nature of their behaviour and its legal consequences, they are more suggestible and they are easier to catch. Learning disabilities may also lead to feelings of frustration, which in turn may lead to violence and even homicide. Also, in panic or frustration, such people may commit arson or sexual offences that relate to their difficulty initiating and sustaining interpersonal and sexual relationships.

CRIMINAL RESPONSIBILITY

Criminal responsibility is a legal concept and begins at 7 years in the Republic of Ireland; 8 years of age in Scotland but at 10 years of age in England and Wales and Northern Ireland. Individuals can commit serious offences before this age, but in the UK they will not be held legally responsible (doli incapax) and cannot be convicted, although they may be placed on a social services care order and held in a secure children’s home. After the age of 10 years in England and Wales, an individual is considered legally responsible for his or her actions, unless they were due to:

- a mistake;
- an accident;
- duress;
- necessity, e.g. self-defence;
- responsibility being affected by mental disorder.

It is questionable how good psychiatrists are in judging responsibility as opposed to diagnosing mental disorder.

Some offences require specific guilty intent (mens rea) as well as an unlawful act (actus rea), for example murder, rape and arson (i.e. specific intent). Other offences do not require proof of guilty intent, for example motoring offences (i.e. basic or non-specific intent). Certain mental states interfere with the patient’s intention (mens rea) and may be defences in law to the actus rea.

Insanity has always been regarded as a defence in English law. A judge in King Alfred’s time was hung for having ordered the hanging of an insane man. By the early eighteenth century, for insanity to be a defence in law it had to be such as to cause the subject to be like a ‘wild beast’ – devoid of all reason and memory. However, in 1780 a soldier was acquitted of murder because he was found to be suffering from a delusion about the victim as a result of insanity.

Following an offence, an individual may be detained under a civil section of the Mental Health Act 1983 (e.g. Sections 2, 3, 4, 136), or cautioned by the police, or charged. If charged, the individual may be remanded on bail or in custody (e.g. in prison) until the court case.

Mental abnormality as a defence in court

In most cases, the alleged offender stands his or her trial. If the defendant is found guilty or pleads guilty, he or she then presents the medical evidence in mitigation to alter the sentencing of the court; for example, instead of a custodial sentence, the individual may be placed on a community rehabilitation (old probation) order with or without a condition of in- or out-patient psychiatric treatment or be detained in hospital under Sections 37 and 41 of the Mental Health Act 1983. In countries other than the UK, mentally abnormal offenders are not legally convicted.

In certain uncommon cases the offender offers evidence of their mental disturbance, either:

- to excuse their being tried (not fit to plead); or
- to agree to having done the act but not to have been fully responsible at the time (insane or diminished responsibility or automatism or infanticide).

In these cases, the psychiatric evidence is presented as part of the arguments to the court and is heard before conviction.

Criminal Procedure (Insanity and Unfitness to Plead) Act 1991

Unfit to plead

A mentally disordered offender may plead that he or she is unfit to plead (under ‘disability’ in relation to trial). This refers to the time of trial.

The defendant would have to prove, using medical evidence, in a Crown Court hearing, that he or she was not fit to do at least one of the following (based on the original test used in 1836 in R v. Pritchard):

- Instruct counsel (so as to make a proper defence)
- Appreciate the significance of pleading
- Challenge a juror
- Examine a witness
- Understand and follow the evidence of court procedure.

The defendant does not have to be fit to give evidence him- or herself.
If raised by the judge or the prosecution, this must be proved beyond reasonable doubt, but if raised by the defence, this only has to be proved on the balance of probabilities. This is a very rare plea and is likely to be successful only in cases such as severe mental impairment or for patients who are extremely paranoid, for example about the court or their legal representatives. In psychotic patients, unfitness to plead is significantly related to thought disorder and delusional thinking. Physical illness, such as pneumonia, may also result in unfitness to plead and stand trial.

If the individual is found unfit to plead, a decision for a Crown Court judge since the Domestic, Violence, Crime and Victims Act 2004 (see Appendix i), then there is a provision for a trial of the facts. If the individual is found unfit to plead, then this results in discretionary sentencing, including detention in hospital, a guardianship order, a supervision and treatment order or absolute discharge.

Historically, the concept originates from dealing with deaf-mute people. In medieval times, defendants were pressed under weights to give a plea, without which they could not be convicted or executed or their property given to the Exchequer – hence, the phrase ‘press for an answer’.

In Scotland, individuals are found unfit to plead more commonly, including in cases where in England they would be convicted and detained under a Section 37 hospital order. Fitness to plead is also often a major issue in the USA, where the term ‘competency’ is used.

In England and Wales, as an alternative to finding the individual unfit to plead, Section 37(3) of the Mental Health Act 1983 can be used, including in a magistrate’s court, for detention without conviction, or the individual can be remanded to hospital for treatment (e.g. Section 36) in order to get the individual well enough to be fit to plead.

Not guilty by reason of insanity (‘special verdict’) (insanity defence) (McNaughton Rules)

Historically, this defense arose from the case of McNaughton in 1843. McNaughton, believing himself to be poisoned by Whigs, attempted to shoot the prime minister, Robert Peel, missed (or misidentified), and shot and killed Peel’s secretary. Because McNaughton was deluded and insane, he was acquitted, but this caused a great deal of argument, including from Queen Victoria (‘Insane he may be, but not guilty he is not’), and the law lords were asked to issue guidance for the courts in response to five questions. Their guidance is known as the ‘McNaughton Rules’.

In this defence, the offender is arguing that he or she is not guilty (not deserving of punishment) by reason of his or her insanity. It has to be proven to a court, on the balance of probabilities, that at the time of the offence the offender laboured under such defect of reason that he or she met the McNaughton Rules – that is:

- the individual did not know that what he or she was doing was wrong (forbidden by law).
- If an individual was suffering from a delusion, then his or her actions would be judged by their relationship to the delusion – that is, if the individual believed their life to be immediately threatened, then they would be justified in striking out, but not otherwise.

Technically, this plea may be put forward for any offence, but in practice it is usually put forward only for murder and other serious offences. In fact, such a plea is rare.

Evidence from two or more medical practitioners, one approved under Section 12 of the Mental Health Act 1983, is required before the return of the verdict ‘not guilty by reason of insanity’. Such a verdict implies lack of intent. However, legally a psychiatrist can only give evidence regarding an individual’s capacity to form intent (a legal concept), not the fact of intent at the time of the offence.

Under the Criminal Procedure Act 1991, if found not guilty by reason of insanity, then the judge has freedom to decide on the sentencing and disposal of the defendant (discretionary sentencing), including detention in hospital under forensic treatment orders of the Mental Health Act 1983.

- A psychiatrist does a retrospective mental state examination for the time of the offence when assessing whether the individual is not guilty by reason of insanity (McNaughton Rules).
- In the McNaughton Rules, the legal concept ‘disease of mind’ is used. (In diminished responsibility, the legal concept ‘abnormality of mind’ is used.)
- From case law, ‘mind’ refers to reason, memory and understanding. ‘Disease’ can be organic or functional, permanent or temporary, treatable or not treatable, is ‘internal’ (R v. Quick) or ‘manifests in violence and is prone to recur’ (Bratty v. AG for N Ireland 1961). It can also include epilepsy (R v. Sullivan, 1984).

Criticism of the McNaughton Rules and diminished responsibility

The McNaughton Rules are now almost obsolescent. Points against them are include the following:

- ‘Hardly anybody is “mad” enough to fit the rules’ (Lord Bramwell). Even McNaughton would not have been.
- The rules assumes a doctrine that mind is made up of separate independent compartments, of which cognition is most important (a Victorian view).
- The rules are too unfair, as abnormal mental states do not fit into rigid categories.
- The rules ignore the importance of emotional disturbance and failure of will, when cognition is normal.

Homicide by mentally disordered offenders in England and Wales

Definition

Homicide is the killing of another human being. It is not necessarily unlawful.
Epidemiology
There have been around 500–600 homicides each year in England and Wales in the first decade of the twenty-first century.27 These figures include for 2003 the 172 victims of Dr Harold Shipman, an English general practitioner (GP) who killed many of his elderly patients. Around a third of all homicide victims are female (half killed by their partners). This compares with around 16,000 externally caused deaths each year (of these, half are suicides, others misadventure, accidents, etc.). Of note is that in England and Wales between 1996 and 1999, the three highest at-risk occupational groups of being homicide victims were security staff (25 victims), medical staff (24 victims) and social workers (14 victims).28

Legal classification in England and Wales
Homicide may be lawful or unlawful.

Lawful homicide
Lawful homicide may be:

- justifiable, e.g. on behalf of the state, such as actions taken by people in the army or the police force;
- excusable, e.g. a pure accident or an honest or reasonable mistake.

Unlawful homicide
Unlawful homicide is defined in England and Wales as the unlawful killing of any reasonable creature in being and under the Queen’s (or King’s) peace. Types of unlawful homicide include:

- murder;
- manslaughter;
- child destruction;
- genocide;
- causing death by dangerous driving;
- suicide pact;
- infanticide.

Clinical categories of homicide
Parricide, the killing of near-relatives, is disproportionately committed by males in late adolescence29 and includes patricide (killing of one’s father), matricide (killing of one’s mother, which in the UK is more common than patricide10 and tends to be committed by people with schizophrenia,31 perhaps reflecting the psychological difficulty of normally doing so), uxoricide (killing of one’s wife) and filicide (the killing of one’s child).

Serial killing involves killing individuals over time, spree killings involve killing individuals in different locations during one episode, and mass killing involves killing multiple individuals at the same time and in the same location.

Murder
Murder is an offence at common, as opposed to statute (Parliament-passed) law in England and Wales. It is defined as an unlawful killing with malice aforethought. Malice aforethought requires an intention to kill or to cause grievous bodily harm. Murder, like any other crime requiring proof of intent, involves proof of a subjective state of mind on the part of the accused. The actus reus of murder consists of both of the following:

- An unlawful act
- The act causes the death of another human being.

Murder results in a mandatory life custodial sentence in England and Wales. On average, 11.5 years is served in prison, and then the prisoner is released on life licence. A few murderers do serve life.

Manslaughter
Manslaughter may be categorized into three groups:

- Voluntary manslaughter
- Involuntary manslaughter
- Corporate liability.

The third of these will not be considered further here.

Voluntary manslaughter
There are cases of homicide in which the defendant would be guilty of murder if it were not for the availability of one of the following partial defences: diminished responsibility, provocation, killing in pursuance of a suicide pact.

Diminished responsibility (Section 2 Homicide Act 1957)
As a reaction against the fact that mentally disordered people who had killed were still being hanged, given the then mandatory death sentence for murder (abolished in the UK in 1965), despite other defences, such as not guilty by reason of insanity (the McNaughton Rules), a movement was created to bring in a defence of diminished responsibility – that is, the responsibility of the offender is not totally absent because of mental abnormality but is only partially impaired; therefore, the offender would be found guilty but the sentence modified. This was made law in the Homicide Act 1957 and applies only to a charge of murder. The murder charge is reduced to manslaughter on the grounds of diminished responsibility.

Under the 1957 Homicide Act (Section 2), as a defence against the charge (only) of murder, the offender may plead that at the time of the offence, he or she had diminished responsibility. The offender has to show that at the time:

where a person kills … he shall not be convicted of murder if he was suffering from such abnormality of mind, whether arising from a condition of arrested or retarded development of mind or any inherent causes or induced by disease or injury, as substantially impaired his mental responsibility for his acts.

‘Abnormality of mind’ is left to the defendant (or his or her medical advisors) to define and is not synonymous with mental disorder as defined in the Mental Health Act 1983. It
has been ruled in the Court of Appeal, in the case of R v. Byrne (1960), regarding the defence that ‘abnormality of mind’ would have affected at the time of the offence the individual’s perception, judgement (between right and wrong, between good and bad), or the voluntary control of (capacity to control, a legal concept) his or her actions.

Thus, abnormality of mind is:

A state of mind so different from that of the ordinary human beings that the reasonable man, earlier defined as ‘a man with a normal mind’, would term it abnormal. It appears to us to be wide enough to cover the mind’s activities in all its aspects, not only the perception of physical acts and matters, and the ability to form a rational judgement as to whether the act was right or wrong, but also the ability to exercise will power to control physical acts in accordance with that rational judgement (R v. Byrne 1960).

The authoritative interpretation of the term ‘abnormality of mind’ was given by Lord Parker (R v. Byrne 1960) as follows:

Whether the accused was at the time of killing suffering from ‘any abnormality of mind’ in the broad sense in which we have indicated above is a question for the jury. On this question medical evidence is, no doubt, important, but the jury are entitled to take into consideration all the evidence including the acts or statements of the accused and his demeanour. They are not bound to accept the medical evidence, if there is other material before them which, in their good judgement, conflicts with it and outweighs it. The aetiology of the abnormality of mind (namely, whether it arose from a condition of arrested or retarded development of mind or any inherent causes or was induced by disease or injury) does, however, seem to be a matter to be determined on expert evidence ...

‘Substantially’ is also undefined and is left to the jury to decide, although the doctors may give their opinions.

Substantial does not mean total... At the other end [it] does not mean minimal or trivial. It is something in between. (R v. Lloyd 1996).

The effect of a successful plea of diminished responsibility is to reduce the charge from murder to manslaughter. The verdict ‘unites the judge’s hands’. Murder carries a statutory sentence of life imprisonment, but the court is free to make any sentence at all with regard to manslaughter, including a hospital or community rehabilitation (probation) order or, indeed, a life prison sentence, in which case research has shown that such individuals may spend longer in custody than those convicted of murder. This may reflect concern that although abnormality of mind was identified in these cases of diminished responsibility, no ameliorating treatment is undertaken, for example in hospital, if the individual received a life prison sentence.

In addition to a report supporting the plea of diminished responsibility, the psychiatrist may also, if appropriate, wish to arrange for the appropriate hospital treatment and offer the appropriate Mental Health Act 1983 section (detention) recommendations to the court to help them with their sentencing (e.g. sections 37 and 41 of that act).

The diminished responsibility defence has been used where a defence of insanity would have no hope of success. Examples include:

- mercy killing;
- when the subject kills his or her spouse in a state of reactive depression;
- individuals who kill in jealous frenzies;
- individuals who are subject to an ‘irresistible impulse’ to kill (cited more often in the USA);
- subjects who kill and who are ‘deranged’ by psycho-pathic disorder.

The diminished responsibility defence has largely replaced the insanity defence in England and Wales for individuals charged with murder.

The most important points in favour of diminished responsibility are that:

- it allows for an overall assessment of the person;
- it allows more flexible sentencing.

Against diminished responsibility are the following points:

- There is a problem of balancing the concept of responsibility with ‘determinism’, e.g. does a greater propensity to lose one’s temper imply less responsibility?
- It assumes that a distinction can be made between psychopathy and ‘wickedness’ in terms of moral or criminal responsibility.
- Does diminished responsibility mean less power to resist temptation? If so, should the irresponsible be punished less than the responsible?
- Does an irresponsible act in a normally responsible person indicate a greater aberration of mind than irresponsible behaviour in an irresponsible person?
- If a person is found to have diminished responsibility, then it may mean that the court will return such a person to society faster than a responsible offender.

**Provocation (Section 3 Homicide Act 1957)**

Provocation is the sudden or temporary loss of control under provocation that might make a ‘normal’ person kill. Whether this occurred is for the jury to decide, although a psychiatrist’s opinion may be requested. More recently, psychiatric evidence about the propensity of individuals with certain vulnerable personalities or conditions, such as learning disability, to be provoked has been accepted as admissible.

Following criticism that this defence is used inappropriately by individuals who kill after losing their temper, and that it is not sufficiently tailored to those who kill out of fear of serious violence, for example those subject to prolonged domestic violence (as illustrated in the case of R v. Ahulwalia, 1992), the Ministry of Justice has proposed that this defence should be replaced with a new partial defence...
for people who (i) kill in response to fear of serious violence or (ii) have a justified sense of being seriously wronged.13

**Killing in pursuance of a suicide pact (which the offender has to prove) (Section 4 Homicide Act 1957)**

A suicide pact is defined as being a common agreement between two or more people, having for its object the death of all of them, whether or not each is to take his or her own life.

**Involuntary manslaughter**

Involuntary manslaughter refers to cases of homicide without malice aforethought. It can take several forms, including the following:

- An unlawful and dangerous act: ‘constructive manslaughter’ – the *actus reus* consists of an unlawful act that is dangerous and causes death.
- Gross negligence: the *actus reus* consists of a breach of a duty of care that the accused owes to the victim, with the result that the breach leads to the victim’s death.

**Infanticide**

Under the Infanticide Acts 1922 and 1938 (Section 1), infanticide is defined as having occurred when a woman by any wilful act caused the death of her child under the age of 12 months, but at the time of the act or omission the balance of her mind was ‘disturbed by reason of her not being fully recovered from the effect of giving birth to the child or the effect of lactation consequent upon the birth of the child’. This is technically an offence rather than a defence.

The grounds for this plea, as an alternative to murder, are less stringent than those for diminished responsibility (i.e. there is no need to prove abnormality of mind); nor does it require proof of a mental disorder, for example mental illness. It is the policy of the Director of Public Prosecution and the Crown Prosecution Service to use this plea for such mothers. It does not apply to adopted children or to any child other than the youngest (otherwise a manslaughter plea has to be used), as it is possible to give birth on two occasions within 1 year.

When this plea was introduced, many such mothers had acute organic confusional puerperal psychoses. Nowadays, infanticide is rather an historical anachronism; only about one in six of such mothers have functional puerperal psychoses, the remainder being not dissimilar from those who batter their children. A conviction for infanticide usually results in a sentence of a community rehabilitation (probation) order, often with a condition of psychiatric treatment (out- or in-patient).

**Amnesia**

Some 40–50 per cent of people charged with homicide claim amnesia for the actual act.

Amnesia is not in itself a defence, but the underlying condition may be – for example, a post-traumatic state, epileptic fit or acute psychosis. In the 1959 Podola Appeal case in England and Wales (Podola’s amnesia was, in fact, not genuine), it was ruled that even if amnesia is genuine, it is no bar to trial.

Amnesia may be feigned by lying or caused by:

- hysterical amnesia (denial);
- failure of memory registration owing to overarousal (comparable to ‘exam phobia’);
- alcohol;
- other psychoactive drugs;
- head injury.

**Drugs and alcohol**

It has always been considered in England and Wales that a person is fully responsible for their actions if they knowingly used drugs or alcohol (voluntary intoxication). It is assumed that everyone knows that drunkenness is associated with aggressive and irresponsible behaviour and therefore one is responsible for not becoming drunk. The same rule applies to drug abuse. This would not apply if an individual were ‘slipped’ drugs or alcohol or if their doctor did not inform them of the side effects and interactions (e.g. with alcohol) of prescribed medication.

Successful defences have been based on:

- being so drunk as to be incapable of forming intent in offences requiring specific intent;
- developing a mental illness, e.g. psychosis, as a result of the ingestion of a drug or alcohol (as in delirium tremens);
- where the use of a drug, which might be legitimate, produces a mental state abnormality that could not have been anticipated by the subject, e.g. hypoglycaemia after the use of insulin.

Thus, overall, successful defences following consumption of alcohol or drugs are based on either (i) involuntary intoxication or (ii) if intoxicated voluntarily, lack of specific intent where offences, such as murder, require this.

**Automatism**

Automatism is a rare plea generally restricted (although not entirely) to cases of homicide. The defendant pleads that at the time of the offence their behaviour was automatic (no *mens rea*). The law uses this term to mean a state almost near unconsciousness. It refers to unconscious, involuntary, non-purposeful acts where the mind is not conscious of what the body is doing. There is a separation between the will and the act, or the mind and the act – ‘Mind does not go with what is being done’ (Bratty *v. AG for N Ireland*, 1963).

This is an extremely rare plea and has been successfully pleaded, particularly in cases of homicide, for offences occurring during hypoglycaemic attacks, sleepwalking or sleep, for example fighting tigers and snakes in dreams.
Mentally Disordered Offenders Involved with The Police and Courts in England and Wales

Following an offence, an individual may be admitted informally to a psychiatric hospital, compulsorily detained under civil sections of the Mental Health Act 1983 (e.g. Section 2, 3, 4, 136), be cautioned by the police, which the individual has to voluntarily accept, or be charged. If charged, the individual may be remanded on bail or in custody (e.g. prison) until the court case. The police may also check whether the person is an absconding detained patient and return him or her to hospital under Section 18 or Section 138.

Under the Police and Criminal Evidence Act 1984 (PACE), there is a code of practice that covers detention, treatment and questioning of people by police officers. If the individual is suspected by a police officer to be mentally disordered, then an ‘Appropriate Adult’ must be informed and asked to come to the police station. This should ideally be an individual trained or experienced in dealing with mentally disordered people rather than an unqualified relative. An Appropriate Adult should be present while the individual is told their rights and can advise the person being interviewed, observe the fairness of the interview and facilitate communication with the interviewee. They may also require the presence of a lawyer.

If a decision is taken by the police to prosecute, the case is passed to the Crown Prosecution Service, which will also consider the public interest and likely adverse effects of prosecution of a mentally disordered individual.

**Police and court liaison**

**Terminology**

- **Diversion or early diversion:** this is the transfer to the healthcare system of a mentally disordered individual in police custody or at first court hearing.
- **Diversion or police or court diversion schemes:** specific psychiatric services provided to the police or courts, usually to a magistrate’s court (where 98 per cent of offenders are tried). Such services reduce the time on remand in custody for mentally ill individuals but may not affect the long-term risk of offending. However, it is unlikely that serious offenders, such as those charged with murder, will be suitable for such diversion.

**Psychiatric issues relevant to police and court liaison include:**

- Evidence of mental disorder
- Need for out- or in-patient psychiatric treatment
- Urgency if in-patient psychiatric treatment required
- Nature of alleged offence and risk to others
- Fitness to remain in police custody
- Fitness to be interviewed by police
- Fitness to plead if individual is to appear in court.

Remember that the technical legal offence may not reflect the actual risk. For example, arson may be of a wastepaper bin in front of others on a busy hospital ward or committed with intent to endanger the lives of others in a tower block. Similarly, possession of an offensive weapon may have been with a view to seriously harming others.
Fitness to remain in police custody

- There is no legal definition.
- An individual may be unfit to remain in police custody due to physical illness or psychiatric disorder.
- Serious and immediate risk to an individual’s health will usually make the individual unfit to remain in police custody. Detention under a civil section of the Mental Health Act 1983 may then be indicated.

Fitness to be interviewed by police

- There is no legal definition.
- The individual should be able to understand the police caution after it has been explained.
- Full orientation to time, place and person is required.
- Fitness may be questioned if the individual is likely to give answers due to their mental disorder that may be wrongly interpreted by the court.
- If the individual is fit to be interviewed but has a history of mental disorder, then an Appropriate Adult should be present. Such individuals can be provided by Appropriate Adult schemes.

False confessions (after Gudjonsson 1993)35

Three types of false confession have been described:

- Voluntary: e.g. due to depression or morbid guilt.
- Coerced-compliant: due to being pressurized during the interrogation. Individuals often retract such false confessions after interrogation.
- Coerced-internalized: the individual becomes confused by interrogation and comes to believe the false story. This is seen particularly in people with learning disability.

In cases of possible suggestibility and false confessions:

- assess the individual’s intellectual level;
- use the Gudjonsson Suggestibility Scale.

Procedure before trial

The presumption is always in favour of remanding an individual on bail rather than in custody. Bail could include a condition of residence in a psychiatric hospital, although the individual would be an informal patient there unless detained under the Mental Health Act 1983.

Where the individual might otherwise be remanded to prison, the Mental Health Act 1983 allows for the following:

Section 35 – remand to hospital for report

This order can be made under Subsection (3) (i) ‘if the court is satisfied on the written or oral evidence of a registered medical practitioner that there is reason to suspect the accused person is suffering from mental disorder’; and (ii) ‘the court is of the opinion that it would be impractical for a report on his mental condition to be made if he were remanded on bail’.

A hospital bed must be available within 7 days. If awaiting a bed, the accused must be kept in a ‘place of safety’, e.g. a ‘police station, prison or remand centre or any hospital the managers of which are willing temporarily to receive him’ (Section 55(1)). The remand period is for a maximum of 28 days, although it is renewable for further periods of 28 days, without the necessity of the patient attending court, up to a maximum of 12 weeks. Part IV provisions on consent to treatment do not apply, and so the individual cannot be treated without their consent, except in an emergency under common law. Some psychiatrists therefore additionally detain such individuals under Section 3 when they wish to treat them without their consent; the code of practice states that this may be considered if there is a delay in getting to court. The use of Section 36 might, however, then be more appropriate.

Section 36 – remand to hospital for treatment

This may be used only by the Crown Court and is an alternative to remand to custody. It can apply to individuals waiting for trial or sentence. It requires the written or oral evidence of two doctors that the individual is ‘suffering from a mental disorder of a nature or degree which makes it appropriate for him to be detained in hospital for treatment’. It cannot be used for people charged with murder. The remand is for a maximum of 28 days, although this may be renewed for further periods of 28 days, without the necessity of the patient attending court, up to a maximum of 12 weeks. Part IV provisions on consent to treatment apply. A hospital bed must be available within 7 days and the individual must meanwhile be kept in a ‘place of safety’ (Section 55(1)). Problems arise if the individual has to wait for more than the maximum 12 weeks of the order to appear in the Crown Court. In these circumstances, detention under a civil section or the use of Section 48 may be required.

Section 48 – remand to hospital of other prisoners (including those on remand in custody)

This section gives the Justice Secretary powers to direct the transfer to hospital of a person waiting for trial or sentence who has been remanded in custody. It also applies to individuals detained under the Immigration Act 1971 and civil prisoners. The Justice Secretary requires two medical reports, which do not need to specify the availability of a bed at a particular hospital, stating that the individual has a mental disorder of a nature or degree that makes it appropriate for him or her to be detained in hospital for medical treatment and that he or she is in urgent need of such treatment. The period of detention is variable and can continue to the time of sentence. This order has increasingly been used to divert severely mentally ill (psychotic) offenders from custody to hospital, even when the need may not be ‘urgent’. It has the advantage that it does not require a court hearing to impose the order. On occasions, e.g. when an acutely mentally ill offender has appeared in court, such an individual may only nominally be remanded to a named custodial facility and, by arrangement with the Ministry of
Justice, is transferred directly to hospital without being placed in custody.

Unfit to plead (Criminal Procedure (Insanity and Unfitness to Plead) Act 1991)
This was described earlier.

Mental disorder as a defence
As described previously, such defences include the following:
- Not guilty by reason of insanity (McNaughton Rules)
- Diminished responsibility: Section 2 of the Homicide Act 1957
- Infanticide Act 1938.

Sentencing
The following options for sentencing were made available under the Mental Health Act 1983.

Hospital order – Section 37 of the Mental Health Act 1983
This may be made by the Crown Court or a magistrate’s court, the latter being able to make such an order without conviction under Section 37(3) as long as the court is satisfied that the individual committed the act or omission in question. The individual has to be charged with an imprisonable offence rather than simply any offence. For this sentence to be made, a hospital bed must be available within 28 days, beginning from the date of the order. The patient, meanwhile, must be kept in a ‘place of safety’ (Section 55(1)). The availability of a bed within 28 days and the evidence of two registered medical practitioners, one approved under Section 12 of the Mental Health Act 1983, are essential before the court can impose such an order.

Interim hospital order – Section 38 of the Mental Health Act 1983
If it is uncertain that a full Section 37 hospital order is appropriate, then this can be tested out by making an interim order. It can be made for up to 12 weeks in the first instance and then renewed by the court for periods of up to 28 days at a time, to a maximum of 1 year. The patient does not have to attend court in person when the order is renewed. This order is also useful for psychiatrists who are uncertain whether the individual's mental disorder is going to be amenable to psychiatric treatment, for example in cases of personality disorder. If, in the end, a Section 37 hospital order is not considered appropriate, then the court can use its discretion to otherwise sentence the individual, including to prison.

Restriction order – Section 41 of the Mental Health Act 1983
Section 41(1) states:

... where a hospital order is made in respect of an offender by the Crown Court, and it appears to the court, having regard to the nature of the offence, the antecedents of the offender and the risk of him committing further offences if set at large, that it is necessary for the protection of the public from serious harm so to do, the court may, subject to the provisions of this section, further order the offender shall be subject to special restrictions set out in the section, without limit of time; and the order under this section shall be known as a ‘Restriction Order’.

That the order is made ‘without limit of time’ reflects the therapeutic uncertainty of how quickly an individual will progress. One of the two doctors recommending Section 37 must attend court to give evidence, but it is for the court to decide whether a Section 41 restriction order should be imposed. The main restrictions are that the patient can only be absolutely or conditionally discharged, given leave of absence, or transferred to another hospital with the approval of the Justice Secretary. A restriction order therefore is an added safeguard, so that the decision to, for example, discharge, is not left to the responsible clinician alone.

If conditionally discharged, compulsory aftercare, which will involve statutory supervision by either a social worker or probation officer and usually a psychiatrist, is required. The main advantage of this order for professionals is that it facilitates the long-term management of mentally abnormal serious offenders by specifying the conditions of their discharge, for example their place of residence, such as a supervised care home or hostel, and compliance with psychiatric treatment, including medication, upon threat of recall to hospital. If recalled, the individual is subject to a mandatory mental health review tribunal hearing within the first 6 months.

Guardianship order – Section 37 of the Mental Health Act 1983
The grounds are as for a Section 37 hospital order. It is used rarely. A proposed guardian must agree to it. If the patient absconds from a place where they are required to live, then they may be recaptured and returned there. There are, however, no effective sanctions for a patient refusing to cooperate with psychiatric treatment, for example with medication treatment, although attendance to see a psychiatrist can be enforced. It was hoped in the 1975 Butler Report that this order might be increasingly used, but many social services departments are reluctant to use this order for mentally abnormal offenders, although again it can facilitate the management of a mentally abnormal offender in the community.

Hospital and limitation directions – Section 45A of the Mental Health Act 1983
This was brought in by the Crime (Sentences) Act 1997 (on 1 October 1997). It is referred to as the ‘hybrid order’, as it is a prison sentence accompanied by hospital and limitation
Psychiatric community rehabilitation (old probation) orders
These can be made in any court for any offence other than one with a fixed penalty, such as murder which carries a mandatory life prison sentence, but they do require conviction. Supervision by a probation officer is for a specified period between 6 months and 3 years. In cases where there is a condition of psychiatric treatment, the court will require evidence from a doctor approved under Section 12 of the Mental Health Act 1983. Conditions may include that the subject receives treatment as an in-patient or in a nursing home or as an out-patient at a specified hospital or place from or under the direction of a named doctor. The court must explain the requirements of the order to the offender and obtain the offender’s consent. If the individual subsequently refuses to cooperate with psychiatric treatment, then the doctor can only report this to the supervising probation officer, who may take proceedings on these grounds for breach of the probation order. Detention in hospital under the civil provisions of the Mental Health Act 1983 is an alternative, if appropriate, in such circumstances.

After sentencing
Transfer direction from prison – Section 47 of the Mental Health Act 1983
This allows the Justice Secretary to order the transfer of a sentenced prisoner following conviction if he or she has a mental disorder. The patient is subject to consent to treatment provisions. This order can continue until the earliest date of release, whereupon a notional Section 37 hospital order automatically follows without the need for further completion of legally required medical recommendation reports. Commonly, a restriction direction is also made under Section 49, which has the same effect as a restriction order under Section 41. Such individuals can be returned to prison to complete a sentence before their earliest date of release, for example if they recover from their mental illness or they no longer require in-patient treatment. The two groups of individuals most frequently transferred from prison on this order are those who develop mental illness during a prison sentence and those where the mental illness was missed at the time of sentence.

Transfer of individuals kept in custody during Her Majesty’s Pleasure – Section 46 of the Mental Health Act 1983
This also covers members of the armed forces. It has the same effect as a hospital order with restrictions without limit of time.

PSYCHIATRIC EXPERT EVIDENCE AND PSYCHIATRIC COURT REPORTING
The areas of psychiatric expert evidence and psychiatric court reporting are summarized in Boxes 76.5 and 76.6.

Table 76.1 details forensic treatment orders under the Mental Health Act 1983. Box 76.7 shows the Mentally Disordered Offenders and the Crime Sentences Act 1997.

Box 76.5 Psychiatric expert evidence
- Fitness to plead
- Mental responsibility, e.g. not guilty by reason of insanity, diminished responsibility
- Mental disorder, e.g. mental illness, learning disability, personality disorder
- Is the client treatable?
- Have arrangements been made for such treatment, e.g. community rehabilitation order with condition of out-patient treatment, or in-patient treatment under Section 37 of the Mental Health Act 1983?
- Is the client dangerous? e.g. Section 41 Mental Health Act 1983, placement in a special hospital
- Suggestions about non-psychiatric management, e.g. community rehabilitation order, supervised hostel.

Problem areas in police/court liaison and reporting
A plea of not guilty
If the individual is pleading not guilty or is undecided upon their plea but you think the individual was mentally ill at the time of the offence, it is best to say, for example, ‘for the time of the offence, Mr X showed symptoms of mental illness such as …’ This avoids having to comment on likely guilt before a plea is entered.

Explaining the relationship of mental illness to offending
An offence may have arisen directly from paranoid or passivity delusions due to mental illness or indirectly due to a deterioration in personality and social functioning, for instance in schizophrenia. There may be no relationship between the offence and the mental disorder. The offence and legal consequences may precipitate a mental illness, for example depression.

Personality disorder
If you do not think the individual’s personality difficulties are amenable to specific in-patient psychiatric treatment, then say so and add the words ‘In the absence of mental illness I do not consider him detainable under the Mental Health Act’.
Box 76.6 Court reporting

A report may be requested:
- by a court (magistrate’s, crown or higher), usually through the probation service. Written authorization by the court must be given;
- by the defence solicitors, in which case the patient’s written permission is required before giving a report to the solicitor, which remains the solicitor’s and client’s to use or not in court.

Information required for a report includes:
- information about the charge;
- a social enquiry report from a probation officer;
- a list of previous convictions;
- previous medical hospital records;
- previous reports (social and medical);
- depositions where available, e.g. Crown Court, but not magistrates’ cases.

The history will be taken from the patient and, if possible, a relative or friend.

The client should ideally be examined fully physically.

Questions that the court or solicitor will be particularly interested in include the following:
- Does he or she have a mental disorder?
- Is it susceptible to or requiring specific treatment?
- Can arrangements be made for such treatment, e.g. hospital, out-patient?
- Is the client dangerous?
- Have you any suggestions as to the client’s management, apart from the psychiatric aspects?

After interview and examination of other reports, etc., one can valuably discuss the case again with the probation officer or others, such as other psychiatrists involved in the case:
- Discuss particularly your findings and compare them with other professionals’ observations, which may reveal gross discrepancies.
- Discussion may reveal unexpected channels for disposal or unforeseen difficulties.

The general principles of the written report are as follows:
- It should be in clear English, and technical terms should be avoided if possible. If such terms are used, an explanation of them should be given, e.g. paranoid (persecutory) delusions (false beliefs), auditory and visual hallucinations (voices and visions).
- Use the report to help the court reach the most appropriate disposal for the patient.
- The report is a recommendation to the court. The court may have other psychiatric opinions that oppose yours and may itself be unconvinced by your opinion. Thus, the onus is on you to provide the evidence in the report for your opinion.
- The onus is also on the reporting doctor to make all the necessary medical arrangements for the disposal and management of the patient.
- Be accurate, complete and brief. The court is extremely busy and will resent a turgid, overwritten medical report. For magistrates’ courts, which may deal with dozens of cases a day, around two pages may suffice; even then, only the opinion may be read.

People use different forms for their report, but the following is suggested. Paragraph numbers and headings can be used for clarity and are valued by the legal profession:

- Para 1 – Introduction: inform the court of when and where the patient was seen, and at whose request, what information was available, who the informants were, and sometimes what information was not available. State the current offence(s) for which the patient is charged and its date, and the plea if known, i.e. guilty or not guilty.
- Para 2 – Past medical history: inform the court of this and of the result of medical examination, e.g. ‘Physical examination revealed no abnormality’.
- Para 3 – Family history: report the important, relevant points, including family history, or not, of psychiatric disorder and criminality.
- Para 4 – Personal history: report the important points of the patient’s physical development (e.g. birth, milestones), early development (e.g. bed-wetting (enuresis)), schooling (e.g. truancy) and occupational history (e.g. difficulties with a job, sackings, difficulty sustaining employment, difficulties with colleagues or supervisors at work).
- Para 5 – Sexual history: be reasonably discreet. The report may be read in open court.
- Para 6 – Previous personality: report details of personality in terms of social interaction, emotions and habits, e.g. drinking, gambling, drugs.
- Para 7 – Past forensic history: technically, past convictions should not be admissible before conviction, but they are admissible when the report is to assist sentencing. In practice, often only one psychiatric report is prepared for both trial and sentencing.
- Para 8 – Past psychiatric history: report dates, diagnosis, relevant details and relationship of mental disorder and treatment to offending.
- Para 9 – Circumstances surrounding index offence(s): report the circumstances leading to current offence(s) and the defendant’s state of mind at the time of the offence, sticking to the phenomena reported, e.g. ‘for the time of the offence, the patient gives a history of tearfulness, loss of hope, poor sleeping... These are symptoms of a depressive mental illness’.
In general it may be best to allow the law to take its course when the individual is free to take it up, or as a condition of a community rehabilitation (previously probation) order.

**Substance misuse**
In general it may be best to allow the law to take its course and to offer treatment or help on a voluntary basis only when the individual is free to take this up, except where specific drug rehabilitation residential placements are recommended as a condition of, for instance, a community rehabilitation order, to which, however, the patient must agree. In general, the recommendation is usually that the individual must stop abusing alcohol or drugs, and that this is something that the individual must primarily decide to do, although the ability or will of the individual to do so may be in doubt, but the individual may additionally be helped by services in doing so.

### Box 76.7 Mentally disordered offenders and the Crime (Sentences) Act 1997

- **Mandatory life sentence** for second ‘serious offence’ (attempted murder, manslaughter, rape, attempted rape) unless exceptional circumstances (which do not include mental disorder alone)
- **Hospital direction and limitation direction** (equivalent to restriction order) for psychopathic disorder only; if patient benefits, can stay entire sentence in hospital
- **Transfers to hospital:**
  - Court and Justice Secretary can specify unit
  - Justice Secretary’s consent required for transfer of restricted patients between hospitals, even if in same trust
  - Section 47 transfer now allowed to mental nursing home
- **Interim hospital orders:**
  - Maximum duration extended to 1 year (from 6 months)
  - Can use before a hospital direction.
Individuals citing hearing a ‘voice’ telling them to commit an offence where a mental illness is not suspected

Note the absence of other characteristic symptoms of severe mental illness, such as of schizophrenia. Such isolated voices may reflect only pseudo-hallucinations, which are usually perceived as in the mind rather than external space, occur in individuals with severe personality disorder under stress, or may be due to substance abuse.

History of mild head injury or mild learning disability

Such a history does not necessarily imply that the condition is of a degree that would adversely affect the individual’s ability to otherwise normally sustain him- or herself adequately in the community and be responsible for their acts. Frequent problems occur in people with borderline learning disability who are not suitable for learning disability services, although the courts and social services look to the medical profession to manage them in spite of the ‘normal’ intelligence level. Their offending is usually due to personality difficulties.

PSYCHODYNAMIC AND EPIDEMIOLOGICAL ASPECTS OF HOMICIDE

Homicide followed by suicide

This outcome, which precludes a criminal trial, occurred in around 7 per cent of such offences between 1966 and 2004 in England and Wales. The rates of homicide followed by suicide have probably been higher in England and Wales in the past, with estimates of up to a half attempting suicide and a third succeeding in the 1960s, at a time when most homicides were domestic, with an overrepresentation of female offenders and child victims and thus perhaps more psychologically difficult to cope with the consequences.

Psychodynamic aspects

Most individuals who have killed do not regard themselves as typical murderers, and many resent the implications of the word ‘manslaughter’. Nevertheless, although murderous thoughts can be normal, acting on them is not. Homicide can be seen as preventing something even more psychologically worse for the individual. After committing homicide, some individuals, due to psychological defence mechanisms, may appear callously indifferent, idolize the victim, or claim amnesia as the act is too painful to think or talk about.

In terms of prevention, the Jason Mitchell Inquiry in the UK argued that all psychiatric in-patient units that include offenders with disturbed personalities should have access to specialist psychodynamic expertise to provide a psychodynamic formulation of the case.

Trends in homicide rates due to mental disorder in England and Wales

Using the legal classifications of homicide described in this chapter, Large and colleagues have shown that, in England and Wales, the annual number of homicides due to mental disorder rose from fewer than 50 in 1957 to more than 100 in the 1970s but has now returned to the earlier low levels while other homicides have continued to rise. The initial rise in homicide by mentally disordered people was attributed to the same factors responsible for the increase in other homicides, such as substance misuse and increased availability of weapons, and the subsequent decline to the improved awareness of, services for and treatment of mental disorder.

These findings contradict those of Coid, who argued that the rate of homicide by mentally ill people is related to the prevalence of mental illness, which itself is fairly constant in all countries – that is, in countries with high homicide rates, this is due to high numbers of non-mentally ill offenders, their violence being related to criminal activities, drug-dealing and subcultural and economic factors, and, as a consequence, these countries with high homicide rates had a lower proportion of mentally ill homicide offenders.

There is thus no evidence of increasing rates of homicide by mentally ill people in England and Wales (this is also supported by Bennett and Taylor and Gunn) in spite of this being the media and public perception, which in turn probably reflects only increasing awareness. Homicides by mentally ill people have a negligible effect on public safety in England and Wales compared with other factors, such as road-traffic accidents.

VIOLENCE AND MENTAL ILLNESS

Violence has multifactorial causes and is a biopsychosocial environmental phenomenon. All behaviour has a biochemical basis. Although biochemical abnormalities can cause psychological symptoms, including aggression, there is also increasing evidence that psychological events, such as severe abuse in childhood and severe psychological trauma in adulthood, may cause neurobiological abnormalities, for example in serotonin (5-hydroxytryptamine, 5-HT) metabolism in adults, which in turn is associated with aggression, which is usually inhibited by serotonin. Models of violence are shown in Table 76.2. No model can adequately explain all violence and different models may be best for different situations.

Aggression, using the biological definition, is intraspecific fighting. Normal aggression is seen in all members of a species, but pathological aggression or violence is excessive in degree or arises from mental disorder. Almost all forms of mental disorder can be associated with aggression and violence (Table 76.3), although anyone can become violent. There has been a debate about whether aggression is an instinct – that is, genetically determined but called out by

PCP, phencyclidine; TLE, temporal lobe epilepsy.
the environment – or learned. Probably there is a normal
inborn assertiveness, with aggression being secondary to
early developmental deprivation and insults or mental dis-
order, rather than a primary drive.
Karl Lorenz has noted that a personal bond and individ-
ual friendship is found only in animals with highly devel-
oped intraspecific aggression.\footnote{44} In fact, the more aggressive
the particular animal or species, the firmer is the bond. Real
intimacy thus may occur only when individuals share real
aggressive and good feelings.
Aggression often follows frustration and threat, for
example in a person with low self-esteem, and increasing
tension. Aggression may be displaced from the original
object on to a symbolic representation of it, for example
arson, or anger towards the mother displaced on to women
in general. Aggression can also be a social phenomenon,
for example in altruistic aggression and war.
Violence is action while dangerousness is a potential and
a matter of opinion. The term ‘risk’ is now used increasingly
in professional practice in preference to ‘dangerousness’. Risk
is, ideally, a matter of statistical fact. It emphasizes a
continuum of levels of risk, varying not only with the
individual but also with the context. It may change over
time and, in principle, should be based on objective
assessment. Dangerousness tends to imply an all-or-none
phenomenon and a static characteristic of an individual.
However, risk assessment is less important than risk
management, although risk management does not imply
risk elimination.
Risk factors include dispositional factors (e.g. demo-
graphic factors), historical factors (including past violence),
constitutional factors (including stress and social support)
and clinical factors (including diagnoses, symptoms and
substance abuse). Risk may change rapidly over time.
In the past, factors associated with violence were said to
be the same, regardless of whether the offender was men-
tally ill – that is, personality disorder, impulsivity, anger,
vigorous family background and substance abuse.\footnote{45} However,
since 1992, studies have shown that having a diagnosis of
mental illness is associated weakly with violence due to a
subgroup with specific types of symptoms such as paranoid
(persecutory) delusions (false beliefs) and delusions of pas-
sivity (being under external control). It is thus certain
symptoms, and not particular psychiatric diagnoses alone,
that are associated with violence. Nevertheless, the risk of
violence is still better predicted by being a young male than
by having a diagnosis of schizophrenia.\footnote{46}
Psychiatrists are better than chance or laypeople in pre-
dicting violence and better still at assessing situations
where there is no risk; however, they tend to underestimate
the risk of violence in females.\footnote{47} Professionals also under-
estimate the high background base rates of violence in the
community in general; for example, up to 40 per cent of
males in a London sample had been seriously violent by the
age of 32 years.\footnote{48} The majority of violence never results in
criminal charges. This also applies to in-patients who are
violent, where formal charges may often be seen as serving
little purpose if the patient is to remain in hospital.
Among individuals with mental illness, affective disor-
ders are underrepresented in forensic psychiatric facilities.
Violence is, however, increased in people with schizophre-
nia,\footnote{49} especially those who have drifted out of treatment,
and in young males with acute schizophrenia compared
with those with chronic schizophrenia. Violence may arise
directly from positive symptoms of mental illness, such as
delusions (false beliefs) and hallucinations (e.g. voices).
Mental illness, especially schizophrenia, may, however, lead
indirectly to violence through associated deterioration in
social functioning and personality, so that such individuals
become more antisocial and impulsive and develop a lower
tolerance to stress. This may lead to disputes in court in
England and Wales about the disposal of such individuals
with few or no positive psychotic symptoms who have
killed, with such individuals sometimes being given,
wrongly, an additional diagnosis of personality disorder to
explain their violence. A mentally ill individual may also
behave violently for ‘normal’ emotional reasons, such as
fear and anger, and then experience accompanying corre-
sponding psychotic symptoms, such as hallucinations of
aggressive content. Violence, law involvement and impris-
onment may precipitate mental illness.
For a mentally ill person, the key issue is whether the
individual has a delusion of a content on which he or she
might act dangerously, for example of persecution or infi-
delity, but even then not all morbidly jealous individuals,
for instance, assault their partner. Twenty per cent of people
presenting to hospital with their first episode of schizophre-
nia have threatened the lives of others, but among these
patients half have already been ill for a year.\footnote{50} Overall,
however, it is unusual for a person with schizophrenia to
present for the first time with serious violence including
homicide. One established period of higher risk is within a
few months of discharge from hospital.\footnote{51} People with both
schizophrenia and substance abuse have higher rates of
violence than those with substance abuse alone, who in
turn have higher rates than those with schizophrenia alone.\footnote{46}
Research has generally shown, but not universally,\footnote{52} a
consistent association between violence and delusions, par-
ticularly of threat/control override content, for example
persecutory delusions, passivity delusions and thought
insertion.\footnote{53} These findings are in keeping with social psy-
chology theory that violence in general is associated with
the individual feeling under threat or losing control of his
or her situation.
Based particularly on the work of Steadman and
Monahan’s group in the USA (the McArthur Foundation
Violence Risk Assessment Study),\footnote{54} the Royal College of
Psychiatrists for the UK and Ireland in 1996, in its booklet
Assessment and Clinical Management of Risk of Harm to
Other People, detailed ‘warning signs’ of which profession-
als should be aware.\footnote{55} These were:
believes of persecution or control by external forces;
previous violence or suicide attempts;
social restlessness;
poor compliance with medication or treatment;
substance abuse;
hostility, suspiciousness and anger;
threats.

Psychiatric patients tend to peak for violent offending at a later age than the general population. It is important to be aware that the oft-quoted ‘best predictor of future behaviour is past behaviour’ (after Kvaraceus) is based on non-psychiatric populations and, in any case, accounts for only 5 per cent of the variance. A history of previous violence is required for this to be relevant in any case. Among severely (psychotic) mentally ill people, delusions of threat/control override appear to be better predictors than past behaviour.

Among all individuals, including mentally ill people, a history of expressed threats (as opposed to generalized anger), substance misuse and personal deprivation or abuse are associated with violence. Indeed, it has been suggested that homicide rates in general may be reduced in the UK by coordinated multi-agency responses and more policy and educational initiatives targeted specifically to counter domestic violence, child abuse, alcohol abuse and the carrying of knives and other weapons.

Law-breaking behaviour in general, and violence in particular, usually decreases when the basic needs of an individual are met. For instance, an individual with schizophrenia who kills may have a characteristic history of not only poor compliance with medication, leading to relapse of his or her mental illness, but also of being in a situation of social isolation and poor home conditions. Some individuals may even offend to remove themselves from their situation in the community to the security of prison or hospital. The risk of self-harm or suicide is, however, greater for people with schizophrenia, even if they have before behaved seriously violently, than is homicide or serious harm to others.

In summary, although no mental illness is characterized by serious violence, including homicide, the existing evidence suggests that there is a link between mental illness and violence. Mental illness is a risk factor, but not a large one, and the risk is increased by substance abuse.

Developments in brain scanning may elucidate this area further. Our research group has found evidence, using 31-phosphorus magnetic resonance spectroscopy (MRS), of increased cerebral metabolism in male patients with schizophrenia who have dangerously offended, compared to matched individuals with schizophrenia who had not so offended (Figure 76.4). A strong connection has been hypothesized between the supramarginal region corresponding to Brodmann area 39/40 and Broca’s area, which may correspond largely to the arcuate fasciculus, with the connectional pattern of the language regions of this model fitting the network of parietotemporal–prefrontal connections that participate in working memory. This points to the possibility of an abnormality in neural circuits involved in verbal working memory in this group of patients.

These results, and additional findings relating to lipid peroxidation, may be consistent with increased cerebral oxidative stress in patients with schizophrenia who have seriously and dangerously offended.

Avoidable deaths: the national confidential inquiry into suicide and homicide by people with mental illness, University of Manchester, England

This inquiry for England and Wales was set up in 1996 to collect detailed clinical information on homicides and suicides by individuals in contact with mental health services.

Shaw and colleagues, using data from this inquiry over a 5-year period from April 1999 to December 2003, identified 249 such cases of homicide from a total of 2670 homicides – that is, 9 per cent of all homicides. This equated to 52 patient homicides a year. There was no evidence of a rise in homicides, including stranger homicides, by mentally ill...
People. The typical perpetrator of stranger homicides in England and Wales is a young male who has been drinking alcohol or abusing drugs.61

People with schizophrenia were responsible for 30 patient homicides a year. Half were current or recent patients, but one-third had no previous contact with services.

People with personality disorder and a history of current or previous contact with psychiatric services were responsible for ten cases per year.

Rates of mental disorder in all perpetrators of homicide were as follows:

- Lifetime mental disorder: 30%
- Schizophrenia (lifetime): 5%
- Contact with mental health services: 18%
- Contact within past 12 months: 9%
- Mental illness at time of offence: 10%
- Convicted of manslaughter on grounds of diminished responsibility (Section 2 Homicide Act 1957): 4%
- Hospital order: 6%.

Fourteen per cent of homicides (7 per year) were considered ‘most preventable’ due to service failures, for example lack of adequate supervision or poor compliance.

The resulting recommendations included the following:

- Ensure high-risk patients receive enhanced care-planning, backed up by peer review: lack of this was considered the cause of 53 per cent of the most preventable homicides.
- Respond robustly when a care plan breaks down: lack of response was considered to have caused 18 per cent of the most preventable homicides. Twenty-five per cent of patient homicides were preceded by non-compliance.
- Develop services for dual-diagnosis patients: 36 per cent of homicide cases had dual diagnoses, i.e. mental disorder and substance abuse.

A review of homicides by patients with severe mental illness was also conducted by Maden, who looked at 25 cases from the National Confidential Inquiry into Homicides by psychiatric patients between 1995 and 2007.64 Maden emphasized the value of structured clinical assessment of violence risk, especially using the Historical Clinical Risk-20 (HCR-20).65 The HCR-20 includes 20 items of historical (H) factors (which reflect long-term risk), clinical (C) factors (which reflect current risk) and risk-management (R) factors. It thus covers both dynamic and actuarial risk factors. It can be used as an enquiry guide and a prompt rather than a numerical rating scale. The cases reviewed by Maden resembled forensic psychiatric service cases with high H item scores, but most were under general psychiatric services at the time.

Lack of patient compliance and compulsory treatment in the community were seen by Maden as the major issues. The Mental Health Act 2007 for England and Wales has now introduced increased powers to treat patients compulsorily in the community. Risk assessment alone however was deemed insufficient without adequate risk management.

A dual diagnosis with drug and alcohol misuse was present in 23 of 25 cases reviewed by Maden. Intoxication at the time of the homicide offence was very frequent. Abstinence was therefore recommended as a condition of discharge from hospital. The need for setting limits and early intervention was highlighted. Clinicians should be clear where to draw a line for intervention. Maden also made the point that diagnosis is only one factor in the assessment of the risk of violence. Drug-induced psychosis is just as dangerous as schizophrenia. The importance of involving carers was also emphasized, as they are most at risk.

However, risk management does not equate to risk elimination, and some violence, including homicides, by mentally disordered people is probably inevitable.

**Inquiries into homicides by psychiatric patients**

Such inquiries have been mandatory in England and Wales since 1994,66 following a critical and widely reported inquiry into the killing in 1992 of Jonathan Zito by Christopher Clunis, who had chronic schizophrenia.65 Such inquiries have emphasized failures in care due to poor communication between professionals and agencies, downgrading of previous violence, failure to recognize and manage social restlessness and escalating problems, lack of contact of subjects with consultant psychiatrists, rigid catchment area practice, lack of resources (e.g. acute beds, trained staff), failure to use the Mental Health Act appropriately to detain for reasons of health before violence occurs, and lack of carer involvement, although the latter may raise issues of patient confidentiality. Non-compliance with treatment in the community has perhaps been the most common major factor characterizing these cases. However, even Hippocrates noted that patients tend not to take their prescribed treatments. Also, there can be no real ‘supervision’ in the community in the sense of continual observation.

Overall, such inquiries have highlighted not the limitations of risk assessment, as real as these are, but failure to communicate or manage known risk. Improving community psychiatric care may thus be more useful in reducing the risk of violence than attempts at perfecting risk-assessment instruments. Certainly, the use of standardized structured risk-assessment instruments would not alone prevent most homicides by psychiatric patients.

**Government responses to inquiry findings**

The political pressure of ‘something must be done’ led to the following:

- Care-programme approach (CPA)68
- Supervision registers69
- Guidance on Discharge of Mentally Disordered People69
- Mental Health (Patients in the Community) Act 1995 (supervised discharge order)
Community treatment order under the Mental Health Act 2007.

The usefulness of the above measures remains open to question. The CPA is a process rather than a treatment; individuals may be unable or unwilling to comply, and their families may or may not wish to be involved. On the positive side, the CPA is a needs-led multidisciplinary approach to developing a care plan, which has to be monitored and should always include a risk assessment. Drawbacks to its implementation include lack of resources, large caseloads, increase in time required for meetings and documentation, and it leading to defensive practice.

These government responses also occurred against a background of a general decline in psychiatric hospital beds (from 152,000 in 1954 to 53,700 in 1993). Those psychiatric patients who have been violent in the community, however, tend not to be those who might previously have been on long-stay wards. However, if one closes 100 long-term hospital beds, there is an additional need for about 10 new acute beds in order to cope with resulting revolving-door admissions, and this can lead to a lack of acute beds for the emergency admission of violent patients. Increasing the number of hospital beds alone is not the whole solution, as there is also a need for other measures such as short-term crisis community facilities. Although inquiries emphasize the need for direct face-to-face contact between professionals and the patient, an average inner-city caseload for a social worker is 20 and for a consultant psychiatrist 450–500, with 300 new patients a year – and yet CPA arrangements are technically required for all patients and a legal duty of care applies to any patient to whom a professional talks. Funding has also not been related to epidemiology, for example in urban areas where there is an excess of schizophrenia due to social drift and where drug abuse and a younger population are also more evident, and there has otherwise been increased identification of cases, including via court and prison-diversion schemes. One response by clinicians has been to increase the rates of detention under the Mental Health Act 1983, which has been most pronounced for Section 3 and for mental illness. Although there has been no significant change in the number of Section 37 hospital orders, there has been an increase in Section 41 restriction orders. Another response has been the development of assertive outreach programmes.

Proactive measures to manage violence include adequate training of community mental health terms and the development of protocols for potential violent scenarios in hospital and in the community, for example for home visits. Risk assessment should also lead to the identification of warning signs indicating early signs of relapse or increased risk. The importance of communication between the GP, hospital and social services, housing, police and probation is paramount. Clearly, the better a patient is known, the more likely the accuracy of the risk assessment. If there is doubt about the safety of continued community care of an individual prone to violence, admission should be considered.

The Royal College of Psychiatrists has produced clinical practice guidelines for the management of imminent violence. This covers ward design and organization, the need for adequate space, comfort and privacy, the anticipation and prevention of violence, including by fostering open communication with patients, anticipating risk and avoiding confrontation in a crisis, training for staff to recognize warning signs of violence and to self-monitor verbal and non-verbal behaviour, and training in the appropriate use of medication. However, the guidelines acknowledge the lack of funding available for training, the shortage of qualified staff, and the levels of stress currently reported among those who work in the mental health field and deal with violence.

HABIT AND IMPULSE-CONTROL DISORDERS AND RELATED OFFENCES INCLUDING ARSON & SHOPLIFTING

Impulse-control disorders are disorders in which the person acts on an impulse that is potentially harmful and that he or she fails to resist. The impulses are usually perceived as pleasurable (egosyntonic). There is an increasing sense of wishing to commit the act, with a sense of pleasure occurring once the act has been committed. These disorders have also been conceptualized as non-substance-related addictions. They do not represent personality disorders. They are described in the fourth edition of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (text revision; DSM-IV-TR) as ‘impulse-control disorders’ and in the World Health Organization’s (WHO) ICD-10 as ‘habit and impulse disorders’.

In DSM-IV-TR, their essential features include the following:

- There is a failure to resist an impulse, drive or temptation to perform an act that is harmful to the person or to others.
- For most disorders, the individual feels an increasing sense of tension or arousal before committing the act and then experiences pleasure, gratification or relief at the time of committing the act.
- Following the act, there may or may not be regret, self-reproach or guilt.

Included are the conditions of pathological gambling, pyromania, kleptomania, trichotillomania and intermittent explosive disorder.

The ICD-10 has a similar definition for this group of disorders (Table 76.4), but it also includes intermittent explosive (behaviour) disorder. The ICD-10 points out that these disorders have no clear rational motivation.

Pathological gambling, pyromania and intermittent explosive (behaviour) disorder are more common in men,
while kleptomania and trichotillomania are more common in women. There is an absence of epidemiological studies of the prevalence of these disorders, but rates among psychiatric in-patients may be higher than in the general population. Using the Minnesota Impulsive Disorders Interview,\textsuperscript{72} Grant and colleagues found the following rates, mainly co-morbid with depression, among in-patients:\textsuperscript{73}

- **Kleptomania**: 8%
- **Pathological gambling**: 7%
- **Intermittent explosive (behaviour) disorder**: 6.4%
- **Trichotillomania**: 3.4%.

Overall, such impulse-control disorders are probably underdiagnosed.

Other disorders, such as pathological buying (oniomania or shopaholism), characterized by buying items that are not needed and often storing them unopened, and workaholism, have also been considered to be impulse-control disorders but are not classified as such in DSM-IV-TR or ICD-10. Such behaviours may be motivated by a need for compensation or as a substitute for something missing in life or as a depressive equivalent.

Impulse-control disorders may lead to offending either directly, for instance in pyromania, or indirectly, for instance for financial gain in a pathological gambler. Individuals who commit crimes due to such a disorder have, however, usually been deemed legally culpable for their actions, even though their propensity is psychiatrically considered to be irresistible. It has been argued, however, that this may be a legal injustice, as such individuals clinically apparently have little or no control over their actions.

The interface between impulse-control disorders and offending raises philosophical questions, including questions about the nature of free will and whether all behaviours are determined by the effects of genes, environment and background. Are people with impulse-control disorders less responsible for their behaviour, and should they therefore be punished less than people of normal responsibility? Even if impulse-control disorders have a biological basis, in clinical practice the aim is, however, to encourage the patient to take responsibility for his or her actions.

**History**

During the eighteenth century, the concept of ‘monomania with propensity’ developed, referring to the fact that apparently insane, incomprehensible actions did not always appear to be the result of delusional thinking. This and subsequent historical developments have been discussed by Gibbens and Prins, who cite the following historical landmarks:\textsuperscript{74}

- Philippe Pinel (1745–1826), in the eighteenth century, referred to ‘mania without delirium’ as being a disease of the willpower.
- Esquirol referred in 1885 to instinctive monomanias, including homicide, fire-setting and alcoholism – that is, respectively, homicidal monomania, pyromania and dipsomania, where the individual acts ‘without passion or motive but only under involuntary instinctive impulse’.
- Referring to some cases of theft and homicide, Rush in 1810 described them as an illness of the moral willpower and equated this illness with the involuntary movements of convulsions.
- Mathey coined the term ‘kleptomania’ (theft) to add to the list of other manias, including dipsomania and pyromania.

<td>Pathological stealing (kleptomania)</td>
<td>Repeated failure to resist impulses to steal objects that are not required for personal use or monetary gain</td>
</tr>
<tr>
<td>Trichotillomania</td>
<td>Noticeable sense of tension before and a sense of gratification during and immediately after the act</td>
</tr>
<tr>
<td>Intermittent explosive (behaviour) disorder</td>
<td>Hair-pulling usually preceded by mounting tension and followed by sense of relief or gratification (responds to behaviour therapy and SSRI antidepressants)</td>
</tr>
</tbody>
</table>

As noted by Topp, it was a Frenchman, Marc, in 1833 who first used the term ‘kleptomania’ when describing a number of wealthy individuals who carried out bizarre, worthless thefts in which they had little intrinsic interest and to which they confessed spontaneously when challenged.

Subsequently, it has been considered that instinctive monomanias such as kleptomania are very rare and, indeed, it has been questioned whether they, in fact, exist. Terms such as ‘pyromania’ and ‘kleptomania’ have indeed tended to be increasingly discarded. Neustatter doubted whether kleptomania existed as an entity, but, if it did, he suggested that it was part of a psychopathic personality that gives way to impulses.

**Differentiation from obsessive–compulsive disorder**

An important differentiation in this area is between compulsions and impulses. Compulsions, as seen in obsessive–compulsive disorder, are characterized by non-situational preoccupation with subjective compulsion, despite conscious resistance, such preoccupations being thoughts (ruminations or obsessions) or acts (rituals or compulsions). Where there is poor impulse control, impulses are poorly resisted, and this is much more common than compulsions. In the case of obsessive–compulsive disorder, patients in general do not act on their ruminations, unlike people with poor impulse control. The key difference between impulse-control disorders and obsessive–compulsive disorder is that although both may lead to relief of anxiety and tension, in obsessive–compulsive disorder the thought of carrying out the act must not in itself be pleasurable – that is, the thought must be egodystonic.

**Pathological gambling**

This is defined in ICD–10 as persistently repeated gambling that continues and often increases despite social consequences. Gambling involves risking something of value, not necessarily money, in a game or other uncertain event, with the aim of achieving greater value. There is a range of gambling behaviours, from the culturally normal to hazardous, professional, problematic and pathological gambling. In contrast to professional gamblers, who may carefully plan their gambling and base it on information in order to increase the risk, pathological gamblers will myopically gamble despite repeated and heavy losses, resulting in adverse family and social consequences and financial ruin, to which they appear hyposensitive. Four phases may be distinguished: winning, losing, desperation and eventual giving up. Problems do not arise from the gambling itself but from the consequences, as seen in alcoholism. Indeed, pathological gambling shows features characteristic of an addiction, with loss of control, extremes of emotions reflecting autonomic nervous system changes, and withdrawal phenomena when not gambling.

DSM-IV-TR defines the essential feature of pathological gambling as a chronic and progressive failure to resist impulses to gamble, with behaviour leading to much damage to personal and family life. Evidence suggests this to be a valid and reliable diagnosis. Efforts to control, resist or stop gambling generally fail, and the behaviour has been equated to an addiction, with withdrawal symptoms of irritability and restlessness if the person is unable to gamble, and an escalation in the size and frequency of bets or other stakes in order to achieve a desired level of excitement. Such individuals tend to respond to repeated losses by gambling further to ‘chase’ their losses, in spite of increasing debts, marital breakdown and law involvement. They anticipate losses, as shown in functional magnetic resonance imaging (fMRI) studies (reduced activity in the ventromedial prefrontal cortex), even while their appetite for gambling and their impulsivity increase, and they will continue gambling until they have lost their available resources. Psychodynamically, they appear unconsciously to aim to lose their money. They tend to focus on their winnings, disavow or deny their losses, lack the courage to own up to losses, and gamble more to break even. This is a pattern also seen in stock-market ‘rogue traders’.

Pathological gambling may also lead to disturbances in eating, sleeping and sexual relationships, and to difficulties in sustaining employment. Lying to and relying financially on friends is also characteristic. Some gamblers steal in order to finance their habit, and pathological gambling may come to light only following a court case regarding an acquisitive offence such as theft, fraud or embezzlement. Some individuals present following an overdose or self-harm, which occurs in 10 per cent of pathological gamblers, or with depression. Suicide occurs in 2 per cent of attenders at Gamblers Anonymous (Gam-Anon). Legg-England and Gotestam have reviewed pathological gambling in detail.

**Epidemiology**

Gambling itself is common, with estimates of prevalence around 40 per cent of the British population and 60 per cent of the US population. Even these figures may now be underestimates, given the current availability of national television and other lotteries. Wardle and colleagues found the prevalence of gambling in the UK to be 68 per cent, but 48 per cent when the UK national lottery was excluded. Gambling is said to be more common among Chinese people and less common among Scandinavian people. It is more common in men, people with a past history of psychiatric disorder and criminals. Problem gamblers cause themselves or others to suffer. It is possible to lose control and bankrupt oneself through gambling in just one day. Pathological gambling is associated with tolerance and withdrawal phenomena and has been found to have a prevalence of 0.25 per cent in Australia and 0.77 per cent in the USA. Shaffer and Korn reviewed 120 studies and suggested a lifetime rate of 1.6 per cent, a figure not dissimilar
to that for schizophrenia. Wardle and colleagues in the UK estimated that 0.5–0.6 per cent of the population were problem gamblers. The Royal College of Psychiatrists in the UK in 1977 described around 10 per cent of prisoners as pathological gamblers.

Pathological gambling is certainly more obvious but probably also more common among people, especially men, who indulge in horse- and dog-racing, in which losses soon become apparent. Female pathological gamblers, on the other hand, have been reported to be more likely to make use of specialized helplines. In the UK, it is said that women prefer bingo, which may lead to less pathological gambling and in which losses tend to be smaller.

Aetiology
The predominant motivation for pathological gambling is the sense of thrill and pleasure at the risk-taking, as reflected in changes of heart rate demonstrated during gambling. Winning produces euphoria, said to be comparable to the effects of amphetamines, and helps individuals to switch from negative internal mood states, including despondency and loneliness. Dostoyevsky, in his autobiographical novel The Gambler, described the reward of a sense of power obtained from gambling. Freud, commenting on this, considered that Dostoyevsky did his best writing after a big loss from gambling as he was then freed from unconscious guilt feelings concerning patricidal urges that inhibited his creativity. Gambling has also been described as serving to gratify oedipal wishes, for example wishing to defeat a tyrannical father or to woo a mother. Moran cited social pressures, early exposure to gambling, and a father who gambled or drank alcohol as aetiological factors among male gamblers, while having an alcoholic spouse who was often absent was characteristic more of women who gamble. Gambling increases with the number of gamblers in one’s social network, being initially a social activity, but when pathological it is usually undertaken alone.

Learning theory has suggested that the pattern of intermittent (variable ratio) reinforcement, the most potent schedule for conditioning, particularly applies to gambling, where repeated losses with frequent near-misses are combined with occasional random wins with immediate pay-outs. The prospect of small but immediate rewards is preferred to higher but delayed rewards. Evidence of psychological dependence may become manifest by the appearance of what can be considered withdrawal symptoms and craving following the stopping of such activity.

Biological factors may also be important. The orbitofrontal cortex and anterior cingulate gyrus are involved in reward mechanisms. Potenza and colleagues undertook an fMRI study of pathological gamblers, which showed, compared with controls, decreased activation of the orbitofrontal cortex, basal ganglia and thalamus, which have been linked to impulsivity and disinhibition.

Pathological gambling has been suggested to be associated with low central serotonin levels, as seen in other impuls-control disorders, and low central dopamine activity, as seen in other addiction disorders. Serotonin is involved in mood and impulse control, and dopamine in reward, pleasure and motivation. Of note is the increasingly recognized phenomenon of individuals with Parkinson’s disease, who have low levels of the neurotransmitter dopamine, presenting for treatment of gambling after having been treated with pro-dopaminergic agents such as L-dopa. Noradrenaline (norepinephrine), which is involved in arousal and excitement, and opioids, involved in urges and pleasure, may also be important.

Co-morbidity
Although pathological gambling often arises in the absence of other psychiatric disorders, personality disorder, especially antisocial, narcissistic and borderline types, and depression may also be present. The presence of personality disorder will, however, explain only part of the excess of impulsivity. Hypomanic or manic episodes of bipolar disorder, which may be associated with general overspending and grandiose beliefs about one’s wealth and ability to make money, including the ability to counter losses, may also lead to excessive gambling. Problem gambling is associated with attention deficit hyperactivity disorder (ADHD), delinquency and recidivist offenders, and is especially high among young offenders.

Risk factors
These include being male, being over 45 years of age, cigarette-smoking, alcohol abuse, low income, having debts, being a foreign national, having a depressive disorder, flat affect, having the metabolic syndrome, and sleep difficulties in females. A history of previous treatment for gambling is an important risk factor.

Assessment
This should include eliciting when gambling started and when it became regular, who introduced the individual to gambling or encouraged the individual to gamble, the circle of gambling friends, and the history of escalation in patterns of gambling. Is gambling increased when the individual is despondent or after alcohol consumption?

The onset and presence of symptoms of pathological gambling should be noted, for example inability to stop despite debts, withdrawal symptoms such as restlessness and irritability when not gambling, chasing losses, and raising stakes for the thrill.

The motivation to change should also be assessed. Stages of change include the following:

1. Precontemplation, when the need to change is recognized.
2. Contemplation, when the problem is acknowledged and the individual is willing to change.
3. Action taken to change.
4. Maintenance to sustain control of or abstinence from gambling.
Screening instruments such as the South Oaks Gambling Screen (SOGS)\(^9\) can be useful, especially in screening populations at risk (a score of 3–5 out of 10 indicates problem gambling, while a score over 5 indicates pathological gambling). The SOGS may produce excessive false-positives compared with the National Opinion Research Center DSM Screen for Gambling Problems (NODS)\(^9\), which was developed as a population-based telephone screening tool to identify gambling problems according to DSM-IV criteria.\(^9\) Stinchfield found that the SOGS demonstrated good to excellent classification accuracy in his large gambling treatment sample, but it had poorer accuracy in the general population sample, with a 50 per cent false-positive rate; the SOGS overestimated the number of pathological gamblers in the general population compared with DSM-IV diagnostic criteria.\(^9\)

A further tool is the Canadian Problem Gambling Severity Index,\(^9\) which contains 9 items of the 30-item Canadian Problem Gambling Inventory (CPGI).

**Management**

Health promotion to populations at risk as identified by screening to counter excessive gambling before problems develop is ideal. However, pathological gambling may not always follow a chronic and persistent course. Slutske reported that among individuals with a lifetime history of pathological gambling, 36–39 per cent did not experience any gambling-related problems in the past year, even though only 7–12 per cent had ever sought either formal treatment or attended meetings of Gamblers Anonymous.\(^9\)

About one-third of the individuals with pathological gambling disorder in her study of two nationally representative US samples were characterized by natural recovery.

Co-morbid psychiatric disorders should be excluded or treated, for example depression. As with other addictive behaviours, selective serotonin reuptake inhibitor (SSRI) antidepressants at high doses have been recommended,\(^9\) as has the opioid antagonist naltrexone. The selective noradrenergic reuptake inhibitor (SNRI) venlafaxine, the 5-HT\(^1A\) partial agonist buspirone, the stimulant cognitive enhancer modafinil, and the psychostimulant methylphenidate have all been used.

Cognitive-behavioural therapy (CBT), which concentrates on reducing the preoccupation with gambling and can involve motivational interviewing and risk- and harm-reduction strategies, has been used successfully and has also been combined with a 12-step group programme.\(^9\)

There is no real evidence for the efficacy of psychodynamic psychotherapy or aversive behavioural therapy in this disorder. Dickerson described 22 uncontrolled studies offering a variety of management approaches, including most forms of psychotherapy.\(^9\) Support and counselling for the family, which can include brief focal marital counselling, may also be required.

Help is often sought only as a result of the consequences of gambling, such as debt, deteriorating marital and other relationships, and law involvement, rather than as a result of a primary desire to stop gambling itself. Most gamblers cannot contemplate complete abstinence, although some may consider as a reasonable goal stopping gambling for a number of months, with a view to continuing controlled gambling thereafter.

One approach is for the family income to be paid into an account over which only the gambler’s partner has control.\(^9\) Gamblers Anonymous adopts the approach used by Alcoholics Anonymous and may be more helpful than standard traditional psychiatric approaches. For relatives, Gamblers Anon is available for mutual support, akin to Al–Anon for relatives of people with alcoholism. Local citizens’ advice bureaux and money advisory services may assist with resulting financial difficulties.

Few pathological gamblers will consider a goal of total abstinence. In spite of management approaches, the prognosis is generally considered poor, although 10 per cent stop spontaneously and progression and chronicity are not inevitable. Relapse rates after treatment vary from two-thirds to 70 per cent. Duration of the disorder and neurocognitive measures of disinhibition and decision-making are powerful predictors of relapse in pathological gambling.\(^9\)

As the ease of availability of gambling increases, so does the risk of developing pathological gambling. For example, legislation controlling casinos and countering society’s hedonistic attitudes to, for instance, national lotteries and so on may be important in prevention, although a study by Bondolfi and colleagues in Switzerland showed no increase in pathological gambling following an increase in the opening of casinos.\(^9\)

**Pathological fire-setting (pyromania)**

ICD-10 defines pathological fire-setting as repeated fire-setting without any obvious motive. There is an intense interest in watching fires burn and feelings of increasing tension before the act and intense excitement immediately after it.

In DSM-IV-TR, it is referred to as pyromania and also classified as an impulse disorder. There is deliberate and purposeful fire-setting on more than one occasion. Tension or affective arousal is present before the act. There is intense pleasure, gratification or relief when setting fires or when witnessing or participating in their aftermath. Such individuals, also referred to as ‘firebugs’, are fascinated with, curious about and attracted to fire.

This group of fire-setters includes those who are described as having an irresistible impulse and a repeated urge to set fires, which they do not fully understand and about which they are often inarticulate. They are often isolated and inadequate people who set a number of fires impulsively and who may escalate the seriousness of their fire-setting. This group also overlaps with people who set fires for tension or depression reduction – that is, as an anxiolytic or antidepressive act. Such individuals discover
that fire-setting relieves feelings of despondency or tension. An analogy can be made with the calming effect that normal individuals report when observing and sitting in front of a glowing open fire.

In the past, fire-setting by men was considered to be frequently associated with direct sexual arousal by such an act – that is, the use of fire as a fetish – and there was considerable psychodynamic interest in the symbolism of fire, for example flames of passion, burning desire, blazing rows and so on. Freud described the glow of fires as reflecting sexual excitement and the motion of flames as symbolic of the phallus in action. However, although a number of fire-setters may indeed obtain a sense of excitement from their actions, those who are specifically sexually aroused and who may even masturbate after setting fires are rare.

Pathological fire-setters are a subset of those who tend to set more fires and to whom the fire is a thing of interest in itself. Individuals have a fascination with fire and hence the arson appears outwardly motiveless. There may also be an associated fascination with fire engines and calling out the fire service. The making of false telephone calls to the emergency services can result in a charge of ‘wasting electricity’ in the UK.

Other clinical features include evidence of advanced preparation and indifference to the consequences of fire-setting to property or life.

It is rare in children but more common in male adolescents, particularly those with poor social skills and learning difficulties.

The offence of arson

Arson is the offence associated with fire-setting and is the unlawful and malicious (wilful) destruction of or damage to property by setting a fire. Legally, the more serious charge is arson with intent to endanger life or being reckless as to whether life was endangered. Owing to problems of detection, only 5 per cent of cases of arson end in successful prosecution in the UK. In the UK, one in eight schools is subject to arson each year.

If an individual is charged with arson, it is important to reconstruct in detail what happened at the time of the offence, for example reading witness statements related to the case and not simply depending on the actual legal offence category. For instance, arson may be the setting fire to a wastepaper bin in a busy hospital ward in front of observing staff and fellow patients, or an impulsive or planned serious fire, in circumstances unlikely to be detected, with intent to kill. Of psychodynamic note is the fact that fire almost uniquely can make things disappear, including evidence. Historically, one reason individuals were burned at the stake was to avoid the spilling of blood.

Epidemiology

Approximately 40 per cent of all serious fires in the UK are started deliberately. Six per cent of fires in the UK are recorded as arson. Arson is responsible for 1 per cent of all serious crimes in the UK. However, as the evidence is often burned, only about a quarter of arson offences result in conviction. The peak age for arson is 17 years for men and 45 years for women. Eighty per cent of people convicted of arson are men. There is increased incidence of arson among people with learning disabilities and people with alcohol dependence syndrome. Fifty per cent of cases of arson follow alcohol abuse, especially binge drinking of alcohol.

Clinical classification

Numerous attempts have been made to classify arson clinically, for example by Puri and colleagues. There is no typical arsonist. Psychiatric difficulties are common, but the most common diagnoses are personality disorder and substance abuse, in up to two-thirds of cases, with about 8 per cent of arsonists having a psychosis. Pure pyromania appears rare (1%) among convicted arsonists.

A classification based on these studies is as follows:

Fire as a means to an end (motivated)

Individuals who set few fires include the following:

- **Psychosis, such as schizophrenia:** such individuals may set fires to, for instance, burn out the devil or evil, or in response to hallucinatory voices.
- **Displaced revenge, anger or jealousy:** rather than overt direct aggression against an individual, aggression may be displaced into setting fire to that individual’s property. For instance, an employee who is told off by the boss, may, rather than retaliate directly, physically or aggressively, return after business hours to set fire to the boss’s property. This is the most common reason (in almost 50% of cases) found by psychiatrists among arsonists referred to them.
- **Cover-up of other crimes, e.g. homicide:** modern forensic science, however, usually overrides such attempts at a cover-up.
- **For insurance:** this has become increasingly common in recent years, e.g. setting a chip-pan fire to finance the redecoration of a kitchen.
- **Political motivation:** e.g. to further their rise to power, Nazi storm troopers set fire to the Reichstag in 1932 in Berlin.
- **Adolescent gangs:** individuals are generally more likely to be disinhibited and behave antisocially in a group than when alone. This group is associated with a low rate of recidivism, except among gang leaders.

Individuals who set more fires include the following:

- **Desire to be powerful or a hero:** members of this group often have an inadequate personality. Their low self-esteem is bolstered by the sense of power they feel at the results of their having set fires, e.g. the panic and the emergency services with flashing lights rushing to the scene. Sometimes this is combined with a desire to be a hero, so that after setting a fire the individual may rush
into the premises and rescue pets or elderly or infirm people. On occasions, they are caught owing to being seen repeatedly or even photographed, for instance in a local newspaper, at the scenes of the fires.

- To earn money: this occurs when part-time firemen on call-out rates set a fire. It is a particular problem in rural areas and in some countries such as France. Some individuals may be drawn to the fire service because of their fascination with fire, and psychodynamic associations have been made regarding the phallic symbolism of hoses. Anthropologists and evolutionists have suggested that females may have been impressed by the ability of males to put fires out by urinating.

- As a cry for help: to bring attention to a distressed emotional state.

Fire as a thing of interest
This includes pathological fire-setting (pyromania).

Differential diagnosis of pyromania
This includes conduct, adjustment, affective and psychotic disorders.

Co-morbidity of pyromania
This may include substance misuse, past history of sexual or physical abuse, and personality disorder, especially antisocial personality disorder. High rates of previous sexual abuse in women who set fires have been described frequently in clinical practice.

Assessment of arsonists
Assessment depends not only on a careful, detailed history and mental state examination but also on the gathering and study of objective information such as witness statements related to the case. It is important to determine the presence or absence of psychiatric abnormality, especially at the time of the offence, and its relationship with the offence itself. It is important to determine whether there is a history of previous fire-setting and to examine precipitants.

It should be noted that suicide by fire is particularly associated with schizophrenia, perhaps explaining the choice of this most painful means of suicide. Historically, it has been described in the early nineteenth century among Hindu widows in India (suttee) and among monks protesting in Vietnam during the twentieth-century Vietnam War.

Management
This should clearly address any underlying or co-morbid psychiatric disorders. For example, psychological intervention with CBT may be helpful, particularly in cases of pyromania.

The potential dangers of fire-raising must always be borne in mind. The view of the fire service is that a large fire is merely a small fire not brought under control.

In cases where an individual is charged with arson, the courts will be particularly concerned with the protection of the public. The courts are likely to be unwilling in serious cases of arson to consider out-patient care or placement in an open psychiatric ward. Ordinary psychiatric hospitals are also inevitably reluctant to admit patients who have set fires, so if hospital treatment is required it is frequently undertaken under conditions of medium or maximum security. In the absence of a psychiatric disposal, the courts usually impose a custodial sentence. In England and Wales, under the Criminal Damage Act 1971, a maximum sentence of life imprisonment can be imposed for arson (Section 1) or arson endangering life (Section 2).

Prognosis
Further offences of arson are increasingly likely if there has been a history of previous arson and if the offender continues to have an irresistible impulse to set fires or to relieve tension or obtain pleasure or sexual excitement from such fire-setting. Increased risk of further fire-setting is seen in individuals with psychosis, learning disability or dementia. However, in an individual case, it may be difficult to tell whether that individual will re-offend. The risk of further serious offending after a period in prison or hospital is low; however, the risk of re-offending may not be apparent in the short term but only on longer follow-up. For example, Soothill and Pope found a 4 per cent recidivism rate over a 20-year period, and Sapsford and colleagues reported a recidivism rate over time of 2–20 per cent.

Pathological stealing (kleptomania)
In ICD-10, pathological stealing is defined as repeated failure to resist impulses to steal objects that are not required for personal use or monetary gain. Objects may be discarded, given away or hoarded. The person may even later offer to pay for items stolen. An increasing sense of tension before and a sense of gratification during and immediately after the act are seen.

Epidemiology
Kleptomania is usually seen in women of a mean age of 36 years, with a mean duration of illness of 16 years (often after an onset in childhood). The term ‘kleptomania’ comes from the Greek for ‘stealing madness’. The disorder is generally said to be rare, with fewer than 5 per cent of arrested shoplifters giving a history consistent with kleptomania. However, such individuals rarely seek psychiatric help and often avoid detection, so that estimates of the prevalence of kleptomania have been variable – even up to a quarter of all shoplifters. Up to a quarter of people with bulimia nervosa are said also to meet the diagnostic criteria for kleptomania. Kleptomania is certainly more prevalent in females than males, unlike other impulse-control disorders such as intermittent explosive disorder and pyromania, where males predominate. Onset is around 20 years of age, but diagnosis is usually made one or two decades later. The individuals concerned are...
typically married. Males may be underrepresented because they are more likely to receive custodial sentences precluding re-offending in the community during periods of imprisonment.

Clinical features
Stealing is perpetrated without much planning and without the assistance of others. The objects taken are not needed for personal use or for their monetary value and may be given away, discarded or returned surreptitiously, or kept and hidden. The individual invariably has enough money to pay for the stolen objects, but the theft is not committed to express anger or vengeance. Typically, when diagnosed, such individuals have appeared in court several times, feel guilt or remorse, but have not sought psychiatric treatment. There is often a history of a number of years of chronic dysphoric mood, and of the display of signs of depression and anxiety. Individuals’ relationships and marriages are often unhappy. There is frequently a history of sexual difficulties and dysfunction and a past history of a turbulent childhood. Individuals often show poor impulse control generally and evidence of personality disorder, but the stealing is not primarily the result of conduct disorder or antisocial personality disorder. They share similarities, therefore, with people who have a past history of childhood sexual abuse.

Differential diagnosis
In ordinary shoplifting, the act is usually well planned, although it may be impulsive, but it is motivated by need or monetary gain and the objects taken are for the individual’s use or to be used for financial gain. Some individuals who shoplift may attempt upon arrest to simulate kleptomania; they are then referred to as ‘malingering’.

Shoplifting may also occur in conduct disorder, antisocial personality disorder, depression, hypomanic or manic episodes, schizophrenia and organic mental disorders, but in such circumstances the act is related to the primary diagnosis.

Co-morbidity
This includes eating disorders and substance-abuse disorders. Kleptomania may be precipitated by major stressors such as life events. Depression is common, and bipolar disorder may not be infrequent.108

Aetiology
There is no definite evidence of a specific genetic or inherited predisposition, although a biological basis has been suspected; for example, Grant and colleagues found decreased white-matter integrity in the inferior frontal brain regions in women with kleptomania.109

Kleptomania has been viewed as a variant of depressive disorder. People with kleptomania often have depressive symptoms, and the theiving itself may produce a stimulating excitement that has an antidepressive effect. Kleptomania has also been viewed as a variant of obsessive–compulsive disorder, but only about half of people with kleptomania experience with stealing the relief of tension characteristic of that disorder, and in obsessive–compulsive disorder there is not typically the sense of gratification seen in kleptomania.

Psychodynamic theories
Psychodynamic theories of kleptomania have included the following (Figure 76.5):

- **Loss substitution**, in which kleptomania provides symbolic compensation for threatened or actual loss110

![Figure 76.5 Psychodynamic theories of kleptomania](image-url)
• Drive theory, which considers kleptomania in terms of a forbidden activity, engaged in secret and thus having a sexual basis
• Perversion, in which stolen objects represent fetishes as described by Fenichel
• Defensive strategy used by females, e.g., to acquire a symbolic penis to counter castration fears
• Self-psychological theory, in which kleptomania is seen as a response to narcissistic injuries and a means to counter fragmentation of self.

Management
In keeping with the view that kleptomania may be an equivalent of depressive or obsessive–compulsive disorder, kleptomaniac individuals often respond well to antidepressant medication, especially SSRIs such as fluoxetine. CBT has also been found to be effective. Psychotherapeutic approaches, including family therapy, have also been reported. A self-imposed ban on shopping may, however, be required where treatment fails.

Prognosis
The condition tends to be chronic but waxes and wanes.

The offence of shoplifting
The technical offence is theft from shops, an offence that, as with all offences of theft, requires the intent permanently to deprive, as well as the act, in order for the offence to be proved in court. Intent would clearly be indicated if an individual were seen to be hiding an object in their coat and to be looking around to make sure they were not being observed. In absent-minded shoplifting, there would, in theory, be no intention to deprive.

Epidemiology
In the UK, about 5 per cent of all shoppers shoplift. However, up to 50 per cent of goods taken from shops may be taken by the staff of those shops, as is the case with many thefts from businesses. Sociologists have viewed shoplifting as a social disorder created by a consumer society and precipitated by the visual provocation of shop displays. Open shelves increase sales and reduce the requirement for staff, as in supermarkets, but they are associated with increased shoplifting, with such businesses having to take this into account in their business planning. Some items are left near the checkout to encourage impulse buying but, in addition, provide easy but inexpensive objects to be shoplifted. Objects are often taken suddenly on impulse and are of trivial value or useless. Some individuals appear to regard shoplifting as an accepted perk of shopping and may pay for other items.

Until the early 1970s, most shoplifters in the UK were women, who then undertook more of the shopping than now, and 15 per cent showed evidence of psychiatric disorder. Ninety per cent did not re-offend after conviction. However, the majority of shoplifters in the UK are now male and aged 10–18 years, as reflected in signs on shops limiting the number of children allowed in at one time. Males are now more likely than females to have previous convictions. The incidence of psychiatric disorder has been reduced to about 5 per cent, and it is questionable now whether shoplifting deserves more psychiatric attention than other thefts (90% of all offences are acquisitive). The previous predominance of female offenders coincided with the view that female offenders in general tended to be psychiatrically disordered, which may explain the tendency of courts to request psychiatric reports more often in shoplifting offences than in other, male-dominated offences.

Classification
Shoplifters have been subject to lay and legal stereotyping as needy, greedy or seedy. Bluglass distinguished three groups of shoplifters: professional, amateur and associated with psychiatric disorder. Building on Bluglass’s work, a more detailed classification is as follows:

Shoplifting for simple gain, plus excitement with or without associated marked antisocial attitudes
The principal motivation is excitement. Such individuals are responsible for a significant proportion of shoplifting in large cities. Individuals often feel less constrained by another country’s laws when abroad. This category also includes organized gangs and people with chaotic lives who steal impulsively and commit other offences. They may come from antisocial families and be subject to relative poverty. Such shoplifting may be associated with resentment and feelings of bitterness associated with other individuals’ lifestyle.

Shoplifting associated with psychiatric disturbance
The most common association in this group has historically been with depression in people of previous law-abiding personality. A study in Montreal found that 1 per cent of 1649 shoplifters had depression or bipolar disorder. People in this group may include isolated younger women with children, but also include middle-aged women isolated from their families, who have lost children, who have experienced the loss of a husband (including loss owing to his career) and who may have significant physical complaints or ill-health or be chronically depressed. Shoplifting may be an early symptom of depression. The depression may also be associated with acute losses. Law involvement, including court appearances and associated publicity, can precipitate self-harm or suicide, especially when offenders are depressed.

In cases of shoplifting and depression, the motivation may arise from feelings of guilt or a desire to be caught and punished, may be a cry for help, or may represent an act of self-comfort or a treat. Other dynamics include secondary gain in newly poor people to ‘keep up appearances’ and stealing something for oneself that is not purchased with money from parents or a partner. In married female offenders, there may particularly be sexual difficulties or rejection and marital problems. Shoplifting may be an act of revenge
on a partner to induce shame or punishment. For instance, it may result in the female having to be accompanied by her male partner when shopping in future or alternatively in the male partner having to undertake the shopping from which the woman can then opt out. For such individuals, a prison sentence may at one level be a relief from their marital or family situation.

Other psychiatric disorders associated with shoplifting include anorexia and bulimia nervosa, which may reflect both hunger for food and impulsivity, and early dementia, which is associated with disinhibited behaviour, lower resistance to temptation, poor judgement and late-onset offending. Shoplifting may also occur on occasion in association with other psychotic mental illnesses, alcoholism and learning disability.

**Absent-minded shoplifting**

This implies no intent permanently to deprive and, if successfully argued in court, a not guilty verdict will result. Such shoplifting may result from undue preoccupation, distractions or harassment, for example caused by the shopper’s own accompanying children. Other causes cited include claustrophobia in shops and various medical or psychiatric drugs that impair concentration or cause confusion. It is the prescribing doctor’s responsibility to warn of such side effects from medication. Although a defence based on medication side effects, including the effects of benzodiazepines, is not infrequently put forward in court by shoplifters, in reality it is rarely a primary cause.

**Shoplifting in children**

This peaks around age 14–15 years, with boys being predominant. Boys steal sweets and books, while girls tend to steal cosmetics and clothes. The items stolen are usually of little value. The most common group is ‘normal’ children stealing for excitement. However, child shoplifting may also occur due to subcultural standards or as an expression of emotional disturbance, for example as an act of defiance against parents, as a cry for help, or in association with feelings of depression, worthlessness and guilt.

**Assessment**

An examination of the history and mental state of the individual should elucidate the motives and detect any evidence of formal psychiatric disorder. The motive may often initially appear obscure, with useless objects or objects of trivial value taken suddenly on impulse, sometimes as a treat or arising from concealed resentment. Alcohol or drug abuse is often associated with shoplifting. Additional information should be obtained if possible, for example from the arresting police officer. It is often useful to discuss the case with the probation officer if one has been requested by the court to prepare a social enquiry report, which should also be read. It is essential to establish whether there is a history of previous convictions for shoplifting and any past psychiatric history and its relationship to offending.

**Management**

If it is argued on psychiatric grounds that there was no intent to shoplift and the patient pleads this successfully, then a finding of not guilty will result. However, individuals are often deterred from such a defence, for example a defence involving absent-minded shoplifting, as it will often require a number of court appearances and considerable legal expense to plead this successfully, and it may well involve local publicity.

Where the court accepts that intent permanently to deprive was present, the individual is legally convicted of theft. If the individual does have a psychiatric disorder, including kleptomania, requiring treatment, then psychiatric evidence may be used in mitigation with a view to altering the sentence; for example, a psychiatric recommendation of out-patient psychiatric treatment may be made as part of a community rehabilitation (the old probation) order.

**Trichotillomania**

This is a habit and impulse disorder characterized by noticeable hair loss resulting from recurrent failure to resist impulses to pull out the hair. Hair-pulling is usually preceded by mounting tension and followed by a sense of relief or gratification. It is not itself directly associated with criminality, although it can be associated with personality disorder, which in turn may be associated with offending. It has been well reviewed by Walsh and McDougall.\(^\text{115}\)

**Intermittent explosive (behaviour) disorder or episodic dyscontrol syndrome**

Intermittent explosive (behaviour) disorder is included in ICD-10 under habit and impulse disorders, while intermittent explosive disorder is included in DSM-IV-TR under impulse-control disorders, and is characterized by episodes of sudden unprovoked violence. Onset is in adolescence, and males outnumber females in a ratio of four to one. It was originally conceptualized as a form of limbic epilepsy, but this has not been borne out. The syndrome may, however, be associated with soft neurological signs and temporal lobe electroencephalogram (EEG) abnormalities, and it may be helped by anticonvulsants such as carbamazepine and sodium valproate. These are also mood stabilizers, and lithium and SSRI antidepressants may also help, suggesting a link to mood (affective) disorder. This disorder, in fact, usually occurs in people with a severe, often explosive personality disorder with a propensity under stress to intemperate outbursts of anger and impulsive violence when frustrated, which equates to the emotionally unstable impulsive-type personality disorder of ICD-10 and falls within the antisocial personality disorder of DSM-IV-TR. It is of note that half of persistently aggressive offenders in general are said to have an abnormal EEG record, often an immature record (persistence of excess posterior slow-wave
activity), characteristic of people with psychopathic disorder and not diagnostic of epilepsy.

**Conclusions**

Impulse-control disorders are a disparate group of conditions with different characteristics and epidemiologies. Whether the urges and impulses and resulting criminality are irresistible is open to question. Perhaps no impulse is irresistible, if an individual is motivated to try hard enough to resist. Certainly in practice, impulse-control disorders appear to be controllable at times but uncontrollable at others, when momentary excitement leading an individual to act on the impulse appears to overwhelm control. A disordered function of control may better describe the situation than an irresistible impulse. Indeed, the impulse to act is often combined with a desire not to act.

The conditions included in habit and impulse-control disorders do not reveal an identical psychopathology. Pathological gambling is a more complex condition, requiring attention to the whole person, than an impulse-control disorder such as trichotillomania. A pathological gambler shows features akin to substance addiction, with characteristic histories of escalation from use, abuse, and then addiction with tolerance and withdrawal symptoms, with gambling becoming the centre of the person’s life, unlike the situation in pyromania or trichotillomania.

Impulse-control disorders are at least as prevalent as schizophrenia, but the research interest in such disorders and the evidence base for treatments are limited. Current treatments demonstrated to be effective include CBT and SSRIs. Other treatments for impulsivity with a weaker evidence base include SNRIs, anticonvulsants, stimulants such as methylphenidate, and the cognitive enhancer modafinil. Other approaches being considered and researched include biofeedback, repetitive transcranial magnetic stimulation, deep-brain stimulation and stereotactic neurosurgery.

**NON-ACCIDENTAL INJURY OF CHILDREN**

The term ‘non-accidental injury of children’ has replaced the term ‘baby battering’, coined by Kempe and Kempe in 1961 as an emotive term to highlight the problem.\footnote{The term ‘baby battering’ has been replaced by ‘non-accidental injury’ as an emotive term to highlight the problem.}

Characteristic features of different members of the families in which non-accidental injury of children occurs are as follows:

- **Children:**
  - Usually under 3 years of age
  - Failure to thrive
  - Persistent crying
  - Multiple injuries in time and space
  - Delay in reporting and contradictory histories of injuries.

- **Parents:**
  - Often abused themselves and unhappy children
  - From lower social class families
  - Isolated and no support
  - Marital disharmony
  - Unwanted pregnancy
  - No contraception.

- **Mother:**
  - Often teenager, unmarried, neurotic or with a learning disability
  - Expects love from child
  - Not infrequently taking diazepam.

- **Father:**
  - In about half the cases, not the biological father
  - Two-thirds not married
  - Often has a personality disorder
  - Criminal in two-thirds of cases; one in three has a conviction for violence
  - Beats wife in one-quarter of cases
  - Competes with the child, whom he rejects, for his partner’s attention.
Abduction of older children, usually by a man with a sexual motive. Abduction by parents, usually in custody disputes. The Abduction Act 1984. There are three main groups: 1. Baby-stealing, the least common group, usually carried out by women. In the UK, in the nineteenth century children were stolen in order to obtain their clothes. When females steal babies, in general the babies are well cared for and usually quickly recovered.

Categories of baby-stealing
These include the following:
- **Comforting offences**: e.g. people with learning disability who steal a baby to play with or for comfort
- **Manipulative offences**: the motive may be an attempt to influence the woman’s partner in an insecure relationship by presenting the baby to him and pretending the child is his, e.g. following a miscarriage of a pregnancy by him or threatened desertion
- **Psychotic offences**: motivated by delusional ideas, e.g. that the child is a Messiah.

**SPOUSE ABUSE AND INTIMATE PARTNER VIOLENCE**

The term ‘spouse abuse’ has replaced the term ‘wife battering’. Historically in England and Wales, in the sixteenth century a male was not allowed to beat his wife after 10 p.m. In the eighteenth century, the ‘rule of thumb’ applied, as a result of which a male was not legally allowed to beat his wife with a stick or implement wider than a thumb. Under the Matrimonial Causes Act 1878, a husband was allowed a free hand with his wife to the extent that he could forcibly return his wife to their home.

The true incidence of such abuse is obscured by the hidden nature of the behaviour and problems in definition, for example over the degree of violence. This category accounts in England and Wales for 16 per cent of all violent crimes and results in two homicides of females a week; 40 per cent of these are killed in the bedroom or kitchen. The abuse is often associated with psychological abuse and behaviour linked to excessive jealousy and control of money. In the USA it has been estimated that in 25–30 per cent of marriages, one partner will push, shove or grab the other at some point. Punches and kicks occur in 13 per cent of marriages, and beating up or using a weapon occurs in 5 per cent of marriages. Surveys show that although women attack their husbands at a not substantially lesser frequency, such attacks are much less violent and usually defensive.

Male abusers are often inarticulate and demanding and find violence empowering. Typologies include men with a frequent loss of temper and men who undertake cold deliberate assaults, as well as overcontrolled individuals who eventually ‘snap’ under stress. Jealousy within the relationship is a factor noted in two-thirds of cases. Half of...
offenders have been exposed to domestic violence as a child. Fifty per cent of assaults follow alcohol abuse. Being a male abuser has also been associated with gambling, unemployment and a criminal record. Offenders are often remorseful following their violence but this does not prevent repetition. Women may be trapped in violent marriages economically, due to a lack of alternative housing, because of feelings of responsibility for their children, or by learned helplessness. A graphic account of spouse abuse has been given by Pizzey.119

Battered woman syndrome

This has been described as being characterized by:

- depression;
- loss of self-esteem;
- post-traumatic stress disorder;
- substance abuse;
- suicidality;
- physical health problems
- sexual problems.

Intimate partner abuse affects mainly women. If intimate partner abuse is suspected, it can be difficult to persuade the female victim to admit that she has been physically and mentally abused. A Canadian screening randomized trial found that women prefer self-completed questionnaire approaches to face-to-face questioning.120 Assessment of the victim must be carried out with great sensitivity. Check that the victim is not suicidal or depressed, that she is not abusing alcohol or drugs and that she does not have an anxiety disorder.

Management

Management can be difficult, particularly if the victim denies the abuse and insists on returning to the abusive partner. If there is a high risk of the abuse continuing, social services may need to be involved and the police may need to be informed. If the risk is lower, and the victim and her partner agree, then marital therapy may be arranged.

Voluntary refuges are now widely available. Anger management techniques can be applied to offenders. A non-molestation injunction can also be sought, including with attached power of arrest. A new multidisciplinary case conference management approach (MARAC) has been developed in the UK.

ELDER ABUSE

Estimates of up to 500,000 older people being abused a day in the UK have been made. Elder abuse includes violence, neglect and emotional abuse of elderly relatives, often surviving widowed elderly mothers. The term ‘elder abuse’ replaces the term ‘granny bashing’.121 The offender is often a son or daughter (50% aged ≥60 years) of the victim and lives with the victim. The British prevalence rate is 1.5–5.6 per cent. Abused elders are no more physically or mentally infirm than non-abused elders.

The abuser may be otherwise under stress from marital or financial problems, be depressed, have a history of substance misuse or a personal history of abuse themselves, and be unable to cope with the added stress of looking after the victim, who may be emotionally and economically dependent. Unresolved emotional conflict is often present.

There is often a history of families being reluctant to take over the care of elder relatives but being put under pressure to do so. Occasionally, elder abuse arises due to an equally aged spouse having to cope with or care for the victim. Emotional conflict may be present between the abuser and the abused. Unqualified staff in poorly managed nursing homes may also abuse elderly people.

Victim vulnerability factors, such as disability, dementia or paranoid illness, may be present.

Non-accidental injury of children, spouse- and elder-abuse, reflect the fact that most violence is in the family, where individuals are most physically and emotionally close to others.

SPECIAL SYNDROMES

Morbid jealousy (Othello syndrome)

Delusions of infidelity about a sexual partner can lead an individual to examine, for example, the partner’s under- wear and sexual organs, in an attempt to find proof of unfaithfulness, and, on occasions, attempt to extract confessions by violence. It not infrequently leads to severe aggression towards, and the killing of, the sexual partner about whom the delusions are held. The condition occurs in males over six times more commonly than in females (c.f. erotomania, which is more frequent in females). It usually commences in the forties, after about 10 years of the relationship, and is present for about 4 years before presentation. It is responsible for 12 per cent of homicides due to mental illness.122

Aetiology

Evolutionary theories suggest that males may be predisposed to sexual jealousy as they cannot know whether it is their sperm that results in a pregnancy. Ten per cent of male birds look after offspring that are not biologically their own.

Morbid jealousy is associated with alcoholism, schizophrenia and delusional disorder. Morbid jealousy may be a forerunner of a later schizophrenic illness, this manifesting only after serious violence. It is also associated with impotence in males. Psychodynamic theories postulate that the suspicious attitudes may be a projection of the individual’s
own desires for infidelity on to the victim-partner or a more internally acceptable, conscious manifestation of repressed homosexuality. Morbid jealousy is often associated with low self-esteem, with resulting feelings of insecurity that the partner may not really love him and may wish to leave him for someone else.

Management
This is often difficult due to lack of insight of the subject and the sexual partner’s belief that they can overcome the subject’s unjustifiable beliefs. Underlying psychiatric conditions should be treated adequately, for example stopping alcohol abuse. Antipsychotic medication may help if compliance can be obtained. Separation of the couple may be the only answer. There is a risk of recurrence in future relationships: an example is the case of Iliffe, who killed four wives in spite of having spent periods in Broadmoor Hospital. It is best to work with a co-therapist, such as a social worker, who remains involved with the partner (e.g. advising her of refuges), while the psychiatrist concentrates on the patient.

Other terms
Rivalry is where two individuals are in competition for the same object. There is no aggression to the object.

Envy is where one individual desires someone or something that belongs to another person. Aggression is to the competitor or the self, but not to the object.

Jealousy is where there are fantasies of losing the object to a rival. Aggression is directed not to the rival but to the object, for example the partner. Historically and across cultures, the main cause of female homicide is male jealousy.

Jealousy can be normal or excessive. Sometimes even in the absence of delusions it may still be termed morbid – that is, for neurotic, obsessional, as well as delusional reasons – including being secondary to an affective disorder. It also arises in paranoid personalities. The boundary between normal and pathological jealousy may be indistinct. However, psychotic jealousy often responds better than neurotic jealousy to treatment.

Delusional jealousy can develop even when the partner has, in fact, been unfaithful. The way the delusional belief develops may be more important diagnostically than the pure content of the belief.

Erotomania (de Clérambault’s syndrome)
This is a delusional disorder that another person, often unobtainable and of higher social status, loves the patient (usually female) intensely. It may be primary or secondary due to a paranoid or affective disorder. It is usually associated with paranoid psychosis or schizophrenia rather than being a pure monodelusional disorder. Only some people with this disorder cause disruptive antisocial behaviour (e.g. making phone calls, writing letters, following the victim), but repeated rebuttals may lead to hatred and dangerous behaviour. Gilles de la Tourette, who gave his name to Tourette’s syndrome, was killed by an erotomaniac patient. Dangerousness is increased if there is a history of multiple delusional objects in the past and a premorbid antisocial personality. De Clérambault, after whom the syndrome was named, shot himself while dressed in a toga and was found by Lacan, the French psychotherapist.

Stalking
This is the wilful, malicious and repeated following and harassing of another person that threatens his or her safety. Eighty per cent of victims are female. Typologies of the stalker include the following:

- The rejected stalker who acts through a mixture of revenge and desire for reconciliation: as a group, these people tend to be more assaultative but more likely to respond to judicial sanctions.
- Intimacy-seeking: these individuals include deluded patients. Such individuals may stalk famous people and mental health professionals.
- Incompetent stalker/suitor: such individuals lack social skills and may be intellectually limited.
- Resentful stalkers: these individuals often intend to cause fear.
- Predatory stalkers: these individuals are rare but may have fantasies about or have intent to commit sexual assaults.

There may also be false victims, including those deluded that they are being stalked. Post-traumatic stress disorder occurs in over a third of victims. Fifty per cent of stalkers threaten violence, three-quarters of whom are not subsequently violent or destructive of property. The risk of violence is increased if there are prior convictions or substance misuse. Stalking offences are now covered by the Protection from Harassment Act 1997 in England and Wales (an injunction combined with a criminal sentence), but prevention, when possible, may be most effective.

Munchausen syndrome (hospital addiction syndrome)
Originally described by Dr Richard Asher in the Lancet in 1951 and named after Baron Karl von Munchausen, Raspe’s 1785 fictious French cavalry officer who lied harmlessly about his military exploits, this is the intentional production or feigning of illness to bring about repeated hospital admissions, investigations and operations. It is a factitious disorder, consciously produced. Symptoms simulated are suggestive of severe physical illness and deceive medical staff. Men appear to be affected more commonly than women. The patient’s history is plausible but overdramatic. Self-inflicted injuries, including simulating symptoms in a bizarre way, for example by swallowing needles, are seen. Abdominal symptoms are most common. Pathological lying
(pseudologia fantastica) is often present. Variants include presenting with psychiatric complaints, including a false history of bereavement. When feigning comes to light, such individuals abscond from hospital. They frequently change their name and the hospitals they approach. To fund their wandering, they may commit theft and create disturbances.

Note: people in prison suspected of feigning mental illness are usually found on follow-up to have been genuinely mentally ill.

**Munchausen’s syndrome by proxy**

In this, physical symptoms are intentionally produced in others, for instance by a mother in her child. The perpetrator frequently has nursing experience. The chosen method of producing symptoms is often by poisoning or suffocation. The term was coined by Meadow.\(^{126,127}\) In one-third of cases, there is a history of fictitious illness in the mother. The father is usually emotionally, if not physically, absent, while the perpetrator appears superficially an exemplary mother. In the past, cameras installed on children’s wards unknown to the mother (now questioned legally and ethically) revealed mothers suffocating or otherwise harming their children in the nurses’ absence. It is rare for the mother to confess, due to feelings of shame and humiliation and low self-esteem, which in turn may lead to prolonged legal disputes about allegations.

**SPECIFIC GROUPS OF MENTALLY DISORDERED OFFENDERS**

**Ethnic minorities**

Afro-Caribbean people, but not Asian people, are overrepresented in the psychiatric and criminal justice systems. The reasons for this are controversial. Studies have shown an excess of Afro-Caribbean people, particularly British-born young men, admitted with a diagnosis of schizophrenia. The rates in their countries of origin are, however, not raised, making genetic factors unlikely to be the cause. Admissions of Afro-Caribbean people are more likely following contact with the police and social services, and following detention under the Mental Health Act 1983, in particular, under forensic Part III sections (25 times greater).\(^{128-130}\) They are also overrepresented in special hospitals, medium secure units and locked wards. Twenty per cent of patients in special hospitals are Afro-Caribbean, but very few of these have had a Mental Health Act 1983 pre-2007 legal diagnosis of psychopathic disorder. Afro-Caribbean people are also overrepresented among those arrested, are more likely to be remanded into custody and are overrepresented in the prison population (5% in the general population compared with 11% of men and 25% of women in the prison population, according to Home Office figures). There is also an excess of women normally resident in West Africa serving sentences in England and Wales for drug smuggling. Afro-Caribbean people are also more likely to be the victims of murder.

Reasons suggested for such overrepresentation of Afro-Caribbean people include sociodemographic factors, such as overrepresentation among young people, unemployed people, lower social classes and socially deprived people, which in turn is associated with higher rates of offending,\(^ {131}\) differences in referral (non-Afro-Caribbean people are admitted via GPs and at an earlier stage than Afro-Caribbean people, who tend to be referred by the courts, the police and probation officers and for whom white psychiatric services may carry more stigma, leading to a later presentation), and overrepresentation among remand prisoners, leading to an increase in identification of mental illness (‘differential filter theory’). In London Afro-Caribbean people represent one-fifth of the population but two-fifths of those detained. The statistics are not explained by drug abuse, higher rates of mental illness in the country of origin, differential migration or the stress of migration. Other factors postulated for the differences include the stress of prejudice and cultural acculturation of second-generation immigrants, higher rates of post-traumatic stress disorder due to being subject to violence in countries of origin, relative lack of father figures and peer group pressures. There is some evidence for stereotyping Afro-Caribbean people as taller and of bigger build and as more violent when mentally ill,\(^ {132}\) but not for systematic discrimination by psychiatrists (as opposed to the courts or the police); however, the institutional racism of psychiatric services was raised in an inquiry into the circumstances of the death of an Afro-Caribbean man, David Bennett, who died after being restrained in a medium secure unit.\(^ {132a}\)

**Substance misuse and crime**

Association of crime with substance misuse may be due to:

- altered mental states due to drug intoxication, withdrawal or long-term consequences, e.g. organic mental disorder;
- acquisitive offences to finance substance misuse;
- technical offences under the Misuse of Drugs legislation.

Crimes requiring specific intent, such as murder, wounding with intent, theft and burglary (in contrast to those requiring basic intent, such as manslaughter, assault and unlawful wounding), can be ‘negativized’ by intoxication.

Drug and alcohol abuse usually has disinhibiting effects on behaviour, impairs judgement and is associated with violence. Alcohol abuse, including acute intoxication, is present in up to one-half of individuals at the time they commit offences of violence in the UK.

Alcohol dependence syndrome is associated with an eight times higher rate of convictions for criminal offences, including especially motoring, drunkenness and acquisitive offences. There may be a history of alcohol abuse for 3
Specific groups of mentally disordered offenders

years before initial offence, within 3 years of which the individual is often dependent on alcohol.

About half of people with a drug dependence syndrome have convictions before they become dependent.

Glue-sniffers may be charged with breach of the peace or depositing rubbish, such as crisp bags from which they have inhaled glue and which are then dropped when the individual becomes intoxicated. In non-mentally ill people, cannabis may be the only drug that has anti-aggressive properties.

**Epilepsy**

The prevalence of epilepsy in prisons in England and Wales was noted in the 1970s to be two to four times that in the general population (7.2 per 1000 compared with 4.2 per 1000). However, a more recent study in 2002 has shown a prevalence of 1 per cent in prison, which is equivalent to that in the community (Figure 76.7). Individuals with epilepsy are no more likely than other prisoners to be serving a custodial sentence for a violent offence. Violence associated with epilepsy is, in fact, rare. Ictal phenomena, including automatism, do not account for this overrepresentation. Alternative explanations include:

- underlying organic mental disorder being responsible for both epilepsy and offending;
- development of epilepsy adversely affecting an individual’s self-esteem and resulting in social rejection, which in turn leads to antisocial behaviour;
- adverse social circumstances leading to both epilepsy and antisocial behaviour, e.g. being a ‘battered baby’;
- a tendency to be impulsive and antisocial, leading to offending and brain injuries and thus post-traumatic epilepsy.

If linked, the most likely relationship between epilepsy and imprisonment is that such individuals show the same biosocial disadvantages.

The association between aggressive behaviour and temporal lobe epilepsy has been reported widely. There is some evidence for amygdaloid foci, but psychosocial factors are also important. As a generalization, however, neurologists say that without a history of a fit, epilepsy is unlikely to be a cause of aggression.

Half of persistently aggressive offenders are said to have an abnormal EEG, often an immature record (persistence of
excess posterior slow-wave theta activity), characteristic of individuals with psychopathic disorder and not diagnostic of epilepsy (Figure 76.8).

Episodic dyscontrol syndrome (intermittent explosive (behaviour) disorder) is characterized by episodes of sudden, unprovoked violence. It was originally conceptualized as limbic epilepsy, which has not been borne out. However, the syndrome may be associated with soft neurological signs and temporal lobe EEG abnormalities and may be helped by anticonvulsants such as carbamazepine. It usually occurs in people with a severe, often explosive personality disorder. However, as already noted, half of persistently aggressive offenders have an abnormal EEG.

Deaf people

One in ten referrals to the three main specialist psychiatric units for deaf people in England (in Birmingham, London and Manchester) come from the police, courts or solicitors. The majority have committed minor or acquisitive offences, but there is a high proportion of those charged with sexual offences, reflecting a lower threshold for referral rather than a disproportionate number of deaf individuals committing sexual offences. Deaf offenders are more likely to be found unfit to plead.142 Grubin found 7 deaf people in his series of 295 cases unfit to plead. Rampton Special Hospital in England provides a maximum secure unit for the deaf.

PERSONALITY DISORDER

Personality disorder is an extreme persistent variation from the normal (statistical) range of one or more personality attributes (traits), causing the individual, their family or society to suffer.

Personality = character (acquired) + temperament (hereditary or congenital)

The history of the term psychopathic personality disorder

During the nineteenth century, it was recognized that there was a group of individuals who had neither mental illness nor mental retardation but who showed abnormally aggressive, antisocial, seriously irresponsible or inadequate behaviour from an early age, with which society felt impelled to deal. In 1801, Pinel, the humanitarian psychiatrist who first unlocked the chains from patients in the French psychiatric hospital Bicêtre, coined the term ‘manie sans délire’ to describe this group of patients. Not all the patients he described appeared to be what we would nowadays call psychopathic. A typical case, however, was that of a man, spoiled by a weak mother, who killed any animal who ‘offended’ him. He was found to be intellectually normal and was able to run his own estate, but he had thrown a woman who was abusive to him down a well.

In 1835, the psychiatrist and anthropologist Pritchard coined the term ‘moral insanity’ for this group of patients, the term ‘moral’ at that time meaning psychological more than ethical. His cases also included individuals with bipolar disorder (manic-depressive psychosis). In 1891 Koch used the term ‘psychopathic inferiority’, in 1909 Kraepelin the term ‘psychopathic traits’, and in 1927 Schneider the term ‘psychopathic personalities’. In 1930, the term ‘sociopathy’ was used by Partridge in the USA, which indicated and emphasized the social malfunctioning of such patients. The term ‘psychopathy’ originally included all personality disorders, which still applies on the European continent. The term became restricted in the USA to antisocial personality disordered people and was imported to the UK with that meaning by Henderson in 1939. He distinguished three kinds of psychopathic personality:

- Predominantly aggressive people
- Predominantly inadequate people (e.g. pathological liars or those who show pseudologia phantastica, swindlers and con artists – who are themselves the most easily conned)
- Creative psychopaths, who have high ability combined with their severe personality disorder, such as Lawrence of Arabia and the Renaissance sculptor Cellini.

The term ‘psychopathic disorder’ was incorporated into the English Mental Health Act in 1959, and in the 1983 Mental Health Act it was defined as a persistent disorder or disability of mind (whether or not including impairment of intelligence) that results in abnormally aggressive or seriously irresponsible conduct on the part of the patient. As a legal diagnosis it was used to detain people suffering from all clinical personality disorders. However, to detain an individual on such grounds, it had to be stated that the condition was treatable. There is no legal diagnosis of psychopathic disorder in the mental health legislation of Scotland or Northern Ireland.

In England and Wales, following the amendment of the Mental Health Act 1983 by the Mental Health Act 2007, the term psychopathic disorder was removed and subsumed under a single definition of mental disorder.

The equivalent of the clinical diagnosis of psychopathic disorder in DSM-IV-TR is antisocial personality disorder, and in ICD-10 it is dissociative personality disorder, although some psychopathic individuals are best described by the category ‘emotionally unstable personality disorder, impulsive type’. The term ‘psychopath’ is also used clinically in a pejorative sense to describe unreliable, uncooperative and often difficult male patients. The definition of psychopathy has also been used in a circular fashion – antisocial behaviour is presumed to be due to psychopathy, and yet psychopathy is presumed present from the behaviour. Table 76.5 summarizes the historical nomenclature.

### Psychopathy

This is a term used:

- as a Mental Health Act 1983 definition, prior to its amendment by the Mental Health Act 2007, allowing detention (of abnormally aggressive and seriously irresponsible patients);
- for antisocial or all personality disorders;
- as a term of abuse for uncooperative, usually male patients.

Characteristics of clinical psychopathy include affectionlessness, impulsivity, seeking immediate gratification, lack of guilt and failure to learn by experience and punishment. There is an association with XYY syndrome.

The classic features of psychopathic personality are shown in Table 76.6.

Cleckley usefully differentiated primary from secondary psychopaths (Table 76.7). As classically described, a primary psychopath would rarely seek assistance from a clinician and is most likely to be found within the penal system. Secondary psychopaths, however, are described with higher levels of anxiety or tension, hidden guilt and regret, and low self-esteem. They may impulsively harm themselves under stress, seek assistance from psychiatric services and have a better prognosis. Contrary to popular belief, psychopaths do not make good soldiers, as they are too impulsive and do not work cooperatively, although they can on occasion undertake breathtaking and heroic acts. The general characteristic of psychopaths – the seeking of immediate gratification of needs – may result in sexual offending.
Management of antisocial personality disorders and psychopathy

In the antisocial group of personality disorders, it may be difficult to engage the patient in treatment. Low stress tolerance may lead the patient to make insistent demands for treatment, including for drugs, and for instant results from such treatment, upon threat of self-harm or harm to others. Patients may often stop treatment themselves, unless they are forced to receive it while detained in hospital or are encouraged to do so during a custodial sentence to speed release. They may do best with younger therapists, whom they perceive as being less authoritarian. However, such patients often lack motivation for treatment.

Group therapy is usually preferable to individual psychotherapy. This may be undertaken within a therapeutic community, where the patient lives with other patients and staff and where the consequences of antisocial behaviour are immediately apparent, which contrasts with the delayed punishment for such behaviour given by the legal system. In therapeutic communities, there is open communication and shared examination of problems between patients and staff in a democratic and communal environment, with regular feedback (reality confrontation) given to individuals about their behaviour. This allows social learning to take place. People with severely handicapped personalities may, however, be unable to tolerate the stress of such a regime and may act out, and they may benefit from a more paternalistic authoritarian approach. Therapeutic community treatment can be effective, as was offered at the Henderson Hospital in Surrey, UK, where research showed subsequent decreases in levels of hospitalization and criminality and also cost-savings in subsequent care, and, for those non-mentally ill personality disordered individuals who are serving a custodial sentence, at both Grendon Underwood and Wormwood Scrubs prisons in England. The Henderson Hospital Unit and HMP Wormwood Scrubs units have now closed.

Among people with borderline personality disorder, interpersonal group therapy and dialectical behaviour therapy have been shown to be effective, the latter reducing parasuicidal behaviour.

Depression, suicidal impulses and general impulsivity and aggression may be countered by low-dose antipsychotic medication, in either oral or depot injection form. The latter helps to overcome the usually poor compliance with oral drug treatment in this group of patients. However, as such treatment is usually required on a long-term basis, there is a risk of tardive dyskinesia. Levels of serotonin in the brain have been shown to be low in the brain of impulsive, self-harming and aggressive personalities, and thus antidepressants, especially the newer serotonin reuptake inhibitors, may also be of benefit, as may lithium carbonate, which also raises serotonin levels, because of its anti-aggressive and mood-stabilizing properties. The anticonvulsant carbamazepine is regarded as a stabilizer of the limbic system and is promoted as a treatment for ‘dyscontrol syndrome’. Benzodiazepines should be avoided, as they may release paradoxical aggression.

Aggressive psychopaths are generally not admitted to medium secure units in England and Wales. Those with a legal diagnosis of psychopathic disorder may be detained in special hospitals such as Broadmoor, where treatment may do little more than keep such individuals out of the community, free from drugs and alcohol, and away from potential victims during the years of their greatest risk to others, while their personality matures naturally with age. The more recent DSPD units are described below.

People with antisocial personality disorder or psychopathy tend to improve naturally with age and maturation. Normal individuals become less emotional and impulsive and more cautious and careful with age. Individuals with psychopathy are most destructive in their early life and tend to ‘burn out’ after age 30–35 years, becoming less anti-social, although family difficulties, such as violence to their partner or children, alcohol and drug abuse, and depression and itself may persist. There is also a higher incidence of death by violence and suicide. It may also increase the vulnerability and adversely affect the course and treatment of co-morbid mental illness, such as depression and episodes of paranoid psychosis.

The Psychopathy Checklist – revised (PCL-R)

This was devised by Hare and is used to measure the presence and level of psychopathy. It has been proven to be a good predictor of risk. A short version (PCL-SV) can be used in non-forensic populations.

The Psychopathy Checklist has two factors:

- **Personality traits:**
  - Superficial
  - Grandiose
  - Manipulative
  - Lacks remorse
  - Lacks empathy
  - Does not accept responsibility
- **Deviancy of social behaviour:**
  - Impulsive
  - Poor behavioural controls
  - Lacks goals
  - Irresponsible
  - Adolescent antisocial behaviour
  - Adult antisocial behaviour.

Only one-third of people with antisocial personality disorder reach the checklist criteria for psychopathy on this scale. Scores on the deviancy of social behaviour factor may vary between cultures, e.g. low in Scotland compared with the USA.

**Neuroimaging findings**

Subjects with high PCL-R scores have been found to have reduced prefrontal grey-matter volumes and reduced auto-
nomic arousal to social stressors. Functional hypoactivation of the amygdala and evidence of dysfunction of the orbitofrontal cortex, which receives projections from the amygdala, have also been found in psychopathy. Amygdala-empathy impairments have been seen as resulting in the callous unemotional traits of psychopathy in the Integrated Emotion System Theory of Blair.

Evidence for treatability
Psychopathic disorder has been removed as a legal category in the Mental Health Act 1983 by the amended Mental Health Act 2007 and incorporated in the category of ‘mental disorder’. The Treatability Test – that is, such treatment is likely to alleviate or prevent a deterioration – was also removed from the Mental Health Act 1983 by the Mental Health Act 2007. The new criterion is that treatment is available that is appropriate to the patient – that is, it must have the purpose of improving the patient’s condition or preventing deterioration.

One important argument for treating psychopathic disorder is that it may lead to the next generation of people with personality disorder.

Dolan and Coid wrote in 1993 that there is ‘no convincing evidence psychopaths can or cannot be treated’. Much the same could be said today. Indeed, there is some evidence that insight-oriented programmes may increase the psychopathic individual’s ability to manipulate and deceive and thus increase the risk.

To summarize, there is evidence for treatability for the following:

- Dialectical behaviour therapy for borderline personality disorder
- Cognitive skills programme:
  - Enhanced thinking skills (UK)
  - Reasoning and rehabilitation (R+R) (USA)
- Drug treatment.

Possible mechanisms for the effectiveness of drugs in personality disorder are suggested in Table 76.8.

Evidence for treatability has also been shown in the following facilities:

- **In prison:** HMP Grendon Underwood near Aylesbury, Buckinghamshire, was purpose-built for treatment by group therapy of offenders with psychopathic personality disorder who are already serving a prison sentence with at least 1 year to serve. Remaining at HMP Grendon is voluntary. Referral is by the prison medical service itself. Psychiatrists in court reports and judges in court can recommend placement at HMP Grendon but cannot order such a placement. Gunn and colleagues showed that self-image, attitudes to staff and behaviour improved in Grendon compared with controls in other prisons. However, the beneficial effect of the prison regime is counteracted by the environment to which the prisoner returns on release – that is, factors in the community after release are just as important in the ultimate outcome. Thus, overall the regime does not significantly affect re-conviction rates for serious offences, but it may do so in terms of the overall number of offences.

- **In hospitals:** Henderson Hospital in Sutton (now closed) was famous for the development under Maxwell Jones of a therapeutic community approach. This unit treated people with psychopathic disorder on an open unit within the National Health Service (NHS). It did best with articulate, intelligent, younger psychopaths without too much violence. The patient had to be resilient enough to withstand this approach and not act out excessively. Those who previously received standard inpatient psychiatric care did less well, probably because this encourages dependency and discourages taking responsibility for oneself. Claims made for beneficial effects included cost-effectiveness through saving from future in-patient psychiatric hospital admissions and prison sentences.

- In the Netherlands, offenders with severe personality disorder can be detained in special forensic psychiatric institutions, Ter Beschikking Stelling (TBS) hospitals, for treatment and rehabilitation into society after having served their prison sentence. A sustained fall in recidivism rates has been reported.

An early forerunner of these special therapeutic communities was the Van Der Hoeven Clinic, Utrecht. This famous secure unit is run as a therapeutic community treating young adult psychopathic offenders by group psychotherapy in combination with an education, rehabilitation and resocialization programme.

The Butler Committee recommendations for psychopaths were that for aggressive psychopaths the law should take its course, e.g. imprisonment, inadequate psychopaths should be placed in hostels with social service care, and people with intervening mental illness hospitalized.

Dangerous and severe personality disorder (DSPD) units have been established in Broadmoor and Rampton special hospitals, and at HMP Whitemoor and HMP Frankland. Their establishment was controversial, but they are now in place. The criterion for admission is that there must be
more than a 50 per cent risk of committing a serious offence due to a severe personality disorder.

**PRISON PSYCHIATRY**

Psychiatrists may be requested to assess prisoners:

- to provide court reports;
- to provide assessments on management and advice, including for sentenced prisoners, at the request of prison medical officers;
- for statutory purposes, such as preparing reports for the parole board.

To visit a prisoner, arrangements need to be made with the healthcare wing of the prison. Psychiatrists may need security clearance. Assessments have to fit in with prison routine, which allows only 2–3 h in the morning or the afternoon to see a patient, and the psychiatrist will usually need to wait for prison staff escorts upon arrival.

Issues relevant to psychiatric care in prison include the following:

- Prevention of offending and imprisonment by psychiatric care in the community
- Police station/court diversion schemes
- Screening should be undertaken on reception of inmates to prison (three-quarters of psychiatric cases may be missed due to inadequate screening\(^{(153)}\))
- Measures to counter suicide risk (highest in first 2 months, especially among young people on remand, who are not necessarily formally mentally ill)
- Return to psychiatric hospital care under the relevant sections of the Mental Health Act 1983 while on remand, by means of court sentence or during custodial sentence
- Substance misuse/detox services – abstinence may result in a medical emergency due to withdrawal; there are also high mortality rates in cases of substance misuse upon release from prison due to loss of tolerance
- Sex offender treatment programmes (SOTPs)
- Special therapeutic community units for sentenced prisoners with personality disorder, e.g. at HMP Grendon in England
- DSPD units at HMP Whitemoor and HMP Franklin.

The Mental Health Act 1983 does not apply in prison, but medical treatment can be administered in good faith under common law in prison where there is lack of capacity to consent and in the best interests of the individual, for example to prevent immediate serious risk to others or self.

The aim is that healthcare in prison should ensure an equivalence of services to NHS care outside,\(^{(154)}\) with 24-h psychiatric care/in-reach for remanded and sentenced prisoners, on both medical wings and ordinary locations, provided by local general or forensic mental health services.

The National Offender Management Service (NOMS) has been established to manage offenders across the criminal justice system.\(^{(155)}\) Healthcare services in prison have been devolved to the NHS.\(^{(156)}\)

**Suicide risk in prison**

Suicide risk in prison is nine times higher than in the community. Risk is highest in the first 2 months in custody. Formal mental illness may be absent.

At-risk groups include:

- people on remand;
- young people;
- people with a history of substance misuse;
- people with a history of violent offences.

Other factors, such as anxiety about the consequences of future court hearings, bullying, isolation and poor conditions in prison, may also be relevant.

Assessment is often compounded by the limited information available in prison. Attempts should be made to gather a background history, including from psychiatric services previously involved in the care of the individual.

Prediction remains difficult. Suicide remains the most common cause of death in prisons and is most commonly by hanging. An assessment, care in custody and teamwork (ACCT) approach has been developed for suicide/self-harm risk assessment based on case management, individualized care-planning and multidisciplinary teamwork.\(^{(157)}\)

Although the prevalence of mental disorder in prison populations is high, with perhaps the majority suffering from mental disorder, albeit mainly personality disorder (40–60%) or substance misuse, and with major depression in 10–12 per cent and psychotic illness in around 4 per cent,\(^{(158)}\) the criterion for transfer to hospital under the Mental Health Act is that the individual requires detention for in-patient psychiatric treatment, not simply that the individual might benefit from psychiatric or psychological help, including in prison. However, shortage of low-, medium- and maximum-secure beds leads to mentally ill prisoners remaining in custody for lengthy periods.\(^{(159)}\) The Bradley Report (2009) has recommended that individuals in prison in need of hospitalization should be transferred within 14 days, as well as other recommendations regarding early intervention, diversion and the development of joint criminal justice mental health teams.\(^{(159a)}\)

A useful guide when assessing offenders with regard to their need for psychiatric treatment is not to focus alone on the offence but to assess the need for in- or out-patient treatment as if one were seeing the individual as a new outpatient case.

**Psychiatry and prisons**

The UK has a daily population of over 80 000 prisoners, with about 130 000 people received each year. There are about 20 male prisoners to 1 female prisoner. Weekly updates on the prison population are available at www.hmprisonservice.gov.uk. This equates to about 1 in 15
children experiencing a parent in prison at some point, or about 25,000 at any one time.

Penrose’s Law described an inverse relationship between the number of psychiatric in-patients and prisoners in a country. The UK has a greater proportion of both compared with the rest of Europe, except for prisoners in Turkey. However, it is true that as the UK’s psychiatric hospital population has decreased, so the prison population has risen. The USA, which has 5 per cent of the world’s population, has 25 per cent of the world’s prisoners (around 2 million), perhaps due largely to policies of zero tolerance to drug-related crime (60% of people in prison are there because of this). One in three of New York’s male African-Americans has been in prison or on parole.

Prisons in England and Wales may be:

- **local**, such as HMP Brixton and HMP Wandsworth, which are closed and for people on remand, awaiting trial or sentence, or for convicted prisoners serving less than 2 years, and serve local courts; or
- **training prisons**, which may be open, such as HMP Ford, or closed, such as the high-security HMP Belmarsh or HMP Long Lartin, for prisoners serving more than 2 years. Some are dispersal prisons for high security risk prisoners, e.g. HMP Wormwood Scrubs.

London’s local prison for women is HMP Holloway. Female training prisons include HMP Styal and HMP Cookham Wood. HMP Durham provides a unit for women requiring special security. HMP Holloway and HMP Styal contain mother-and-baby units. Female prisoners have higher rates of learning disability, personality disorder, neurosis and substance misuse.137,160–162

All prisoners are classified on security considerations, from category A prisoners, who are considered to require maximum security and are subject to many restrictions, down to category D prisoners, who are suitable for open conditions.

Young offender institutions (HMYOI) take people aged 15–21 years requiring custody, for example HMYOI Feltham, near London.

Although custodial sentences prevent re-offending during such sentences and are increasing in length in the UK, 60 per cent of prisoners re-offend within 2 years.

**Prevalence of psychiatric disorder in prison**

Psychiatric symptoms are common in the first 2 months of imprisonment. Between one-third and one-half of prisoners may have an ICD-10 diagnosable psychiatric disorder, but personality disorder and substance misuse are the most common diagnoses. There is an excess of psychoses among prisoners on remand for psychiatric reports, but among sentenced prisoners, the prevalence of psychosis is not raised.

The number of elderly (age ≥60 years) people in prison in the UK increased three-fold between 1988 and 1998, to 1.7 per cent of the population. In more than half of such cases, psychiatric disorder is present, with personality disorder and depression (about 30% often undetected or undertreated) being the most common diagnoses.163

The Mental Health Act 1983 does not apply in prison, but treatment can be given in urgent circumstances in ‘good faith’ under common law.

**Other examples of special units in prisons**

The special unit at Barlinnie Maximum Security Prison in Scotland was developed for psychopaths who had been very violent, for example killing within a prison setting, and who were destructive within the ordinary prison regime. The unit was run as a small therapeutic community with emphasis on developing the inmates’ creative talents, as described in the memoirs of Jimmy Boyle. Admission to this special unit was voluntary.

Herstedvester Prison in Denmark was a forerunner of the prisons attempting to treat psychopaths. Based on therapeutic community principles, it relied heavily on the effect of an indeterminate sentence to motivate prisoners, which is no longer in place. It also used castration for sex offenders. However, follow-up studies showed that 3 years after release, the re-offending rate had returned to that of prisoners from a control group prison.

**VICTIMOLOGY**

Forensic psychiatry has been defined as ‘the prevention, amelioration and treatment of victimisation which is associated with mental disease’164 – that is, victims of specific offences, or mentally disordered offenders who themselves are the victims of childhood abuse or mental ill-health, or of their own offending behaviour and secondary victimization because of it. Forensic, as opposed to other subspecialties of, psychiatry expertise in this area has been questioned. The victims of childhood abuse and neglect develop an excess of psychological sequelae, including post-traumatic stress disorder, and may become offenders in later life – the abused becoming the abuser (‘identification with the aggressor’). A study of 1000 male offenders found that those with post-traumatic stress disorder were five times more likely to have committed acts of serious violence.165

**MENTAL HEALTH LEGISLATION IN THE UK, WITH SPECIAL REFERENCE TO THE MENTAL HEALTH ACT 1983 OF ENGLAND AND WALES**

In the UK there are different legal systems in Scotland, Northern Ireland, the Isle of Man and the Channel Islands to those in England and Wales, although they have developed in parallel. UK mental health legislation covers more than
the compulsory detention of patients, although it is this that is usually concentrated on in descriptions of the Acts. In general, compulsory hospitalization depends not only on a diagnosis of mental disorder within the meaning of the Act in question, but also on its necessity for the patient’s health or safety or for the protection of others.

**Mental Health Act of England and Wales 1983**

The Mental Health Act 1983, which replaced the Mental Health Act 1959, remains the basis of current mental health law in England and Wales, but it was amended substantially by the Mental Health Act 2007.

**Mental Health Act 2007: an Act to amend the Mental Health Act 1983**

The purpose of the Mental Health Act 2007 was to bring mental health legislation into line with service provision, to strengthen patient safeguards and to tackle human rights incompatibilities. Most provisions came into force on 3 November 2008. The Deprivation of Liberty provisions amending the Mental Capacity Act 2005 came into force in April 2009. Age-appropriate services provisions come into force in April 2010.

**Definition of mental disorder**

The previous four categories of mental disorder are replaced by one: mental disorder. Mental disorder means any disorder or disability of the mind. Exclusions for dependence on alcohol or drugs are retained. If a patient has a learning disability, however, this must also be associated with abnormally aggressive or seriously irresponsible conduct if long-term sections (orders) are used.

**Detention criteria**

These are that the individual should have a mental disorder of a nature or degree necessary for the patient’s health or safety or for the protection of others. Appropriate treatment must be available for longer-term sections. The previous treatability test is removed.

**Medical treatment**

A new definition includes a broader range of treatments and applies to manifestations of the disorder rather than only the disorder itself. The phrase ‘under medical supervision’ has been removed.

The term ‘appropriate treatment’ means treatment that is appropriate in the person’s case, taking account of the nature and degree of mental disorder or other circumstances of the case.

**Professional roles**

The role of approved social worker (ASW) is replaced by approved mental health professional (AMHP). This role is open not only to social workers but also to nurses, occupational therapists and psychologists. AMHPs are approved by the local social services authority, which also provides training for this role.

The term ‘responsible medical officer’ (RMO) is replaced by ‘responsible clinician’ (RC), who may also be a psychologist.

**Renewing detention**

This is no longer solely the task of the RC. Another professional person concerned with the patient must agree that the renewal conditions are met.

**Nearest relative**

A patient now has the right to make an application to displace their nearest relative, who may also be displaced by a county court when there are reasonable grounds to do so. This overcomes the risk of the technical nearest relative being an abuser of the patient. Nearest relative also now includes civil partners.

**Supervised community treatment (SCT)**

Supervised community treatment (SCT) replaces supervised discharge and is now also referred to as a community treatment order (CTO). This allows the patient to be under ‘compulsion’ in the community. However, before such an order can be made, the patient must have been detained in hospital (Sections 3, 37, 47). The order is made by the RC and AMHP. It is renewable after 6 months, and then a further 6 months, and then annually. However, this order does not allow forcible treatment outside hospital. The RC can recall a patient for up to 72 h. The RC and AMHP, if agreed, can revoke a CTO, which re-starts the previous order for its full duration – e.g. a further full Section 3. Section 17 leave is still available, but the RC must consider a CTO if leave is greater than 7 days and document the reasons for this.

**Mental health review tribunals (MHRTs)**

Time is reduced before a case has to be referred to the mental health review tribunal (MHRT). An annual referral is required for people under age 18 years.

**Age-appropriate services**

From April 2010, hospital managers must consult child and adolescent mental health service (CAMHS) specialists when detaining people under 18 years of age and ensure that such individuals are admitted to a suitable environment. From April 2010, hospital managers must consult child and adolescent mental health service (CAMHS) specialists when detaining people under 18 years of age and ensure that such individuals are admitted to a suitable environment. Since January 2008, parental authority is no longer sufficient to allow admission of 16- or 17-year-olds as informal patients. The Mental Health Act 1983 must be used. There are also more safeguards for the use of electroconvulsive therapy (ECT) for such individuals.

**Advocacy**

There is a new role for the independent mental health advocate (IMHA), for which formal training is now required. Hospital managers must ensure that advocacy services are available. Advocates have the right to meet with patients in private, to meet with professionals and to access health records with the patient’s consent.
Consent to treatment, including for electroconvulsive therapy

For medication, arrangements are largely unchanged (Table 76.9). However, for patients being treated under an SCT, the patient’s consent is required, as is a Second Opinion Appointed Doctor (SOAD) by the Secretary of State for Health (in practice the Care Quality Commission) within a month. If the patient lacks the capacity to consent, others can authorize.

No ECT can be administered, except in an emergency, if a

MHRT, mental health review tribunal.
patient has capacity and refuses. Patients under age 18 years must have consent and SOAD authorization. No ECT may be administered, unless in an emergency, if a patient lacks capacity but has a valid advance decision (AD) refusing ECT or has an attorney who refuses ECT.

Provisions for mentally abnormal offenders
The new definition of mental disorder is wider-ranging, resulting in Sections 48, 36 and 45A now being applicable to patients with all forms of mental disorder. Restriction orders must be indefinite, not time-limited as was possible previously. There are new provisions for sharing certain information with victims, extending this beyond the Domestic Violence, Crimes and Victims Act 2004.

Revised code of practice
This sets out five guiding principles of purpose to inform decisions under the Act – least restrictive alternative, respect, participation and effectiveness, efficiency and equity.

Mental health review tribunals
These are independent bodies consisting of a doctor, lawyer and layperson whose responsibility is to consider the justification for continued compulsion under the 1983 Mental Health Act. The chair of the MHRT is a lawyer, and in the case of restricted patients is a judge.

Patients are allowed legal aid to assist in representation, for example private psychiatric reports can be commissioned.

The MHRT can order discharge or delayed discharge, and recommend (not order) transfer to another hospital or leave of absence. It can also order discharge or conditional discharge (i.e. with conditions such as place of residence) or a deferred conditional discharge (pending the conditions being in place) of a Section 41 restricted patient.

Table 76.10 shows the eligibility for hearings for civil orders. That for forensic orders is shown in Table 76.3.

Patients on a 72-h detention order have no MHRT rights but can appeal against detention to hospital managers.

The Care Quality Commission
This body now incorporates the Mental Health Act Commission (MHAC; Section 121 of the Mental Health Act 1983) and the Social Services Inspectorate. It is an independent body of about 100 part-time members (doctors, nurses, psychologists, social workers, lawyers and laypeople) appointed by the Secretary of State for health. It, as did the MHAC, provides approved doctors to give second opinions on consent to treatment. It receives, reviews and scrutinizes detention documents and exercises a general protective function for all detained patients. It regularly visits psychiatric hospitals to interview detained patients and makes sure that their complaints are being properly handled. It also visits special hospitals monthly and other psychiatric units once or twice a year.

It is responsible for the code of practice (Section 118) on detention, treatment of all psychiatric patients (informal or detained) and consent to treatment, for the guidance of clinical and administrative staff in psychiatric hospitals and social workers.

Court of Protection
Originally empowered by Section 94 of the Mental Health Act 1983, but made a new body under the Mental Capacity Act 2005, this is for the protection and management of the property of mentally disordered patients. Medical evidence that any form of mental disorder renders a person incapable of managing his or her property and affairs can be put to a judge in the special court of protection. If the judge is satisfied, he or she may then appoint a receiver to act on behalf of the patient, keep the patient’s accounts and manage the patient’s affairs. The receiver may be a relative or friend of the patient, a solicitor, a bank trustee or an official solicitor of the supreme court. The patient and their affairs may be checked from time to time by medical and legal visitors appointed by the Lord Chancellor.

Medical visitors must have special knowledge and experience of mental disorder.

The Court of Protection is used especially for dementing patients, but also for people with other mental disorders, such as mania and schizophrenia. In practice, many acutely ill psychiatric patients upon admission are unable to manage their property, but rapid treatment response makes this rather ponderous procedure of the Court of Protection unnecessary.

Patients’ rights under the Mental Health Act 1983
On admission, detained patients must be advised of their legal status, their rights to appeal to an MHRT, their rights in respect of consent to treatment, those who have authority to discharge them, and the Care Quality Commission.

Correspondence to and from informal patients cannot be interfered with. Correspondence from detained patients in ordinary psychiatric hospitals can be withheld only if the person to whom the correspondence is addressed has asked for that to happen. Special hospitals can withhold correspondence to and from patients, except about staff and to solicitors and members of Parliament (MPs) or the sovereign. (In the latter case, correspondence can be sent free of charge as it is the sovereign’s mail.) Patients in any psychiatric hospital must be informed if their correspondence is withheld.

Informal inpatients have voting rights.

Health and social services have a duty to provide aftercare for detained patients when they leave hospital (Section 117).
Mental Health (Scotland) Act 2003

Section 328 defines mental disorder as any mental illness, personality disorder or learning disability. Sexual orientation, sexual deviancy, transsexualism, transvestism and dependency on or use of alcohol or drugs are excluded from this definition. Under the Act, provisions exist for an RMO, an Approved Medical Practitioner (AMP) (Section 22), a Mental Health Officer (MHO) (in practice a social worker), designated Medical Practitioners (DMPs), Mental Welfare Commission and Mental Health Tribunal. All patients have a right to advocacy (Section 259). Advanced statements are possible under Sections 275 and 276.

Part 5 of the Act details emergency detention orders, Part 6 details short-term admission orders and Part 7 community treatment orders for hospital or community.

Mental Health Act (Northern Ireland) Order 1986

Mental illness is defined in the Act as a state of mind that affects a person’s thinking, perceiving, emotion or judgement, to the extent that they require care or medical treatment in their own interests or in the interests of other people. Medical treatment is defined as including nursing and also care and treatment under medical supervision.

There are definitions in the Act for mental handicap, severe mental handicap and severe mental impairment. To be placed in the severe mental handicap category, there must be associated ‘abnormally aggressive or seriously irresponsible conduct’.

It is stated that no person should be treated as having a mental disorder by reason of only a personality disorder, promiscuity or other immoral conduct, sexual deviancy or dependence on alcohol or drugs.

Part II of the Order allows compulsory admission for assessment for up to 14 days before being admitted for treatment. For the purposes of application for detention in Northern Ireland, the nearest relative can be someone living in the Republic of Ireland or the UK. Temporary holding powers are available for voluntary patients already in hospital, as with the English and Welsh, and Scottish Acts. These holding powers are for 6 h by a professionally registered charge nurse and 48 h by a doctor on the staff of a hospital concerned, which also includes a general hospital.

If the patient is not well enough to become a voluntary patient or to be discharged before the end of the 14-day assessment period, they may in the first instance be detained for up to 6 months if they are diagnosed as having mental illness or severe mental impairment and they remain at high risk of serious physical harm to themselves or others. The period of detention is renewable for a further 6 months and then annually, subject to approval, following an examination by a doctor from another hospital appointed by the Mental Health Commission.

Provisions for consent to treatment and guardianship are similar to those set out in the English Act.

Provisions exist similar to those in the 1983 English Act for individuals involved in criminal proceedings; for example, the courts have the power to remand for examination or treatment, and interim hospital orders are also available. Hospital orders may be made regardless of the apparent availability of places, unlike in the rest of the UK, and a court may also impose a restriction order on the patient’s discharge. In all hospital order cases, psychiatrists are expected to give oral evidence in the court.

Individuals detained for 2 years are automatically referred to an MHRT.

The Mental Health Commission, unlike the English equivalent, covers voluntary patients, people in guardianship and people in residential accommodation or, indeed, anybody with a mental disorder. Where it receives complaints, it has the power to hold a formal inquiry in order to establish the facts.

At any one time, Northern Ireland has fewer than ten patients in Britain’s mainland maximum security hospitals. Northern Ireland has no maximum security hospital itself.

Also of note – therapeutic abortion is allowed in Northern Ireland only where there is undoubted grave risk to the continuing physical or mental health of the pregnant woman. This leads to women crossing from Northern Ireland to the British mainland each year to have abortions.

MENTAL HEALTH LEGISLATION IN THE REPUBLIC OF IRELAND

The Central Mental Hospital Dundrum, which opened in 1850, is the only security hospital in the country. It accepts many prison transfers (remand and sentenced) and also the majority of people found ‘guilty but insane’ and people judged ‘unfit to plead’.

The Mental Treatment Act 1945 remained the main mental health legislation in Eire until recently.

Mental Health Act 2001

This replaces the Mental Treatment Act 1945 and the Acts passed in 1953, 1961 and 1981. However, its implementation has been gradual. Section 4 details the principles underlying the Act, including the best interests of the person but with due regard to the interests of others who may be at serious harm.

Definition of mental disorder

Section 3 defines mental disorder as ‘mental illness, severe dementia or significant intellectual impairment’. Compulsory detention should be as a result of (i) mental disorder causing immediate and serious harm to the patient or to other people; or (ii) because of the severity of the mental disorder, the judgement of the person is so impaired that, if the patient is not admitted to an approved centre, would lead to a serious deterioration; or (iii) because detention in an approved centre is likely to benefit or alleviate the condition.

Mental illness means a state of mind affecting thinking, perceiving, emotion or judgement. Significant intellectual disability means a state of arrested or incomplete development of mind, including significant impairment of intelligence and social functioning and abnormally aggressive or seriously irresponsible conduct.

**Other official terms**

Approved centres include in-patient facilities, hospitals and other facilities registered with the Mental Health Commission (MHC). There are Review Tribunals and an Inspector of Mental Health Services who is a consultant psychiatrist appointed by the MHC.
Important sections of the Mental Health Act 2001

These include the following:

- Application for involuntary admission (Section 9)
- Medical assessment (Section 10)
- Power of the Garda to detain and apply for involuntary admission (Section 12)
- Removal to an approved centre (Section 13)
- Admission to an approved centre (Sections 14 and 15).

Part 4 of the Act concerns consent to treatment for patients subject to compulsion.

COMPARISON OF UK AND REPUBLIC OF IRELAND LEGISLATION

Table 76.11 compares civil detention under mental health legislation in the UK and the Republic of Ireland. Table 76.12 compares the legal provisions for mentally disordered offenders in the UK and the Republic of Ireland.

MENTAL HEALTH LEGISLATION IN CANADA

The courts are under provincial jurisdiction. The ten provinces and two territories also have a court of appeal. The highest court, the Supreme Court of Canada, is situated in Ottawa, the national capital. There is a criminal code that covers mentally abnormal offenders, but their management varies between provinces due to their respective mental health legislations. The criminal code does, however, allow a trial judge to remand an offender for forensic psychiatric assessment, and the court of appeal has similar provision.

There are two maximum-security hospitals in Canada, the Mental Health Centre at Penetanguishene, Ontario, and the Institut Philip Pinel in Montreal.

The maximum-security hospital at the Oak Ridge Division of the Mental Health Centre at Penetanguishene has around 200 patients. The majority are warrants of the lieutenant governor patients, having been found not guilty by reason of insanity or involuntarily patients under the Ontario Mental Health Act 1980. Patients who have been stabilized are referred to long-term medium security units. When fit for rehabilitation in the community, such patients may be referred to a university based forensic service, such as the Clarke Institute of Psychiatry in Toronto.

The Metropolitan Toronto Forensic Service (METFORS) is well known for its provision of psychiatric services to the courts and prisons. METFORS has a brief assessment unit and otherwise undertakes standard forensic psychiatric pre-trial assessments and treatments. In Ottawa there is a well-developed clinic for the treatment of and research into sexual offenders, and it has a close relationship with the probation service.

With the provinces and territories having differing mental health legislation, definitions of mental disorder vary between them. The criteria for involuntary civil commitment are wide in all the provinces, except Ontario, where objective evidence of potential dangerousness to self or others is required. Provinces other than Ontario have less stringent admission criteria regarding general health, welfare and safety. Most provinces require certification by two physicians before involuntary admission of a patient to a psychiatric facility. Periods of detention vary with the various mental health acts of the provinces. Most provinces have provision for police officers to take a person for a psychiatric examination and for judges to order that an individual charged with a criminal offence be examined, admitted and treated in a psychiatric facility.

Regarding consent to treatment, an incompetent involuntarily detained patient has the right to refuse all forms of psychiatric treatment in Nova Scotia and Ontario. If found incompetent, consent from the nearest relative is required; in the absence of the nearest relative, review board procedures exist to hear the case and issue treatment orders.

There is considerable variability in the roles and powers of the mental health tribunals of the various provinces and territories of Canada. People found not guilty by reason of insanity or found unfit to proceed with a trial and who are made subject to conditions of a warrant of the lieutenant governor of the province of Ontario are reviewed by an advisory board, appointed by the lieutenant governor in council on at least one occasion every 12 months.

There are provisions under sections of the Criminal Code of Canada to remand a mentally abnormal offender for a psychiatric assessment for fitness to proceed with trial, if that individual is mentally ill or the balance of the individual’s mind is disturbed. The period of assessment is up to 30 days. If the person is deemed not fit to plead or stand trial, then a trial of fitness is ordered. If the person is found unfit, then the court orders that the person be kept in custody until the pleasure of the lieutenant governor of the province is known. Similarly, if found not guilty by reason of insanity, the individual is also made subject to the terms of the lieutenant governor’s warrant and kept in a place of custody. Custody is nearly always a psychiatric facility with either maximum or medium security.

If the offence committed is minor, then a probation order with a condition of psychiatric treatment may be ordered. Some correctional institutions have programmes for psychiatric treatment. If a prisoner becomes mentally ill while serving a sentence, there are provisions in the criminal code to transfer the patient to a psychiatric facility for treatment.

MENTAL HEALTH LEGISLATION IN THE USA

Most aspects of mental health law are delegated to the various states, so that they can enact legislation to suit local needs. Mental health legislation in the USA has been
mental health legislation in Australia and New Zealand

Mental health legislation in Australia and New Zealand

Each of the six states of Australia and its territories has its own separate mental health act and its own judicial system. Australian law is derived from, but is not identical to, the common law of England. Australian and UK mental health services and laws are, however, similar. Much Australian psychiatric care is privately based, with state provision concentrating on patients with severe (psychotic) mental illness. Mental health legislation in Australia has been under constant review over recent years, with new acts drafted and frequent amendments made to earlier acts. The Mental Health Act 1986 of the State of Victoria introduced a community treatment order. This Act, together with the Mental Health Act 1990 of New South Wales, had a significant influence on the development of legislation throughout Australia.

New Zealand has one Mental Health Act, which also has provisions for the compulsory treatment of patients in the community.

KEY POINTS

- Most mentally abnormal offenders are dealt with by ordinary psychiatric hospital facilities as out- or in-patients.
- Special hospitals treat people with mental disorder who are considered to be an immediate and grave danger to the public if they were to abscond, and who cannot be managed under conditions of medium security.
- Medium secure units in England and Wales provide psychiatric treatment under conditions of medium security, greater than ordinary hospitals but less than special hospitals.
- Juvenile delinquency (law-breaking behaviour) is associated with low normal intelligence, large family size, poverty, unsatisfactory child-rearing, parental criminality and troublesomeness at school.
- Up to one in five boys in London may have a conviction by the age of 21 years, and half of indictable crimes are committed by under-21-year-olds.
- Schizophrenia is associated mostly with minor offending secondary to deterioration in personality and social functioning, rather than with serious or dangerous offences or offences arising directly from delusions or hallucinations.
- Depressive disorder is underrepresented among offenders but is associated with homicide and shoplifting.
- Morbid delusional sexual jealousy is associated with repetitive and serious violence to the individual’s partner.
- In the UK, most mentally abnormal offenders stand trial. If found guilty, they are convicted, but medical evidence is given in mitigation to alter the sentencing of the court, e.g. a hospital treatment order may be recommended instead of a custodial sentence.
- Some offences require specific guilty intent (mens rea) as well as an unlawful act (actus rea), e.g. murder, rape, arson. Other offences do not require proof of guilty intent, e.g. motoring offences (i.e. on the basis of non-specific intent).
- Fitness to plead refers to the time of the trial, not of the offence.
- Not guilty by reason of insanity (the special verdict) refers to the time of the offence. The grounds (McNaughten Rules) are that, by reason of such defect of the mind, the subject did not know the nature or quality of the act, or did not know that what he or she was doing was wrong (forbidden by law).
- Diminished responsibility (Homicide Act 1957) is only a defence to a charge of murder that carries a mandatory life sentence. It refers to

shaped by social and political forces and case law. The emphasis has always been on the least restrictive treatment. Involuntary psychiatric treatment has been considered in many ways out of keeping with the US constitution and philosophy of upholding the individual’s rights of freedom, speech and behaviour.

In the past 30 years, there has been a trend away from detention (certification) on grounds of need for treatment and towards increasing patients’ rights and restricting involuntary treatment. This, together with a desire to reduce the number of in-patients and the cost of their care, has led to the general adoption as a criterion for detention a standard of future or potential dangerousness to the patient or others, rather than grave disability, for reasons of health alone or the patient’s need for treatment. Emergency hospitalization can be initiated without prior judicial approval, but subsequent commitment needs to be ordered by a judge.

Involuntary patients have the right to refuse medication. Medication to control dangerous patients in an emergency has been sanctioned if the need to prevent violence outweighs the possibility of harm to the patient and all less restrictive alternatives have been ruled out. If the patient is not dangerous, then in many states the only way to enforce medication is to have the patient declared incompetent, whereupon treatment conditions can be made, often on the basis of what the patient would have decided were he or she competent to do so rather than what might be in the patient’s best interests.

In keeping with the idea of the least restrictive treatment, orders allowing out-patient committal to psychiatric treatment have emerged in nearly all states. This assists the standard of future or potential dangerousness to the patient or the general adoption as a criterion for detention a standard of future or potential dangerousness to the patient or others, rather than grave disability, for reasons of health alone or the patient’s need for treatment. Emergency hospitalization can be initiated without prior judicial approval, but subsequent commitment needs to be ordered by a judge.

Involuntary psychiatric treatment has been considered in many ways out of keeping with the US constitution and philosophy of upholding the individual’s rights of freedom, speech and behaviour.

In the UK, most mentally abnormal offenders stand trial. If found guilty, they are convicted, but medical evidence is given in mitigation to alter the sentencing of the court, e.g. a hospital treatment order may be recommended instead of a custodial sentence.

Some offences require specific guilty intent (mens rea) as well as an unlawful act (actus rea), e.g. murder, rape, arson. Other offences do not require proof of guilty intent, e.g. motoring offences (i.e. on the basis of non-specific intent).

Fitness to plead refers to the time of the trial, not of the offence.

Not guilty by reason of insanity (the special verdict) refers to the time of the offence. The grounds (McNaughten Rules) are that, by reason of such defect of the mind, the subject did not know the nature or quality of the act, or did not know that what he or she was doing was wrong (forbidden by law).

Diminished responsibility (Homicide Act 1957) is only a defence to a charge of murder that carries a mandatory life sentence. It refers to
the time of the offence and is on the grounds of the presence of abnormality of mind … which substantially impaired mental responsibility for the act. It results in a reduction of the charge to manslaughter, which allows discretionary sentencing, including a hospital order.

- Infanticide is the unlawful killing of a child of under 1 year of age by the child’s mother at a time when the balance of her mind was disturbed due to giving birth or from lactation.
- In general an individual is regarded as legally fully responsible if he or she knowingly took, or was voluntarily intoxicated with, drugs or alcohol unless offence requires specific intent which may be ‘negated’ by intoxication.
- Annesia itself is not a legal defence, although the underlying condition may be. Annesia may reflect lying, hysterical denial, over-arousal preventing registration, alcohol or drug intoxication, or head injury.
- Risk varies not only with the individual but also with the context and over time; it is not a static characteristic, as it is implied by the now less often used term ‘dangerousness’.
- Risk of dangerous behaviour is increased by the presence of substance misuse, the availability and use of weapons, morbid jealousy and the sadistic murderer syndrome.
- Short-term prediction is better than that for the longer term.
- Past behaviour is the best predictor of risk for non-mentally ill people, but for mentally ill people positive psychotic symptoms, such as paranoid delusions and delusions of passivity, are better predictors.
- When risk is identified, a risk-management plan should be developed, but this may not result in risk elimination.
- Most shoplifting offenders are now male. The peak age of offending is 10–18 years.
- About 5 per cent of shoplifters have a formal psychiatric disorder.
- Shoplifting may be an early symptom of depressive disorder or dementia.
- Pathological stealing (kleptomania) is an impulse-control disorder characterized by recurrent failure to resist impulses to steal objects not needed for personal use or monetary gain. It is present in only a minority of shoplifters.
- Arson is unlawfully or maliciously (wilfully) destroying or damaging property by setting fire.
- A more serious charge is arson with intent to endanger life.
- Arson may be motivated for psychotic reasons, or by displaced revenge, anger or jealousy.
- Alternatively, arson may be due to fire being a thing of interest to the fire-setter, as in the impulse disorder pathological fire-setting (pyromania).
- Abused children are usually under 3 years of age and present with multiple injuries in time and space.
- Delay in reporting and contradictory histories of injuries are often given by the parents.
- Abusive parents have often been abused themselves as children.
- High professional awareness is required to allow early recognition.

- Multidisciplinary case conferences are essential for management, and placement of the child on a local authority child protection register may be required.
- In the assessment of violence:
  - Ask informants about a history of violence.
  - Request previous summaries, e.g. of in-patient care, and past psychiatric and probation reports.
  - Document above and otherwise keep and use proper records.
  - Make plans to manage the risk, and document this.
  - Be particularly cautious in cases where treatment is refused, reduced or withheld.

INTRODUCTION

Psychiatry and the law are connected. The law must protect not only the patient but also society, and this raises the problem of individual liberty of the patient (the autonomy of the patient, e.g. concerning consent) versus, among other matters, the compulsory treatment of patients against their wishes (the duty of care of the doctor, e.g. to avoid negligence) – that is, the dilemma between the compulsory care and treatment of mentally disordered people and their rights. This balance has varied through history and varies between countries.

Law

Law is the body of rules sanctioned formally by parliament and the courts and administered by legal fora. It is important to distinguish psychiatric terms and diagnosis, such as schizophrenia, from legal concepts, such as not only particular crimes but also legal diagnostic categories, for example abnormality of mind, giving rise to diminished responsibility, and mental disorder. For instance, the legal concept of psychopathic disorder used in the Mental Health Act 1983 before it was amended by the Mental Health Act 2007 did not equate to the clinical diagnosis of psychopathy. Morality also does not equate with legality, and vice versa.

Legal sources

Common law arises out of common customs developed by judicial court decisions. This results in the law continuously evolving through precedents and exceptions established in court.

Equity refers to the principles of justice in cases not covered by statute or common law.

Legal fields

In criminal law, the state initiates proceedings on behalf of society against an individual where Parliament and other courts have defined an activity as a crime. It includes the offences of murder and manslaughter on grounds of diminished responsibility.

Civil law relates to citizens’ rights and civil wrongs and involves one individual against another as regards any matter defined by parliament or the courts as civil, including the Mental Health Act 1983.

The law courts (legal fora)

Criminal courts

Criminal courts include the following:

- Magistrates’ courts deal with over 98 per cent of all criminal prosecutions in England and Wales – hence, the usefulness of psychiatric magistrate court division schemes. They try cases ‘summarily’ – that is without a jury
- Crown Courts include the Central Criminal Court (the Old Bailey). They are for more serious indictable offences, where cases are tried by a jury
- Appeal Courts (criminal division) e.g. the Courts of Justice in the Strand
- The Supreme Court of the UK, which replaced the House of Lords (Judicial Committee) in 2009.

The UK system of law is adversarial (in contrast to many European inquisitorial systems, which are based on the Napoleonic Code). If called to give evidence, for example by the defendant’s legal advisors, then a witness will initially undergo an examination-in-chief by the legal advisors, followed by cross-examination, in this case by the prosecution, and then a re-examination. It is important for doctors not to overstate their professional views and for them to indicate clearly the limits of their opinion and in what areas they cannot comment. In most cases, a psychiatrist is able
to give his or her opinion to the court in a report. Oral evidence is usually required only where there is dispute regarding medical evidence, for example over diminished responsibility, or where oral evidence is legally required, for example in supporting an individual being made subject to restrictions under Section 41 of the Mental Health Act 1983 in England and Wales.

A magistrate should be addressed as ‘your worship’, a judge in a Crown Court as ‘your honour’ and a High Court judge as ‘my lord’. Barristers address a judge as ‘my lud’, a fellow barrister as ‘my learned friend’ and a solicitor as ‘my friend’.

Civil courts

Civil cases are dealt with mainly by County Courts, although a few matters are heard in magistrates’ courts, for example domestic cases such as maintenance payments. More serious cases are heard in the High Court, including the Courts of Justice in the Strand in London. In County Courts and High Courts, the case is usually heard before a single judge and only rarely in front of a jury, for example in cases of defamation. The single judge when sitting without a jury will therefore decide on both the facts and the law.

The High Court is divided as follows:

- The Queen’s Bench Division, which deals with most cases such as contracts and damages
- The Chancery Division, which deals with financial matters, company law, tax, trusts and wills
- The Family Division, which deals with adoption, divorce and wardship.

There is also an Appeal Court.

The Supreme Court of the UK, which replaced the House of Lords in 2009 as the final UK civil court, considers appeals on grounds of points of law only.

In civil courts the plaintiff seeks ‘remedy’ to alleged injuries such as damage, including psychiatric damage. Damages are to compensate, not punish – hence, damages will be greater for brain damage than for death. Nominal damages may be awarded, for example if a bad reputation is not damaged further by libel or slander. The Criminal Compensation Board is a civil court. Most civil cases are settled before they come to court or at the court before a hearing. The defendant will pay the costs if he or she pursues a case to a court hearing and is not awarded a sum greater than a settlement offered before the court hearing.

Appeals can be made to the European Court of Justice on points of European Law and on questions of citizens’ rights.

Civil psychiatric court reports

Psychiatrists are usually placed under greater scrutiny in civil than criminal cases, and their evidence is more often discredited. It is often prudent to refer to accepted classifications such as the tenth revision of the International Classification of Diseases (ICD-10), e.g. severe, moderate or mild depressive episode, and the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), although the court will take note of a psychiatrist’s experience if a case is atypical. The prognosis in civil cases is usually very important with regard to damages.

Juvenile courts

These deal with juvenile criminal and care/residence order proceedings.

A juvenile court is composed of a special panel of three magistrates, one of whom is usually a woman. The defendant’s name must not be disclosed by newspapers or other media without the court’s permission.

Coroners’ courts

Coroners should be called ‘sir’ when being addressed. If a coroner ‘invites’ you to attend, then attendance is mandatory. It is the court most often attended by the medical profession. Under Rule 22, the verdict must not be framed in a way to determine civil liability.

Mental health review tribunals

These tribunals are quasi-judicial courts. Their decisions can be appealed against at the High Court Queen’s Bench Division, and subsequently in courts above.

Note the difference in burden of proof between criminal courts (beyond reasonable doubt) and civil courts (on the balance of probabilities). For example, an individual may be found not guilty of criminal paedophile offences but may have his children removed from him by a civil court.

PSYCHIATRIC OPINIONS IN CIVIL LAW (CIVIL CAPACITY)

The burden of proof in such matters is on the balance of probabilities.

Issues of mental fitness

Contracts

Contracts require free full consent. If an individual is of unsound mind (not equivalent to being detained under the Mental Health Act 1983) at the time of making a contract, then that contract is regarded as void. However, ‘mentally incapable’ people are bound by contracts unless the other party or parties to the contract knew or should have known of the individual’s incapacity. Under employment law an individual can be dismissed only for behavioural effects of mental disorder, not for mental disorder itself.

Testamentary capacity

This is the ability to make a valid will. To do this in the UK, individuals must be over the age of 18 years and not be of ‘unsound mind’.

This becomes an issue either at the time the individual
makes a will, where a solicitor may ask for medical, including psychiatric, advice, or after the individual's death. Accurately assessing the capacity of a person to make a will would prevent the current high levels of litigation in this area.1

If a patient decides to make a will, then they may ask the doctor attending them to witness the will, particularly if the patient is seriously ill. Doctors should be aware they will be regarded in law as not acting as mere lay witnesses. If a doctor does agree to witness the will, then he or she is said to have 'attested the will', which implies that the doctor considers the patient to be of 'sound disposing mind and memory'. This is most often undertaken by a general medical practitioner rather than a psychiatrist. If the will is subsequently contested, the doctor may be required to appear in court to give evidence about the patient's mental state at the time the patient made the will.

Although not specifically defined in law, to have a 'sound disposing mind' by custom (based on Banks v. Goodfellow (1870)), the individual must:

- know the nature and extent of his property, although not necessarily the details;
- know all people and their names having a claim on his bounty, and the relative strength of their claim (e.g. bearing on the distribution between people);
- have no morbid state of mind that might distort his or her natural feelings and influence his or decisions;
- have the ability to realize the nature of a will and its consequences;
- be able to express him- or herself clearly and without ambiguity.

The presence of mental disorder, such as mild dementia, does not necessarily affect testamentary capacity, although if the will is complex it may do so. Testamentary capacity, however, may be severely affected if the individual has paranoid delusions about an individual who would normally be considered to have a claim on his or her property. The 1826 case of Dew v. Clark established, however, that even if one was deluded (in this case, believing he was being pursued by evil spirits), this did not necessarily preclude an individual from having testamentary capacity.

If an individual dies having left a will, then they die 'testate' and a grant of probate enables the executor or trustee to administer the will. Wills must be in writing, except if on 'actual military service'. Wills must be made without force, fear, fraud and undue influence. A person making a will is a testator or testatrix. The similarity of such words to testes is not by chance. The ancient Romans swore oaths by placing their fingers on the testes. The relevant law is the Administration of Estates Act 1982.

Marriage

Marriage is a contract, so that if an individual has a mental disorder at the time so as not to appreciate the nature of the contract, then that contract is 'voidable' (not void). Lack of valid (competent) consent is rare, as most mentally disordered individuals appreciate the nature of marriage.

A marriage may be annulled if:

- one partner has a mental disorder at the time of the marriage so as not to appreciate the nature of the contract;
- one partner did not disclose that he or she had epilepsy or a communicable venereal disease;
- either party was under 16 years of age at the time of marriage;
- pregnancy by another male at the time of marriage was not disclosed;
- there was non-conssummation (no intromission of the penis);
- one of the partners was forced to agree to the marriage under duress.

Marriage continues until challenged successfully in the courts by one of the parties, resulting in the marriage being deemed 'voidable'.

Legal capacity to marry is different from the legal capacity to have sexual relations.

Apart from an inability to give valid competent consent, an individual may be deemed, even if he or she can give valid consent, as unable to marry due to ‘unfitness for marriage’ – that is, having a mental disorder in terms of the definition of the Mental Health Act 1983, resulting in an incapacity to carry out the ordinary duties of marriage (not just be ‘difficult to live with’). For a marriage to be ‘voidable’ on such grounds, the individual must be incapable of living in a married state or carrying out the ordinary duties of marriage. Psychiatric grounds must be substantial. A registrar will only rarely refuse to marry on the basis of unfitness for marriage but will more commonly do so on the basis of incapacity to consent. Any person, including a doctor, may enter a ‘cavial’ pre-marriage with a superintendent registrar, who must then investigate it.

Sexual relationships between in-patients

Article 8 of the European Convention on Human Rights secures the right of all to respect for private and family life, which is taken to include sexual relationships between patients.

In practice, competent detained in-patients are not precluded from marriage, but secure hospitals, such as special hospitals in the UK (e.g. Broadmoor Hospital), have, on the basis of need for rules governing in-patients, successfully resisted to date the right of such in-patients to have provisions made for sexual relations between them.

The United Nations (UN) Declaration of Rights of Mentally Retarded Persons (1971) gives the right of mentally disabled people to live with their own family. It does not specifically refer to sexual relations, but it is taken to imply this.

It is illegal for male staff to have a sexual relationship with a patient, a male guardian with a subject of a
guardianship order, and anyone with a patient with ‘severe mental handicap’ in the UK.

Divorce
This is covered by the Matrimonial Causes Act 1973. Mental disorder may affect the capacity to consent to divorce. Non-consensual divorce is achievable only on the basis of behaviour as specified in the Matrimonial Causes Act. Thus, mental disorder is the basis for divorce only when it results in the relevant legal behaviour – that is, adultery, unreasonable behaviour (which replaced the term ‘cruelty’), desertion and living apart for more than 2 years if the respondent consents or for 5 years without consent (irretrievable breakdown). ‘Quickie’ divorces are based on filing affidavits, in contrast to divorces defended in court. Mental disorder most often leads to divorce by causing an irretrievable breakdown in marriage due to unreasonable behaviour.

Issues relating to the children of marriage following divorce are governed by ‘supremacy of the interest of the child’. Separation/divorce usually results in residence, which replaced the term ‘custody’, of the children with the mother, unless, for example, mental disorder, among other factors, ‘affects her capacity to love and care for the child’. Contact has replaced the term ‘access’, and the Child Support Agency has taken over many of the past roles of lawyers contesting financial issues related to childcare in court.

A Care Order (Children and Young Persons Act 1989) is taken out where a parent, or the parents, cannot safely care for the child – that is, on grounds of actual, or risk of, serious harm and this is attributable to care. Objective, especially current, behavioural evidence carries more weight than predicted behaviour in court.

Tort
This is a civil wrong to a person, a reputation or the estate of an individual, for example libel, slander, fraud, trespass, negligence or breach of copyright. Mentally disordered individuals are considered incapable of committing a tort unless the disorder does not preclude them understanding the nature or probable consequences of their acts. Defamation, which covers slander (spoken) and libel (written, but also includes spoken words on television, film or video), is not eligible for legal aid and is heard and adjudicated (e.g. amount of damages) by a jury – hence, the occasional huge damages in such cases awarded by a jury. Defences include ‘justification’, ‘fair comment’ and ‘mere vulgar abuse’.

Mentally disordered people as witnesses
Mentally disordered individuals may give evidence in court or make a written statement, but it is for the magistrates or the judge to determine whether they are fit to do so and can understand the nature and obligation of the oath. To this end, medical evidence may be called for and the jury will have to consider how much weight to attach to the witness’s evidence.

Certificate or report of sanity
This may be required for the purposes of a mental health review tribunal, when making a will, when signing legal documents or to rescind receivership.

*Always read carefully and consider with great care any document given to you to sign, because of the risk of legal or professional General Medical Council (GMC) proceedings if you don’t.*

Power of attorney and enduring power of attorney
These remain legally valid if set up before the Mental Capacity Act 2005, which introduced the lasting power of attorney.

A power of attorney is a means whereby one person (the donor) gives legal authority to another person (the attorney or donee) to manage the donor’s affairs.

An ordinary power of attorney is automatically revoked by law when the donor loses his or her mental capacity to manage and administer his or her own property and affairs, and accordingly the attorney’s authority to act under the power then ceases.

Unlike an ordinary power of attorney, an *enduring power of attorney* (EPA; introduced in 1986 after the Enduring Powers of Attorney Act 1985) may continue in force after the donor has lost his or her mental capacity to manage and administer his or her financial affairs, provided it has been registered with the Public Trust Office.

*Guardianship* may be useful to help someone over age 16 years having difficulty with looking after themselves.

An *appointee* is someone authorized by the Department of Social Security in England and Wales to receive and administer benefits on behalf of someone else.

An *advocate* has no formal legal status.

Mental Capacity Act 2005 of England and Wales
The main provisions of this Act are as follows:

- **Designated decision-makers for people who lack capacity:**
  - Lasting power of attorney (LPA) – these are like EPAs but can make health and welfare decisions
  - Court appointed deputies – these replace receivership in the Court of Protection. They can make decisions on welfare, healthcare and financial matters, but they cannot refuse consent to life-sustaining treatment.

- **Two new public bodies:**
  - A new Court of Protection
  - A new Public Guardian will:
    - register LPAs and deputies;
    - supervise deputies;
    - be scrutinized by a Public Guardian Board.

- **Three provisions to protect vulnerable people:**
  - Independent mental capacity advocate (IMCA)
  - Advance decisions to refuse treatment, including, if expressly stated, ‘even if life is at risk’
  - New criminal offence of ill-treatment or neglect of a person who lacks capacity.
**Introduction into law**

- IMCAs became available on 1 April 2007.
- The code of practice and the criminal offence of ill-treatment and wilful neglect became law in April 2007.
- From October 2007, all other elements of legislation, including the new Court of Protection, Public Guardian and Office of the Public Guardian, became operational.
- Deprivation of liberty safeguards (MCA DOLs) became law in April 2009.

**Scope of the Act: exclusions under Section 27**

No decision on the following is to be made on behalf of a person:

- Consent to marriage, civil partnership or sexual relations
- Consent to divorce/dissolution of a civil partnership on the basis of 2 years’ separation
- Consent to a child being placed for adoption or making of an adoption order
- Discharging parental responsibilities in matters not relating to a child’s property
- Consent under the Human Fertilisation and Embryology Act 1990.

Treatment of detained patients under the Mental Health Act 1983 is separate from the Mental Capacity Act. Mental Health Act 1983 consent to treatment provisions apply.

**Capacity**

A person may lack capacity:

- at the material time;
- if he or she is unable to make a decision for him- or herself in relation to the matter;
- because of an impairment of, or a disturbance in the functioning of, the mind or brain (Section 2).

It does not matter whether the impairment or disturbance is permanent or temporary.

**Impairment or disturbance**

The impairment or disturbance may occur in a wide range of situations ... people who are affected by ... alcohol or drug misuse ... delirium ... following head injury ... mental illness ... dementia ... learning disabilities ... long-term effects of brain damage ... grave physical conditions producing confusion, drowsiness or loss of consciousness including as a result of treatment [from the Code of Practice].

**Able to make a decision?**

Under Section 3, individuals should be able to:

- understand information relevant to the decision, including potential consequences of different decisions;
- retain that information for long enough to make a decision – not permanently;
- use that information to make a decision;
- communicate the decision, including by gesture or sign language.

A surprising or unwise decision does not of itself indicate lack of capacity.

**Statutory principles**

Under Section 1(1):

- everyone is assumed to have capacity, unless shown otherwise;
- no one is to be treated as unable to make a decision unless all practicable steps to assist have failed;
- a person is not to be treated as lacking capacity only because he or she makes an ‘unwise’ decision;
- any act or decision on behalf someone who lacks capacity must be done in his or her best interests;
- before any act, there must be consideration of whether the objective can be as well achieved in a less restrictive way.

**Section 4: best interests**

One must consider all the relevant circumstances, in particular the following:

- Involve the person if possible in any decision
- Other wishes/beliefs, made with capacity, or values that indicate preference
- Anyone already nominated, or any carers, etc., e.g. lasting power of attorney or court appointed deputy
- Likely to regain capacity? If so, when?
- Not to seek the subject’s death where the decision relates to life-sustaining treatment; consider whether is in the best interests of the person concerned. (‘Life-sustaining treatment’ is treatment that the provider clinician considers necessary to sustain life.)

**Section 4(a): a reasonable belief**

There is sufficient compliance with the best interests requirement if (having complied with the requirements of Section 4) the person making the determination reasonably believes that what he or she does or decides is in the best interests of the person concerned.

**New process for making decisions**

- Advance decision (AD)
- Lasting power of attorney donee (LPA)
- Section 5
- Court of Protection or court appointed deputy (CAD).

**Advance decisions (Section 24)**

An AD is a decision made by an adult with capacity that if:

- at a later time a specified treatment is proposed to be carried out by a person providing health care; and
- at that time he or she lacks capacity to consent to that treatment,

then the specified treatment is not to be carried out or continued.

An AD is not necessarily binding if the following tests are met:

- **Capacity test:** if the person still has capacity to consent to the treatment proposed
• **Validity test:** if the person withdrew the AD at any time when able to do so, or has done anything clearly inconsistent with the AD

• **Applicability test:**
  - Not the treatment specified in the AD
  - Any specified circumstances are absent
  - Reasonable grounds for believing that important unforeseen circumstances exist, not anticipated at the time of the AD

• **Life-sustaining threshold:** an AD is not applicable to life-sustaining treatment unless it is verified by a statement to the effect that it is to apply to that treatment even if life is at risk, and the decision is in writing, signed and witnessed.

**Lasting power of attorney (Section 9)**

An LPA is a power under which the donor confers on a donee or donees authority to make decisions about:

- his or personal welfare or specific aspects thereof; and
- his or her property and affairs or specified aspects thereof.

This includes authority to make such decisions in circumstances where the donor no longer has capacity.

The authority conferred by an LPA is subject to:

- any conditions or restrictions specified in the document;
- the provisions of the Mental Capacity Act and, in particular, Section 1 (Principles) and Section 4 (Best Interests).

**Section 5: liability for care or treatment**

Where the Section 5 conditions are satisfied, someone who does an act ‘in connection’ with an incapacitated person’s care or treatment will incur legal liability only if the act would have been unlawful if it was done with consent; as an example, negligent acts are not protected.

Section 5 conditions are as follows:

- The act is ‘in connection with’ care or treatment.
- The person doing it takes reasonable steps to establish whether the subject has capacity.
- The person reasonably believes that the subject lacks capacity.
- The person reasonably believes that the act is in the subject’s best interests.
- If restraint is used, then the person reasonably believes that it is necessary to do the act in order to prevent harm to the subject and that the act is a proportionate response to the likelihood of the subject’s suffering harm and the seriousness of that harm.

Restraint is the use, or threat of use, of force to achieve an outcome, or restriction of liberty of movement, whether or not resisted.

**The Court of Protection and its elements**

The Court is assisted by:

- the Public Guardian;
- the deputies;
- the Court of Protection visitors.

*Section 16 powers of the court: where a matter concerns personal welfare or property and affairs, and a person lacks capacity in relation to it, then the court may decide the matter or appoint a deputy (CAD) to make decisions about where to live, contact with others and medical treatment.*

Powers of the court over property and affairs include:

- managing, buying and selling property;
- trade, profession, business and partnership matters;
- contracts and debts;
- wills and trust powers;
- legal proceedings.

**Advocacy and Independent Advocacy Service (Section 35)**

The appropriate authority must arrange for IMCAs to be available to support people to whom decisions proposed under Sections 37, 38 and 39 relate:

- **Section 37:** serious medical treatment
- **Section 38:** accommodation provision by National Health Service (NHS)
- **Section 39:** provision of accommodation by local authority.

Exceptions include where there is:

- a person nominated by the subject (in whatever manner) to be consulted in matters affecting his interests; or
- a donee of an LPA created by the subject; or
- a deputy appointed by the court (CAD) for the subject; or
- a donee of an EPA created by the subject under earlier legislation.

In such circumstances, the duty to consult an IMCA in relation to decisions under Sections 37–39 does not apply.

**Deprivation of liberty safeguards**

The Mental Health Act 2007 updated existing mental health legislation and was used as a vehicle for introducing the deprivation of liberty safeguards into the Mental Capacity Act 2005. The new safeguards provide a framework for the lawful deprivation of liberty of people who lack capacity to consent to arrangements made for their care or treatment in either a hospital or care home, and who need to be deprived of liberty in their own best interests in order to protect them from harm.

The Mental Capacity Act 2005 Deprivation of Liberty Safeguards (MCA DOLS) are a response to a European Court of Human Rights (ECtHR) judgment in October 2004 in the Bournwood case of HL v. UK. The court found that a man with autism and a learning disability, who lacked the capacity to decide about his residence and medical treatment, and who had been admitted informally to Bournwood Hospital, was unlawfully deprived of his liberty in breach of Article 5 of the European Convention on Human Rights (ECHR).
The MCA DOLS remedy to the breach of the ECHR is perceived as a major step towards better protecting the rights of vulnerable individuals in hospitals and care homes. They will make a big difference to the people in care who have no or only limited choice about their life. However, there is no doubt that implementing the safeguards will be challenging for care homes, primary care trusts (PCTs) and NHS trusts.

In the main, the people covered by the safeguards will be those with severe learning disabilities, older people with one of a range of dementias, and people with neurological conditions such as brain injury. The safeguards apply only to those people not covered by the Mental Health Act 1983.

The safeguards apply to people in hospitals, including independent hospitals, and care homes registered under the Care Standards Act 2000, whether they have been placed there by a PCT or a local authority or through private arrangements.

The MCA DOLS apply to people in hospitals and care homes who meet all of the following criteria. The person must:

- be aged 18 years or over;
- have a mental disorder such as dementia or a learning disability;
- lack capacity to consent to arrangements made for their treatment or care;

**Figure 77.1** Overview of the deprivation of liberty safeguards process
• need to have their liberty taken away in their own best interests in order to protect them from harm.

Figure 77.1 gives an overview of the deprivation of liberty of safeguards process.

ISSUES OF PSYCHIATRIC DAMAGE

Normal ordinary emotional reactions such as grief are not eligible for compensation, but ‘psychiatric damage’ (legal term ‘nervous shock’) is. Issues regarding psychiatric damage have arisen in cases of post-concussional syndrome, accident and compensation neurosis, malingering, victims of torture, pathological grief and, since 1989, post-traumatic stress disorder, following the sinking in the English Channel of the ferry Herald of Free Enterprise. The vulnerability of the complainant is not relevant (e.g. an ‘eggshell skull’ is no defence) and the defendant must take the plaintiff as they find him or her. Dissociative (conversion) disorders constitute psychiatric damage, but malingering does not, although in practice there is a spectrum between these conditions and it is thus important to assess the degree of unconscious production of symptoms. In general, symptoms persist longer, the longer it takes to settle a case, regardless of whether there are issues of compensation or not.

Cases arising from the Hillsborough football stadium fire in Sheffield, England in 1988 led to rulings that symptoms are eligible for compensation if they result from the individual being directly subjected to the trauma, from seeing in real life a close (first-degree) but not a distant (e.g. nephew, fiancé) relative being killed, from seeing the killing of a close relative broadcast on television, and from hearing about this from a third person such as a police officer. Symptoms attributed to news about those not related, for example learned from the radio or from watching a recording of the disaster on a television programme, did not lead to compensation. In fact, police officers attending the scene were compensated before these cases were heard.

For psychiatric damage an individual must have a psychiatric illness. Psychiatric damage can be:

• secondary to physical sequelae, e.g. after loss of a limb;
• primarily psychological;
• psychological but secondary, such as witnessing the fate of another person, e.g. a lecturer having a heart attack.

A psychiatrist must define the mental disorder and give a prognosis, which is very important in cases of damage. The court then puts a ‘tariff tag’ on the disorder and prognosis.

Psychiatric negligence (a tort)

There are three elements:

• A duty of care to a ‘neighbour’ (with whom the defendant has a natural relationship): this applies to the NHS in the UK. If an individual is under private care, then he or she can also sue for breach of contract
• Breach of duty of care: this includes technical and advice errors
• Damage to other party results: i.e. foreseeable and would not have happened anyway.

The onus of proof is on the plaintiff to prove that a breach of duty of care caused damage.

An individual is usually judged by the standards of his or her professional peers or by a professional standard. Costs may result from nervous shock, cost of care and loss of work.

The following are some common causes of psychiatric negligence in order of frequency, according to UK medical defence societies:

• Suicide or attempted suicide (50%): this is due to failure of assessment or management. Proper care should have been present. If suicide is not prevented, then the presence of good operational suicide policies, documentation of suicide risk and management plans to counter it in the medical records, and the informing of all relevant staff, such as nursing staff, of the suicide risk will be defences.
• Negligent use of drugs (30%): this arises from the wrong drug being prescribed, the patient not being monitored properly or not being warned properly, or no proper consent procedure being followed. This arises particularly where drug toxicity results. For example, with lithium:
  • Delays in laboratory telling doctor result
  • Failure to check patient’s thyroid and renal functioning
  • Failure to monitor blood levels
  • Most due to use of diuretics.
• Misdiagnosis: especially failure to diagnose organic disorders.

Other causes include homicide by a patient, sexual misconduct of a doctor, breach of confidentiality and lack of supervision (advice, instruction, monitoring and control), for example by a consultant of a trainee. In practice, a doctor should never have a relationship with even an ex-patient.

Cases are scrutinized to see whether ‘reasonable care’ compared with that of professional peers was present – that is, that the clinician used reasonable clinical judgement to weigh up the risks of illness, treated or untreated, and the risks of treatments or also alternative treatments and their risks.

An error of judgement or mistake becomes negligent if an individual did not exercise reasonable care. Psychiatrists as a specialty consult medical defence associations frequently but are not among the medical specialties at high risk of litigation.

Negligence cases arise from:

• the dereliction of duty directly causing damage to plaintiff (the ‘4Ds’ of US law);
• a bad outcome plus bad feelings, e.g. guilt, rage, grief, surprise.

It remains likely that, in spite of the current litigious culture, psychiatry is no different from other medical specialties in that, for every case of negligence brought, many more meritorious cases are not.

Medical records
If a risk is identified and documented, then it is incumbent on the psychiatrist to manage that risk and to record a management plan, for example to tell staff of the risk. The importance of good medical records is rightly emphasized as a way of countering litigation – ‘if it’s not recorded, it didn’t occur’. However, psychiatrists will often have the opportunity to expand on their written records, for example if cross-examined in court. Merely recording the patient as saying that he or she is ‘not homicidal’ or ‘not suicidal’ in the records would not prevent successful litigation if other evidence suggested otherwise; for example, a suicidal patient may deny being at risk of suicide but clearly be at risk of committing suicide on the basis of admitted symptoms of severe depression. NHS medical continuation sheets have letters and numbers at the base of the page, which give some indication of the age of the sheet, and this can sometimes reveal when entries are made inappropriately after an adverse event.

LEGAL PRINCIPLES UNDERLYING MENTAL HEALTH LAW
In Western countries, mental health law originates from the efforts by the state in the early nineteenth century to protect the public from violent acts of ‘mad’ people. Subsequently, laws developed to protect vulnerable mentally ill individuals from their own neglect or self-harm and from abuse or exploitation by others.

Political ideology has influenced psychiatric services, even in the past 50 years; for example, in the Soviet Union, a diagnosis of ‘slow schizophrenia’ was used to detain political dissidents, and in Italy ‘Law No. 10’ sought to close mental hospitals.

International declarations and principles relevant to the involuntary admission and treatment of mentally ill people include the following:

- The European Convention for the Protection of Human Rights and Fundamental Freedoms (1953)
- United Nations Principles for the Protection of Persons with Mental Illness and for the Improvement of Mental Health Care (1991), and its international covenant on civil and political rights.

Cases brought by individuals against their governments at the Court of Human Rights in Strasbourg led to the committee of ministers of the Council of Europe enunciating further principles – Recommendations for the Legal Protection of Persons Suffering from Mental Disorders Placed as Involuntary Patients (1983).

Internationally approved principles include the following:

- Detention can only be by procedure defined in law.
- The individual or their representative must be informed of a decision to detain and the reasons for it.
- There should be a review of decisions to detain by an independent body, including independent from the state.
- The individual has a right of appeal against detention.
- Mental disorder should not include social non-conformity alone.
- Mental disorder should be of sufficient severity to justify the initial deprivation of liberty and the continuation of detention.
- Detention should be reviewed at regular intervals.
- Circumstances and facilities of detention should be approved by law for that purpose, and such premises should be inspected regularly by an independent body.

Other issues highlighted have included the need for a legal framework to cover the following:

- Consent to treatment by detained patients
- Validity of detaining those for whom no effective treatment or resources exist
- Compulsory treatment in the community.

The World Health Organization (WHO) in 2003 described general principles for the development of mental health legislation. These include the following:

- The ‘least restrictive alternative’ principle applies.
- If institutional treatment is required, then voluntary admission should be encouraged, with involuntary care being used only in exceptional circumstances.
- Information gathered should be treated as confidential.
- Free and informed consent to treatment should be available. Treatment without consent should be undertaken only in exceptional circumstances, for example involuntary patients lacking capacity to consent and where treatment is required to improve mental health or prevent deterioration in mental health or prevent risk of harm to self or others.
- The rights of involuntary patients are protected by rights of appeal against involuntary care and the ability to obtain a second opinion.
- Legislation should state explicitly the circumstances under which involuntary admission should be considered.
- Provision should be made for automatic independent review of involuntary admission or treatment.
- Guardians should be appointed for people not capable of making decisions.
- Involuntary treatment in the community should be considered.
Legislation may also lay down the framework for delivery of psychiatric services nationally, for example statutory requirements on local health authorities to provide services. Legislation alone generally does not improve services without corresponding funding. Legal safeguards should not be unworkable or exceedingly expensive and divert funding from services, and procedures should not be excessively detailed and impractical.

Deprivation of liberty is a major matter for any citizen, and such a human rights issue remains the most important issue in mental health legislation.

**THE OVERLAP OF LEGAL AND ETHICAL CONSIDERATIONS IN PSYCHIATRY**

**Ethics**

Ethics is a branch of philosophy. It is the science of the philosophy of morals. Ethics is concerned with which actions are right, which ends are good, whether the rightness of actions is inferable from the consequences, and whether the virtuousness of motives is inferred from the rightness of actions; for example, is it less bad to shoplift from a supermarket than from a corner shop, or for a person who repeatedly loses his temper to kill compared with one of previously good character who does so?

The word ‘ethics’ originates from the Greek ethos (nature, disposition) and the word ‘moral’ from the Latin moris, the generic form of mos (custom). Although the two words are often used synonymously, ethics is the science of the philosophy of morals, and morals is the practice or enactment of ethics. (Latin terms usually refer to real everyday matters, while Greek terms refer to an idealized theoretical understanding). Thus, ethics involves the analysis of universal principles on which decisions are made, while morals regulate day-to-day judgement and refer to particular actions and beliefs. The law is silent on many matters. Theoretically, morals should override political and legal requirements. The term ‘moral’ is, however, also tainted by association with immorality and sexual misconduct.

The interest in ethical aspects of psychiatry has increased rapidly in the past 20 years, especially concerning the rights of patients, particularly in their dealings with psychiatrists and particularly in the USA. This concern led directly to the Code of Practice being established as prescribed in the Mental Health Act 1983 of England and Wales.

Ethics may assist where there is uncertainty and assist in obtaining the best-quality judgements. It can help to distinguish facts from values and in elucidating roles and duties. Law may follow ethics, or ethics may follow law.

The four principles of ethical medical practice are:\(^5,6\)

- **Autonomy:** respecting the patient’s wishes.
- **Beneficence:** doing good.
- **Non-maleficence:** avoiding doing harm.
- **Justice:** fairness in the provision of care.

In practice, these principles often conflict and a balance has to be drawn. In medical ethics there is often a central conflict between the autonomy of the patient (e.g. concerning consent) and the duty of care of a doctor (e.g. negligence). Ethical dilemmas cannot therefore usually be solved by an algorithm.

**Expert psychiatric reports**

The Royal College of Psychiatrists states that expert psychiatric reports should be prepared only by a consultant psychiatrist or a trainee under a consultant psychiatrist’s supervision – so, for example, not a prison medical officer. Reports should be independent, regardless of whether the psychiatrist has been instructed by the Crown Prosecution Service or a defence solicitor. The individual should be informed and warned that an interview to provide a court or similar report is not a normal medical interview, is not confidential, and may be used in sentencing and sent even if the subject does not cooperate. This is sometimes referred to as ‘a contract of confidentiality’. However, the British Medical Association (BMA) states that doctors may properly refuse to examine subjects who do not wish to be examined. Problems arise if a psychiatrist is asked to compile a court report on a patient that the psychiatrist knew previously. The BMA advises doctors to make clear to the patient their two roles. It may be necessary to detail in the report only what took place in the interview for the report and not to refer, if the patient does not agree, to the past psychiatric history, and then to state explicitly that this is what has been done. Alternatively, it may be necessary to override the patient’s wishes and to reveal the past psychiatric history, not only for reasons of public interest but also in the patient’s own interest. It is important to distinguish findings, which should be objective and, ideally, agreed by all, from opinion. If reports are requested by a solicitor, then it is the solicitor’s decision as to whether to use or make available the psychiatrist’s report.

Judicial guidance for expert reports is shown in Box 77.1.

**Ethics of predicting dangerousness**

For a psychiatrist, ethical dilemmas may arise when recommending a Section 41 restriction order under the Mental Health Act 1983 of England and Wales in the case of a mentally disordered offender (to protect the public from serious harm), in Mental Health Review Tribunals, and, in the USA, in relation to the death penalty if an offender is a ‘continuing threat to society’. Issues include the inaccuracy of prediction, the traditional medical ethic against the death
penalty, and that if a psychiatrist does not offer treatment but states that the patient is dangerous, this may result in prolonged detention in prison (e.g. people convicted of manslaughter rather than murder in England and Wales, on grounds of diminished responsibility, but who are not offered hospital treatment and who receive a life sentence, serve longer in prison than people convicted of murder).

**Ethics of assessing responsibility**

Responsibility is a legal concept. It is questionable whether psychiatrists, who can make a valid diagnosis of mental disorder, can accurately assess responsibility, for example for reasons of diminished responsibility to reduce the charge from murder to manslaughter in homicide cases in England and Wales. Courts, however, may use psychiatric evidence in mitigating sentencing.

**Ethics of detaining patients**

Patients may have a right to be treated even against their will. In some countries and in certain states of the USA, it is more difficult to detain patients compared with the UK.

**Ethics of consent**

It is assumed, unless contested, that every adult has the right and the capacity (legal concept) (competence) to decide whether or not he or she will accept medical treatment, even if refusal risks permanent injury to health or premature death.

In England and Wales it is illegal to treat without consent, except in an emergency in good faith or under the Mental Health Act 1983 Part IV. Legally if a patient is ‘medically touched’ without consent, this constitutes battery.
Consent should be informed and voluntary, which implies that mental disorder such as dementia does not affect judgement. In practice, a lower threshold for capacity is adopted for patients who consent to treatment compared with those who refuse. Refusal is not the same as lack of capacity to consent. It is important to never threaten to impose treatment if a patient refuses, and always to ensure that a patient is not simply consenting for a ‘quiet life’. A distinction is to be made between coercion and a patient’s acceptance of the reality of his or her situation.

Valid ethical consent requires competence and information, resulting in understanding. Understanding and voluntariness can then result in an affirmative decision.\textsuperscript{9}

Regarding consent being based on sufficient information, to date the standard applied to this in the UK has been predominantly profession-based – that is, giving the level of information that is normally given by the profession in that medical situation based on the duty of care. The alternative standard is patient-based – that is, the level of information necessary in order to allow a patient to operate his or her autonomy. Information should refer to alternative treatments and advice about substantial or unusual risks. No or very little information given may result in the professional being liable to a charge of battery. Inadequate information may result in a doctor being held liable to a charge of negligence (breach of duty of care). ‘Informed consent’ is a US term and is not specifically enshrined in UK law.

A decision about consent may vary over time, and different messages may be given by the patient in different modalities.

A consent form is only evidence as to consent and does not amount to fact of consent.

The UK standard for sufficient information for valid consent is now closer to the US law – the objective prudent patient test (what a reasonable patient should be told) rather than the reasonable doctor medical test (profession-based) – due mainly to changing GMC guidelines.

Relevant case law from England and Wales includes the following:

- **Sidaway v. Board of Governors of Bethlem Royal and Maudsley Hospital (1985)**: the majority of the five Law Lords supported the doctor-based standard of not telling of the 1 per cent risk of damage to spinal cord, after a neurosurgical procedure on the cervical vertebrae. However, the judgment suggested that if doctors were lax in informing patients, then the courts may intervene.
- **Bolam v. Friern Hospital Management Committee (1957)**: the ‘Bolam test’ – a doctor is required to exercise the ordinary skills of a competent practitioner in the field (profession-based standard).
- **Maynard v. West Midlands RHA (1985 1 All ER 635)**: if even the body of medical opinion cited is a minority, this may still be defensible.
- **Bolitho v. Hackney Health Authority (1997 All ER 771)**: in order to avoid negligence, even if following a ‘responsible body’ of medical opinion, a doctor needs to convince the court that the amount of information given or omitted can be defended.

Courts are reluctant to put a percentage figure on risk of which a patient should be warned, as the individual significance of injury to the individual is also important. Always put a note of warnings given to the patient in the notes and in a letter to the patient’s general practitioner (GP) (not the consent form).

Individuals under the age of 16 years can give valid consent if there is sufficient understanding. Parental consent is valid for individuals aged 16–18 years who do not understand.

### Consent in English law for adults (aged \( \geq 18 \) years) and minors

The following apply to competent adult patients:

- The patient may refuse any, including life-saving, treatment (otherwise battery).
- The patient should be given information about the nature of the procedure, any serious side effects, the likely benefits and alternatives (otherwise negligence).

For incompetent adult patients, the following principles apply:

- The doctor should act in the best interests of the patient.
- The patient’s relatives and friends cannot give or withhold consent (they can only assent), but they may be sources of information regarding best interests.

For minors, the following points apply:

- A person under 18 years of age should not be allowed to come to serious harm on the grounds of the minor or the parents refusing consent to necessary and urgent treatment.
- Patients aged 16–17 years are presumed by statute to have the capacity to give consent, unless the contrary is shown.
- A child under age 16 years who does have capacity (‘Gillick competent’ in common law\textsuperscript{10,11}) can give consent, but if the child refuses treatment consent can be overridden by the people with parental responsibility or a court.
- Courts are unlikely to consider that people aged 13 years or under have capacity.
- For children who are not Gillick competent, the people with parental responsibility give consent but have a legal obligation to act in the child’s best interests.

Although psychiatric disorders can affect a patient’s judgement and therefore capacity to consent, this can also occur in medical disorders, albeit less often.

The House of Lords has ruled that doctors have a common law duty (justification of necessity) to act in the
best possible interests of the patient, for example if the patient is physically ill and not competent (e.g. unconscious) or if the patient is permanently unable to consent (e.g. due to severe learning disability) to treatments not covered by the Mental Health Act 1983.

Patients detained under the Mental Health Act 1983 may be able to give free valid consent to treatment, providing they are not complying simply to get out of hospital. The patient should know the nature and consequences of the proposed treatment, the consequences of not having the treatment, and the risks of the treatment.

Although some doctors argue that it would be negligent in the case of patients not consenting if one did not test for medical conditions suspected (i.e. duty of care), this is not accepted legally. Undertaking a human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) test without the patient knowing the nature of such a test, and its personal and social implications, constitutes assault, even if the patient consented to give blood for unspecified or other tests.

Exceptions to usual requirements for consent

- **Implied consent:**
  - By fact of consultation
  - Patient's consent unavailable, but reasonable person would consent, e.g. unconscious patient after overdose
- **Necessity:**
  - Some level of patient incompetence and serious harm or death likely to occur
  - Doctor owes duty of care
- **Emergency:** to prevent serious harm to patient or other
- **Post-suicide attempt:** can reverse effects of suicide attempt (anachronism, as suicide was previously a crime), but can not stop a suicidal patient from leaving hospital if not detainable under the Mental Health Act 1983
- **Detention under Mental Health Act 1983.**

Capacity and competency

Capacity is a legal concept. Competency is clinical concept but is occasionally used legally. The terms mean the ability to know and understand the nature and consequences of legal proceedings, including for medical purposes.

Assessment of capacity

This is required in many branches of medicine, including psychiatry, for example:

- **Old-age psychiatry:**
  - Testamentary capacity
  - Power of attorney
  - Social care, e.g. sheltered home
- **Forensic psychiatry:** fitness to plead and stand trial
- **Liaison psychiatry:**
  - Treatment refusal
  - Leaving hospital without medical consent.

Capacity may vary over time, for example in delirium.

Legal principles relating to capacity

- An imprudent decision is not itself grounds for incapacity (analyse the way decision was made, not the decision itself).
- Capacity is function-specific, not global.
- Standard of proof is on the balance of probabilities.
- There are three stages of assessing capacity (Re C [1994] All ER 819):
  - Comprehension and retention of relevant information
  - Ability to believe information (e.g. no delusion interfering)
  - Weigh information and make decision.

Approaches to making decisions for incompetent patients

- Best interests
- Proxy
- Advance directive (living will)
- Substituted judgements (e.g. if patient became competent, what treatment would he or she choose?).

The final three of these are available in the Mental Capacity Act 2005.

British Medical Association and Law Society guidelines (1994) on assessing capacity

- Can the patient understand the nature and purpose of the procedure or treatment and why it is being proposed?
- Does the patient understand the principle benefits and risks, the alternatives, and the risks and consequences of not being treated?
- Capacity does not depend on detainability under the Mental Health Act 1983.
- Take into account the patient’s anxiety, language problems and cultural and educational background.
- There is no relation to clinical reality, e.g. severity of illness if treatment is refused.

The MB test for capacity (1997) (needle phobia)

- Comprehend and retain information.
- Weigh information in balance and reach decision.

Patient attempts suicide and then refuses treatment in accident and emergency department

Theoretically, if competent, such a patient can refuse treatment. However, medical defence organizations in the UK comment that competence can always be questioned if an individual has harmed him- or herself, and so it is defendable to intervene. The common law justification of ‘necessity’ allows reasonable interventions, including medical treatments, reasonable to the circumstances, where the competence of the individual is unknown.
The overlap of legal and ethical considerations in psychiatry

**Case law propositions on medical treatment**

**Lord Donaldson MR in Re T (critically ill young woman) (adult refusal of medical treatment) (1994)**
4 All ER 649 CA

Incapacity may be due to the following:
- Long-term mental incapacity or retarded development
- Temporary factors:
  - Unconsciousness
  - Confusion
  - Fatigue
  - Shock
  - Pain.

NB: in the case of MB (1997), with needle phobia, panic, indecisiveness and irritability were ruled not to be factors causing incapacity.

Capacity may be reduced, not removed (i.e. could be taught, not simply assessed). The patient’s decision must be independent (e.g. from relatives and religious advisors).

**Thorpe J, in Re C Adult Refusal of Medical Treatment (1994) 1 All ER 819**

Refusal of treatment can be a declaration never to consent or never in some future circumstances, for example to electroconvulsive therapy (ECT) (equivalent to ‘living will’).

Advance directives are now legal under the Mental Capacity Act 2005; for example, the individual may state that, if mental illness relapses again, he or she wants no haloperidol, only risperidone, antipsychotic medication.

**Consent obtained by coercion or duress invalid**

Freeman v. Home Office (1983) All ER 589

Freeman claimed that his relationship as a prisoner with the prison doctor prevented valid consent due to his role in influencing disciplinary procedures. Issue was of covert, as opposed to overt, coercion instead of voluntary consent. The case was lost by Freeman.

Barbara was injected in prison against his will. The case was won by Barbara.

**Too much information may preclude patient making valid judgement**

This was stated by Lord Templeman in Sidaway v. Board of Governors of Bethlem Royal and Maudsley Hospital (1985).

**Medical treatment for mental disorder under Part IV of Mental Health Act 1983**

**Section 63**

Consent is not required for medical treatments that do not fall within Section 57 or 58, for example nasogastric feeding of detained patient with borderline personality disorder refusing to eat ruled by Court of Appeal within scope of Section 63 (B v. Croydon Health Authority (1995) (1 All ER 683).

**Section 145**

Medical treatment includes nursing and also includes care, habilitation, and rehabilitation under medical supervision.

Wall J, in Thameside and Glossop Acute Services Trust v. UCH (1996) 1 FLR 792

Induction of labour and possible Caesarean section of a 41-year-old 38-week-pregnant woman with schizophrenia was ruled treatment within scope of Section 63. The woman consented to induction, but medical staff feared that she would change her mind. The decision was obtained on grounds (i) to prevent deterioration in the patient’s mental state, (ii) that a live baby would promote the patient’s health and (iii) that antipsychotic medication was contraindicated during pregnancy. However, the real issue is competence. Such decisions are often made in a rush, with the patient in labour and taking analgesics, so that ‘not competent’ is accepted. Also such cases are often heard in court often ex-parte with no representation of the individual (which does not prevent liability). Note that the Court of Appeal ruled in 1988 that a fetus is not a person with legal rights.

Re C (adult refusal of medical treatment) (1994)

C’s gangrene was ruled not likely to affect his mental condition. C was a patient at Broadmoor Hospital and was deluded that he was a great doctor. He insisted on no amputation in the future and, in fact, he recovered.

**Confidentiality**

The BMA and the Royal College of Psychiatrists state that the ideal ethical position is that doctors must protect any information acquired in the course of a doctor–patient relationship. The GMC accepts that this is not an absolute position and that doctors can reveal such information if there is an immediate grave risk to the patient or others (‘risk of death or serious harm’). In other circumstances, a doctor should not reveal information until forced to do so, for example by a court order.

The general duty regarding confidentiality is covered in guidelines e.g. from the GMC. Exceptions to confidentiality include the following:
- Court order
- Statute – by law for legal proceedings (all have strict narrow criteria for information that can be divulged):
  - Misuse of Drugs Law: notification of addicts
  - Road Traffic Act 1988: identification of drivers in road traffic accidents
  - Police and Criminal Evidence Act 1984
  - Preventing terrorism
  - Warrant
  - Data Protection Act 1984 (for computer-stored clinical data)
  - Venereal Diseases Regulations 1974 (applies to health authority employees)
Disclosure is allowed in the following circumstances:

- In the public interest
- With consent
- Without identification.

In the UK, a patient or their lawyer can easily gain access to their medical records under the following regulations:

- Supreme Court Act 1981 (personal injury claims)
- Access to Medical Records Act 1988 (reports)

Issues regarding confidentiality to third parties may also arise. Confidentiality is compromised by accessibility of information by multi-disciplinary professionals, such as the following:

- Advocates
- Case workers
- Care assistants/carers
- Social workers who share information with child agencies
- Key workers

Psychiatrists are asked to share information with police, probation officers, including for victim liaison, and for Multi-Agency Public Protection Arrangements (MAPPAs). Always bear in mind the importance of the ‘need to know’ principle and note that people in old age or with learning difficulties pose special problems.

**Incapacity to drive a motor vehicle**

In the UK, the patient should be advised that if he or she does not inform the Driver Vehicle Licensing Authority (DVLA) about a relevant condition, then the doctor is obliged to do so. The only absolutely prescribed psychiatric disability is severe mental handicap. For lesser degrees of mental handicap, in order to be able to drive the individual would need to demonstrate adequate functional ability at the wheel. In the USA, the American Psychiatric Association takes the view that there should be no expectation that a psychiatrist can accurately assess capacity to drive a motor vehicle.

**Consent to disclose**

This is considered reasonable if the patient realizes the nature and consequences. It is also considered reasonable by the BMA and GMC for a doctor to share information with other people who are concerned professionally in assisting with or collaborating in the patient’s clinical care (viewed as ‘implicit consent’).

**Information to relatives and carers**

In general, this requires the patient’s consent. It may be ethical to give information to relatives and carers if it is considered undesirable to tell a patient the full implications of their disorder or the patient is incapable of consent. However, the Royal College of Psychiatrists states that ‘families [are] not on a par with outsiders’.

**Information required by due legal process**

This includes information required by statute, for example notifiable infectious diseases, and by court order. A patient is not ‘privileged’ in UK law, as in some other countries – that is, the patient is not protected from disclosure without his or her consent in all circumstances. If the doctor refuses a court order to disclose, then the doctor is in contempt of court.

Although it is a fundamental principle of administration of justice that legal professional privilege with clients is absolute (this includes lawyer–doctor communications about a client), this does not apply to the doctor–patient relationship. The court respects this private relationship, but the relationship may be outweighed by public interest, legal process or the safety of others. In this respect, the doctor–patient relationship is comparable to that of a journalist and their sources, or a priest and a penitent.

**Duty to society**

In the UK, this can override the duty to maintain patient confidentiality. In the case of W v. Dr H Egdell (Court of Appeal 8.11.89), a psychiatrist revealed a patient’s dangerousness to the then assistant medical director at Ashworth Hospital, knowing that it was likely that this information would be conveyed to the Home Office, although the psychiatrist’s mental health review tribunal report regarding this was not submitted to the tribunal by the instructing solicitors. The psychiatrist’s actions were upheld in court.

A similar ruling was made in the case of R v. Crozier (1990). Crozier attempted to murder his sister. Dr Wright said that Crozier was sane. Crozier was about to be sentenced to prison when a defence psychiatrist, Dr D McDonald, arrived late and gave his report, indicating mental illness, to the prosecution, as a result of which Crozier was detained under Sections 37 and 41 of the Mental Health Act 1983 against his wishes.

The ideal is to try to persuade the patient to give consent, but otherwise the patient must be advised that absolute confidentiality, for example regarding crimes, cannot be given. If a doctor does reveal information without a patient’s consent, then the doctor will need to be able to justify this to the GMC, which takes a very hard line on this issue. Breach of confidentiality can lead to a charge of serious professional misconduct.

In the Tarasoff case in the USA, it became evident to a psychotherapist that his patient, Mr Podder, at the University of California at Berkeley was dangerous. The therapist consulted colleagues and subsequently recommended the patient’s detention in hospital. However, the campus police involved in the detention process released Podder, as he appeared rational and said that he would stay away from his potential victim, Tatiana Tarasoff, who had...
rejected his efforts to continue a courtship. Podder realized that his psychotherapist must have talked to the police, and he broke off treatment. Two months later, in 1969, he shot, stabbed and killed Tarasoff after he had returned from a holiday. Relatives of Tarasoff sued the therapist and the campus police, complaining that they should have warned of the danger (Tarasoff v. Regents of University of California). This was initially dismissed and then upheld at the California Supreme Court, which initially ruled in 1974 that there was a duty to warn Tarasoff. This was later modified in 1976 to place a duty on the therapist to use reasonable care, for example to hospitalize (interpreted as a duty to protect). From this case comes the phrase 'Protective privilege ends where community peril begins'. Similar rulings were later given in other states of the USA, but they have not resulted in the expected increased litigation and have not been made law in the UK. Associated problems include distinguishing real from false threats, and the effect on the patient’s willingness to confide in a therapist. This case reflects the ethical conflict of having to balance patient confidentiality against breaching it and negligence to third parties.

**Medical research**

It may be justifiable to disclose information without a patient’s consent if approved by an ethics committee (e.g. case note studies), but some people question this. A detained patient may not be incompetent to give consent, but there should be no suggestion that participation in research should lead to an earlier release. If the patient, however, is incompetent to give consent, then there is no legal basis for proceeding with research, but in practice, both before and since the Mental Capacity Act 2005, it has been considered ethical to do so if the patient does not resist inclusion in the study, if the relatives are informed and give agreement (assent; although this carries no legal authority as relatives cannot give consent for a patient), and if the patient is considered likely to have consented if he or she had had the capacity. Case history reports are usually disguised to avoid identification, but increasingly, especially among psychotherapists, patients’ consent is being obtained. The World Medical Association’s Declaration of Helsinki is the established guidance for the ethics of clinical trials on human subjects.\(^\text{15}\)

**Information for Mental Health Review Tribunals**

By law, responsible doctors must submit psychiatric reports with or without the patient’s consent, and the patient’s medical records will be made available with or without the patient’s consent to the Mental Health Review Tribunal, usually to the medical member but not exclusively so. Solicitors for patients now expect to be free to examine the medical records for themselves, if the patient consents to this. A copy of the mental health review tribunal psychiatric report is given to the patient unless the doctor states that it will result in serious harm, including to third parties. Reasons must be given for this to the tribunal. It is therefore good practice to discuss one’s opinion with the patient before he or she receives the report.

**Disclosure of information in other situations**

No consent is required for information to be given for hospital managers’ hearings, and managers are not obliged to request to see the records of the patient. Ministry of Justice reports on Section 41 and other restricted patients have not usually had, nor require, the patient’s consent, but it is good practice usually to explain what the Ministry of Justice has been told. The Care Quality Commission (previously Mental Health Act Commission), including its non-medical members, can examine records without a detained patient’s consent, and its medical representatives can similarly do so when considering second opinions regarding consent to treatment.

**Ethics of control of detained patients**

There are rights for staff to restrain or impose treatment on psychiatric patients under common law (to prevent a criminal act, to save life or to prevent serious harm, e.g. when the patient is unconscious) and under the Mental Health Act 1983. Staff are protected under Section 139 of the Mental Health Act 1983, so that patients cannot undertake civil proceedings against staff without leave of the High Court unless there is a prima facie case (e.g. of bad faith or treatment undertaken without reasonable care) or undertake criminal proceedings without leave of the Director of Public Prosecutions.

Physical restraint may include a spectrum from instruction to time out to seclusion. It is important for all staff to follow agreed policies and, in England and Wales, the Code of Practice of the Mental Health Act 1983.

If treatment with clozapine is to be imposed without consent under the Mental Health Act 1983, venepuncture can be undertaken without the patient’s consent (Mental Health Act Commission Practice Note No. 1 June 1993). However, one cannot make a patient swallow tablets.

A duty of care of a doctor may be shared by his or her team. The BMA highlights, however, that a doctor is responsible for the continuing care of a patient until care is handed on to another doctor.

**Ethics of working with prisoners and other detained people**

These ethics have been addressed in the United Nations Declaration in 1981, the World Medical Association 1975 Declaration of Tokyo and the World Psychiatric Association 1983 Declaration of Hawaii, as well as the Royal College of Psychiatrists ethical guidelines specifically concerning psychiatric care in prison (1992).

**Declaration of Hawaii**

As approved by the General Assembly of the World Psychiatric Association in Vienna, on 10 July 1983:
No procedure shall be performed nor treatment given against or independent of a patient’s own will, unless because of mental illness, the patient cannot form a judgement as to what is in his or her own best interest and without which treatment serious impairment is likely to occur to the patient or others.

Ethics of medical care in prison
Particular issues for prisoners are that they cannot choose their doctor and their medical care may be less than desirable. However, prisons are not hospitals. There may be a conflict of interest between the duty of care for the patient and a responsibility to the institution, although it is clear that the doctor’s first responsibility is to the patient and not to the institution. The BMA states that doctors should not be associated with any punishment damaging to health. This may be an issue in prison adjudications of misconduct and fitness for punishment. The doctor may, however, be able to justify their involvement on the basis that their findings may excuse the patient or help in mitigation due to the patient being sick. Administering drugs in prison in general requires the patient’s consent and is not covered by the Mental Health Act 1983. If the prisoner does not consent, then the prisoner may not be treated or secluded, except to save life, to restrain violence or to prevent an irretrievable deterioration in the prisoner’s health.

Ethics of punishment
Punishment may be justified on grounds of revenge, deterrence, reform or the protection of others. Punishment may be on the basis that an individual has free will and thus punishment for his or actions is justified in terms of retribution or ‘just deserts’. The utilitarian view (the greatest good for the greatest number) may justify punishment for reasons of deterrence on the basis that offenders choose to offend. However, although the death penalty for parking offences may stop such offending, such an argument is not usually taken to this extreme.

Doctors and torture
The European Convention of Human Rights Article 3 states that no one should be subjected to ‘inhuman and degrading treatment or punishment’. Inspectors from the Convention make unannounced visits to facilities in countries that are signatories and where people are detained and bring any deficiencies in practice to the notice of those in authority. If no action is taken, the inspectors will publish their findings.

Human Rights Act 1998
This incorporated the European Convention on Human Rights to UK law with full effect from October 2000. Articles relevant to mental health care include the following:

- Article 2: right to life.
- Article 5: right to liberty.
- Article 5 (1): protects patients’ autonomy – no one is to be detained, except in specified cases as prescribed by law.
- Article 5 (1)c: concerns lawful detention of people only if reliably shown to be of ‘unsound mind’, which equates to, but is not referred to as, incapacity.
- Article 5 (4): guarantees the right to a speedy court review of a person’s detention.
- Article 6: right to a fair trial.
- Article 8: right to privacy, including private and family life and correspondence.

Ethics of allocation of resources
Traditional medical ethics, such as the Hippocratic Oath, in which doctors tell each other how to behave but emphasize that their patient should always come first, may provide little help with issues of allocation of resources to other patients.

There is no single ethical solution to the problem of allocating resources. Psychiatrists need to balance legal, practical and ethical issues. For instance, resources could be preferentially allocated to the following:

- The youngest: because they are the most productive and have the longest life (on the basis of utilitarianism and welfare maximization).
- The kindest: on the basis of just deserts.
- The most in need: on the basis of Marxist theory and ‘justice’.
- By chance: on the basis of lottery.

Quality-adjusted life years (QALYS) may be one way forward in trying to balance the demands of, for example, the need for heart transplants against treatment for depression. The dilemma is in trying to meet the overall population’s welfare and other needs (e.g. education) compared with an individual patient’s needs. We are conditioned from childhood, and by society and our own psychological needs, to provide a single answer to a dilemma and, indeed, this is often valued, as in business. However, rarely are there single ‘right’ answers, although there are wrong ones. To balance competing needs, society needs a sense of proportion and to this end will argue about what is right repetitively. Doctors must act as advocates for their own patients, but they must also accept that decisions may be taken by others, such as managers and government, on the basis of cost–benefit.

Multidisciplinary working
A professional may be guided by his or own personal ethics but may also be governed by a code of ethics of his or her profession, which may conflict with that of other professions, for example the insistence of social services of breaking confidentiality where there is any risk to children. This is against a background of society itself becoming
increasingly litigious. Professionals are often left in a dilemma – for example, it may be negligent not to restrain a psychiatric patient, but to do so risks being accused of battery and false imprisonment. General principles are often much easier to discuss and resolve than individual clinical cases. Beware the risk of ‘freedom always wearing the trousers’ in arguments.

The ‘wise doctor principle’ is being replaced by the ‘wise patient principle’. Paternalism in doctors is being replaced by an adult relationship between the doctor and patient.

Ethics of genetic screening
Ethical debate often proceeds on the basis of either assumptions about what the patient wants or what doctors care about; for example, it was previously widely assumed in the case of genetic screening for Huntington’s disease that it would be harmful to the patient if the tests were positive, and thus such testing would be unethical (the principle of non-maleficence). Clinical experience has shown this to be not infrequently untrue.

Euthanasia
Treatment for depression rarely alters the attitude of patients considering euthanasia, which is often settled, considered, rational and fixed.

Methods of ethical reasoning
Most ethical dilemmas in psychiatry and, indeed, medicine, are due to one of the following issues:

- Consent
- Autonomy
- Rationality
- Confidentiality.

Principles
This approach offers a top-down approach to tackling ethical problems – that is, from a general theory to particular cases, for example the ‘four principle’ perspective:

- Autonomy: respecting the patient’s wishes.
- Beneficence: doing good.
- Non-maleficence: avoiding doing harm.
- Justice: fairness in the provision of care.

These principles, however, may conflict in individual cases; for example, respecting the patient’s wishes (autonomy) to have a detailed explanation of his or her condition may be at the expense of time spent with other patients (unjust). Autonomy may include the patient asking the doctor to decide for him or her.

Paradigms (casuistry – case-based reasoning)
This offers a bottom-up approach, starting from cases, and emphasizes two questions:

- What changes to the case would make it clearer what to do?
- What related situations would be less problematic ethically?

For example, in thinking about how to manage risk of death in an individual with mild learning disability pathologically water-drinking, if one alters the scenario, for example to an overdose, then the ethical issues become clearer.

The advantages of this approach include the real life case method and its offering practical solutions. It is, however, professionally centred and can be biased by prejudices.

Perspectives
This approach is based on the practical skill of the capacity to view problems not only from professionals’ perspective but also from the perspective of the patient, the patient’s relatives and other members of the multidisciplinary team. It is thus patient- and knowledge-centred, but it may have the disadvantage of relativism.

Ethical theories
These may be:

- Substantive: concerned with establishing particular ethical conclusions:
  - Deontological (rule-based): these theories emphasize rights, duties and responsibilities, regardless of consequences, e.g. Kant’s ‘categorical imperatives’.17
  - Consequentialist (teleology): these theories emphasize the importance of evaluating the consequences of actions, e.g. utilitarianism.18

For example, on confidentiality, consequentialist reasoning emphasizes the consequences if the patient cannot trust their doctor, while deontological reasoning emphasizes the patient’s right to privacy. Similarly, in a case where one conjoined twin must die in order to allow the other to live, otherwise both will die, or in the oft-quoted example of a certain number of men being in a boat with provisions for one fewer than that number, deontologists would say that one should not kill while consequentialists would emphasize the need for the greatest good.

- Virtue ethics: rather than making binding, often rather negative, rules and duties, virtue ethics emphasizes changing people’s attitudes to embrace the virtues, e.g. compassion, trustworthiness, integrity, conscientiousness and good relationships.

- Analytical: concerned with the meaning of value terms and general logical form of ethical argument.

Ethics, guidelines and clinical practice
A summary of the issues to be considered in ethical dilemmas is shown in Table 77.1.
Some moral philosophers argue that conflict is mere appearance and can be resolved by moral homework. This does not reflect real life, however. Aristotle argued that we should test our ethical convictions against ordinary experiences. Bertrand Russell argued that philosophy teaches one to live with uncertainty rather than to answer uncertainty. General principles can be set down as guidelines, but there will always be exceptions. However, a doctor will always need to be able to justify any divergence from accepted guidelines. Doctors, especially psychiatrists, have to make a lot of difficult decisions quickly, with often incomplete information against the background of heavy workloads and understaffed and under-resourced services and a litigious climate, with medical treatments often not resulting in cure.

Table 77.1 Issues to be considered in ethical and legal dilemmas

</table>

**KEY POINTS**

- Psychiatric (and medical) negligence has three main elements:
  - Duty of care to a ‘neighbour’
  - Breach of duty of care
  - Damage to other party results.
- Other elements include the following:
  - Behaviour below the standard required by law
  - Reasonably foreseeable damage
  - Actual causal connection
  - Bolam principal: if care is in keeping with a body of recognized opinion, then it is usually defendable, but courts act as a safety net and may disagree.
REFERENCES

There is no specific ethics and law section in most curricula for psychiatric trainees. However, if the curriculum and the clinical competencies for psychiatric practice are read carefully, then it will be clear that ethical awareness and the capacity to reason thoughtfully about ethical dilemmas are essential requirements of good psychiatric practice. Arguably, ethical theory and reasoning are central to all aspects of the psychiatric curriculum, because good psychiatric practice is about relationships and ethical theory deals with how we should act towards others. All psychiatrists need ethical competence if they are to be competent in their clinical care of patients, their work with colleagues and their own personal probity.

A useful way to think about this is to complement evidence-based medicine (EBM) with values-based medicine (VBM).1 Certainly, we need facts in order to make decisions, and those facts need to be based on good-quality evidence. But a values-based approach emphasizes two things: first, how many difficult dilemmas in medicine (and especially psychiatry) arise because of different perspectives on values; and second, how an awareness of our value perspectives can help us to make the best-quality ethical decisions possible.

Mrs Jenkins is referred by her general practitioner (GP) because she seems depressed and withdrawn. Her husband comes with her and wants to come into the interview room with her. He insists that she cannot talk to you without him, saying, ‘She needs me, doctor’. What do you do?

The first point to note about this story is its ordinariness. Ethical dilemmas occur daily in psychiatry – sometimes more than once a day. It is therefore easy for psychiatrists to mistake the ethical for the clinical. The dilemma here is that it is ethically and clinically desirable to see Mrs Jenkins on her own. Ethically, she has a claim to privacy, and you have a duty to keep what she says confidential. Clinically, it is essential to speak to Mrs Jenkins on her own, because otherwise you will not be able to find out whether Mr Jenkins is the problem. It will also be clinically relevant if she really is unable to talk to you without him present. However, it is also going to be clinically relevant to interview Mr Jenkins at some point. Ethically, respect for her includes respect for his viewpoint (which does not mean agreement, necessarily); further, he may really be the best person to represent Mrs Jenkins’ viewpoint.

The second point to note is that ethical dilemmas in clinical practice have to be resolved; they cannot be avoided. You will have to answer Mr Jenkins’ request one way or the other. The purpose of taking time to think and read about ethics in psychiatry is to try to learn to make the best-quality decisions you can. Sometimes this will mean taking time to think and talk with other colleagues; discussions with others, especially from other disciplines, are often very helpful.

Third, whatever you decide to do about Mrs Jenkins, you need good-quality communication skills to do it. You may decide that you need to talk to Mrs Jenkins alone, even if it is just to get her consent to her husband joining you. Or you may decide to let Mr Jenkins into the room to get his account of what has been happening, and then ask him if he minds stepping outside so you can talk to his wife alone. However you decide to play it, you need to be able to quickly establish a rapport with two people – one of whom is possibly severely depressed, and the other of whom is anxious or angry or both. The therapeutic relationship is crucially important in psychiatric ethics.

In relation to ethics, therefore, the important skills that every psychiatrist needs to have are as follows:

- **Awareness of the distinction between an ethical dilemma and a clinical dilemma**: the language of ethical dilemmas often involves the words ‘should’ and ‘ought’. You can see Mrs Jenkins with her husband, but ought you to?
- **Awareness of the ways that one can analyse an ethical dilemma using different theories of ethics**: you already have skills in ethical reasoning. The purpose of the training is to improve those skills.
• Awareness of the different perspectives and value systems that you will meet in your professional practice: your values, beliefs and attitudes influence how you make ethical decisions and how you decide what the right thing is to do. However, your values, beliefs and attitudes may conflict with those of the patient or your colleagues.

• Awareness of the role of the law in regulating relationships between people, and responding to ethical dilemmas: the law is secondary to ethics conceptually; it offers a public and social structure for resolving ethical dilemmas. For this reason, it is often helpful to look at what the legal response to a dilemma might be. But legal is not necessarily the same as ethical, as a quick reflection on the Nazi and apartheid race laws makes clear.

• Good enough communication skills to facilitate discussion of views and values by everyone involved in ethical decision-making.

ETHICS AND THE CLINICAL CARE OF PATIENTS

It is (we hope) obvious that it is ethically unjustifiable to give a patient poor clinical care. We think that it is wrong because:

• patients have an expectation that they will be cared for by a doctor when they are made vulnerable by illness or disability;

• you have acquired a duty towards the vulnerable because of your training as a doctor and a psychiatrist. As your knowledge grows, so too do your ethical duties;

• mental disorder makes people especially vulnerable, both in terms of asking for help and in terms of being exploited by others, including healthcare professionals.

CASE 2 BEST INTERESTS AND THE DUTY OF CARE

You are trying to manage Janie according to the best practice guidelines for borderline personality disorder (BPD), which means that you do not admit her except in crisis. She has just been discharged this morning after a lengthy admission; she returns at 11 p.m. the same night, begging to be admitted again. She says that she feels really suicidal and can’t cope outside.

Ethics is the study of how we ‘should’ treat people. During the psychiatric training, you will learn how to treat people’s mental distress, using a variety of interventions. Ethical dilemmas arise when you know that you can take a course of action; but should you? In this case, you can admit Janie: but should you?

A traditional ethical analysis might go like this. You have a duty of care to Janie that arises from your professional identity as a doctor. The ethical aspects of that duty are sometimes summarized as:

• a duty to respect the patient’s autonomy, i.e. respect the judgements they make for themselves, based on good-quality information;

• a duty to do the best for the patient’s welfare;

• a duty not to harm the patient;

• a duty to act justly and fairly.

These principles form the basis of a theory of ethics based on duties of doctors. There are also ordinary ethical principles of being a citizen, including generally telling the truth and respecting the law. Within psychiatry, we might also want to add the duty to do what we can in order to support and enhance autonomy, given that so many of our patients may lack it or have a fluctuating capacity to be autonomous. We have a duty to assess capacity in order to make autonomous decisions carefully. We also have particular duties to act justly and fairly because many psychiatric patients are vulnerable to exploitation in ways that general medical patients are not.

In this case, we could argue that there is a duty to respect Janie’s request for care. In terms of her welfare, she will be safe in hospital, and especially safe from self-harm. There also does not seem to be any failure to respect justice or act fairly if she is admitted. So, from the duty point of view, one could argue that admitting her is the right thing.

But another ethical theory states that the consequences of one’s actions matter most in deciding what is right. If you do admit her, then you are undermining the therapeutic relationship that she agreed with her team. There is an evidence base for treatment of BPD that suggests that long-term admissions are not helpful. You may actually do her a harm in the long run if you admit her.

At this point, clinicians sometimes ask what the law says on these matters. Mental health legislation gives you the power to detain someone if you feel that they need treatment for a mental disorder and are refusing it. You have no legal duty to admit Janie, however, just because she asks you to.

Two other theories of medical ethics are especially relevant in psychiatry: virtue ethics and the ethics of care and values-based practice. **Virtue ethics** sets out what a good psychiatrist is and then invites you to act likewise. In this case, the virtuous psychiatrist has regard both to Janie’s immediate need for relief from anxiety and to her longer-term needs to learn not only how to manage her negative affects but also how to believe that she can. The **ethics of care** places most importance on the relationship with Janie and would suggest that you have a duty to use the therapeutic relationship to relieve her anxiety and her distress, which need not include admitting her. It might mean that you spend 2 h talking to her, helping her to manage her immediate distress.
CASE 3 ETHICS AND WORKING WITH COLLEAGUES

You are asked to go out and assess the mental state of a man at home. When you get there, you find he has barricaded himself inside his room and is crying. His mother is crying too. Everyone is very distressed, and the community psychiatric nurse (CPN), who knows the family well, says, ‘You must arrange for him to be sectioned straight away.’ However, you know that the patient is doing well in his sheltered work placement and that an in-patient admission may lead to the loss of this work. When you put this to the CPN, she is angry and says that you are dismissing her opinion because she is ‘just a nurse’. What is the right thing to do?

Most patient care in psychiatry is delivered by teams of professionals, which reflects the diversity of needs of most psychiatric services users. The role of the psychiatrist has changed from a traditional medical one of making diagnostic and therapeutic decisions, and asking others to carry them out (as might be done by a surgeon), into one in which the different mental health professionals engage with different aspects of the patient’s life. The consultant psychiatrist then acts as a coordinator of information and intelligence about the patient, making sure that no sources of information are overlooked. Although in legal terms the psychiatrist will be responsible for patients (especially any that are admitted under the Mental Health Act), in clinical terms other professionals may take the lead on care coordination.

There are two aspects to this scenario that involve ethical reflection, and they are subtly different. The first aspect is the difference in value perspective between you and the nurse. She is clearly responding to the patient’s immediate distress, and she sees it as her ethical duty to relieve that distress. She may also be thinking about a duty to the patient’s mother, whereas you may be thinking primarily about the patient’s needs, both long- and short-term. Exploring the differences in your perspective will make it easier for you to come to some resolution.

However, the second aspect relates to the values that are put on to professional status. We have professional duties to respect the different contributions that different healthcare professionals make to patient care. Culturally, doctors are often depicted as being the dominant decision-makers in medicine, but in reality the care of very sick patients is always a matter of teamwork, and the clinical care can be compromised if professionals do not work together closely and respectfully. Ethically competent doctors ensure, through good communication skills and discussions about differences in professional opinion, that they are seen to be respectful of their co-workers.

CASE 4 PERSONAL PROBITY

Janie, the patient in Case 2, has made good progress and has been discharged from the clinic. A year later, you meet her at a social event organized by a friend of yours. You and Janie get on well, and she suggests that you meet up again for a drink the following week. When you meet, she confides in you that she had a sexual relationship with one of the other junior doctors that she met in the hospital.

This is a case that raises issues about professional boundaries in psychiatric practice. The ‘boundary’ here refers to the line between our professional identity (those verbal and non-verbal behaviours that mark us as professional) and our personal identity (again, those verbal and non-verbal behaviours that make us who we are personally). In theory, there is a strict boundary between the professional and the personal; when that boundary is crossed, we call it a ‘boundary crossing’ or, in serious cases, a ‘boundary violation’.

Meeting an ex-patient at a party is a boundary crossing; this is an overlap between your personal and professional identities. It needs to be handled thoughtfully so that both parties’ confidences are respected. It is debatable whether psychiatric patients can ever have relationships with their doctors that do not have some professional aspect to them; some would argue that it is not wise to have a drink with Janie, although it is legal and does not undermine any of the ethical duties described above. However, boundary crossings often lead to boundary violations, where there is complete collapse between personal and professional functions; such violations are usually harmful to the patient. Having a sexual relationship with a patient, as this colleague seems to have done, is always harmful to the patient and often to the doctor involved as well.

In these cases, it is essential to get good advice from a trusted senior colleague before any action is taken. There is no legal duty to report this allegation, but the General Medical Council (GMC) takes the view that doctors should always disclose when they have concerns about other doctors’ practices that may cause harm to patients. The ethical justification for disclosure is the prevention of harm to future patients. However, such situations are always personally delicate and potentially distressing for all concerned; it is vital to take the time that you need to discuss any future course of action.

Such cases also bring up the issue of confidentiality or, more properly, the general ethical duty to keep patient information private and to not disclose without express consent. If the patient consents to disclosure, then all is well; in this case, you might say to Janie that you would like to discuss her disclosure with a senior colleague, and if she agrees that is fine. If she disagrees, then this means that your duty to protect Janie’s confidences, and your professional duty to report concerns about others doctors, are in direct conflict.

Respect for confidentiality is not the same as secrecy, and there are justifications for breaching confidentiality; for example, Section 30 Annex B of the National Health Service (NHS) code of confidentiality for all staff states that staff are permitted to breach confidentiality in the ‘detection, investigation and punishment of violent crime’
LAW AND PSYCHIATRY

The law is the codification of a social consensus and is a mixture of statutes (which are debated and made law by Parliament) and case law, which is decided by argument in different types of court. Laws change as social circumstances change, and so what was lawful 200 years ago may not be lawful now. In theory, at least, law should follow ethics, and not the other way round: it may be lawful for you to take some form of action, but it may not be ethically right.

It is not possible to describe all the law with which a psychiatrist should be familiar in a short textbook such as this. What I will set out here are the general areas of law that psychiatrists need to know about, and the types of law in which they may be involved.

Civil and criminal law

There is a crucial distinction between the civil law and the criminal law, namely that they regulate different kinds of social relationship. The criminal law deals with antisocial behaviour: it specifies what shall be a criminal offence and what the penalties are for breaking the law. Criminal offences are those that are antisocial and harmful and result in social condemnation and exclusion. Criminal law determines guilt and innocence; the criminal courts are where magistrates and juries determine whether someone is responsible for a crime and what their punishment should be. Not all social rule-breaking is criminal (traffic and parking offences are a good example), but criminal activity is defined in terms of law-breaking, which is usually defined by legal statutes.

In contrast, civil law matters are about different kinds of problem in social relationships. It starts from the premise that relationships give rise to duties, and if that duty is breached then one party can claim that they have been wronged by the other. Civil law includes medical negligence, family law, contract law, and the law on capacity to make decisions. Psychiatrists need to be familiar with the Capacity Act, which in ethical terms reflects the principle of respect for autonomy. However, the capacity to exercise autonomy may be compromised in different ways and by different illnesses (not all mental); the Act sets out how doctors should behave in relation to patients whose autonomy is impaired.

Psychiatrists may find themselves advising different kinds of court in different ways. Medicolegal work is a specific psychiatric competency, and no junior doctor should attempt it without proper supervision and advice, especially where it involves giving expert testimony in the criminal or family courts. The two most important things to know before getting involved in any medicolegal work are (i) what sort of psychiatric question is being asked, and why, and (ii) whether you are the right person to answer it. If there is no psychiatric question – or there is, but you are not the right person to answer it – then you are entitled to tell any lawyer that you refuse to be involved.

Mental health law

Mental health law is a particular branch of civil law that addresses the problems of citizens who have mental illnesses. Since Roman times, it has been recognized that people with mental illnesses may need special protection because they are mentally vulnerable; it has also been recognized that a small minority pose a risk to the public. Most countries have specific mental health legislation, which is set out in some form of legal statute and then regulated and reviewed by subsequent case law. In England and Wales, Jones's Mental Health Act Manual is an invaluable guide.

Specific legislation is needed because it is generally harmful to detain people against their will, and it is ethically unjustifiable to do harm to others unless there is a strong justification in terms of either the consequences or justice. Psychiatric practice often involves assessing and treating people who either cannot consent or who are refusing for mad reasons, and so there needs to be legislation to protect vulnerable patients. There also needs to be a legal mechanism to protect the public from the tiny minority of patients who may pose a risk of harm to others but for whom the criminal law is inappropriate.

Much of the debate in the past 20 years between psychiatrists, lawyers and the government has been about the extent to which mental health law should be primarily about protecting the public or primarily about protecting the vulnerable patient. At present, psychiatry seems to be in a highly risk-averse mode, where the protection of the public is seen as a primary duty. It has not always been so in psychiatry, and it is to be hoped that this mode will change in the future.

CONCLUSION

Our professional competencies are acquired through training and experience. Our professional ethical identity, however, is made up of our professional values and attitudes. It begins with the MRCPsych training, but it continues to deepen and grow; we never stop learning how to be ‘good’ psychiatrists. Note that we do not have to be perfect; we only have to be (as a famous paediatrician once said), ‘good
enough’. We will inevitably sometimes make mistakes, and mature people learn from those mistakes. The ethical aspect of psychiatry is what makes it fascinating; paying close attention to ethical tensions in the work, and honing ethical reasoning skills, will make the job rich, human and enjoyable for years to come. At least, I have found it so.

**KEY POINTS**

- Ethics is the study of how we ought to treat people.
- Competence in ethical reasoning is essential for psychiatric practice.
- What is legally permissible is not necessarily ethically justifiable.
- In difficult situations, get advice and spend time in discussion: don’t let anxiety rush you.
- Good communication skills make ethical discussions easier.
- Good-quality ethical reasoning involves considering all perspectives, especially the ones you disagree with.
- A good outcome does not justify treating people badly: what is good clinically may not be ethically justifiable.

INTRODUCTION

Violence risk assessment has assumed increasing importance in mental health services over the past two or three decades. Of the many pressures that have led to a greater emphasis on risk, most are not specific to mental health but reflect wider cultural changes. Society as a whole has become more risk-averse. Popular concern about crime and violence borders on hysteria, despite evidence that the frequency of many offences has fallen.

It is tempting to dismiss the increased concern with violence risk as a further example of the health and safety fascism that demands children wear protective goggles to play conkers. It is tempting, but it is also wrong; the other side of the story is that the past 30 years have seen massive improvements in attitudes towards vulnerable people in general and towards victims in particular.

From being virtually ignored, victims have become a central concern of the criminal justice system. Once the rights of victims are acknowledged, the inevitable next step is a greater emphasis on protection and prevention. Specific examples include the greater consideration we now give to victims of rape and other sexual offences, and our willingness to confront the realities of child physical and sexual abuse, much of it perpetrated by carers and authority figures. At the same time, there has been an expansion of offending behaviour programmes aimed at reducing rates of sexual re-offending.

So, although some psychiatrists dismiss violence risk management as interference by the nanny state, a stronger case can be made that it is an aspect of progress towards a more civilized society. Concern for vulnerable people implies a desire to take all reasonable steps to minimize victimization.

THE ETHICS OF RISK ASSESSMENT

One source of professional resistance to violence risk assessment derives from concern that it is unethical. Concern with violence risk has been portrayed as stigmatizing to patients and therefore inconsistent with the caring role of a health professional. We need to confront this attitude head-on. Training in risk assessment is pointless if mental health professionals are reluctant to use it because they see it as a dark art that is essentially anti-patient. Fortunately, there is plenty of evidence to show that good risk management is an essential part of medical care. It is part of a doctor’s duty of care to manage violence risk competently, as the following sections illustrate.

Risk versus safety

Opponents assume that risk assessment attaches negative labels and leads to detention or other adverse consequences. This assumption has no basis. The aim of risk assessment is to distinguish different levels of risk and to inform decisions about resource allocation. The process would be pointless if it labelled all patients as high-risk. Any effective risk-assessment system discriminates between different levels and types of risk and ought to lead to low ratings more often than it leads to high.

Safety is the other side of the risk coin. There can be no ethical objection to describing a patient or, more accurately, a management plan as ‘safe’. On the contrary, it is unethical to deny patients an assessment that would identify them as low-risk simply because the same assessment would identify a (smaller) number of patients as high-risk. Most doctors would have no qualms about an assessment that suggests a patient can be treated safely in a particular setting; once that principle is accepted, there is no basis on which to argue against the same assessment just because the outcome for another patient is an indication of higher risk.

The inevitability of decisions about risk

Mental health professionals routinely take decisions that depend on estimates or ‘guesstimates’ of safety and risk. We take those decisions in a climate of intense scrutiny, where there are often accusations of institutional racism relating to the detention of patients from ethnic minorities. These difficult decisions are not going to go away. We cannot avoid risk assessment and management; the question is how well we are going to do it. The best course of action is to make the decisions, and the ethical dilemmas, explicit.
We can then deal with them transparently so our decisions can be questioned and challenged.

Conflicts in values

It is helpful to make explicit the conflict of values inherent in violence risk management. On the one hand, we place great value on respect for patient autonomy and minimize medical interference in their lives. On the other hand, we value the right of the public to live safely and free from the fear and threat of violence.

This conflict of values is real and we cannot avoid it by emphasizing only one side of the equation, whether it is the rights of patients or those of wider society. Instead, we need to find defensible and transparent means of negotiating that conflict. The process of violence risk assessment and management can help us to find a path through the minefield. It allows acknowledgment of the conflict, and it encourages openness about the compromises we make in order to negotiate a way through the dilemma.

Third-party risk in medicine

Finally, we need to bear in mind the wider context of medical practice. Since medicine now deals with chronic diseases where the aim is management rather than curative intervention, risk management is a core function of most branches of healthcare. The specialist in hypertension aims through treatment to minimize the risk of complications such as myocardial infarction and stroke. The specialist in diabetes aims through treatment to minimize a wealth of complications, including eye disease, renal failure and peripheral vascular disease. In this sense, violence risk management falls within the mainstream of medical practice.

Yet violence risk management in mental health is different because it sometimes involves compulsory treatment, which is, of course, rare in other fields of medicine. Psychiatry is exceptional because of the extent to which it deals with third-party risk, which is rare in most areas of medicine. Once we accept the proposition that some patients with mental disorders and without proper treatment will not only suffer harm but also inflict serious harm on others, we take on obligations rarely faced by medical professionals in other specialties.

Psychiatry is not quite unique in this respect, and there are some examples of third-party risk in physical medicine. They include the control of infectious diseases, restrictions on driving motor vehicles in people who are impaired by visual problems or epilepsy, and medical involvement in childcare proceedings when a mother is unfit through disease to look after her children. In all of these cases, the doctor is required to balance the rights of the patient against the rights of others, whether they are specific individuals or the general public.

Although the examples are hard to find, the principle of management in these cases is absolutely clear. There is a low threshold for intervening and restricting patients’ lives when disease involves risk to others. Society has a low tolerance for any risk to third parties that may be associated with diseases and their medical treatment. It is psychiatry’s misfortune that it deals routinely with third-party risks that are exceptional in other branches of medicine, but the principles are the same.

Common ground

Although there is sometimes a true conflict between the rights of the patient and the rights of the public, there is a lot of common ground. One of the most depressing things about the debate over the 2007 revision of the Mental Health Act 1983 was the tendency of the Bill’s opponents to present patients as an enlightened and embattled minority besieged by a hostile and ill-informed public.

In reality, patients are members of the public too. Mental illness is common and can affect anyone. Patients are more likely to be victims of violence rather than its perpetrators, and so there is a common interest in reducing the prevalence of violence.

The other sense in which there is common ground is that an act of serious violence has profound negative consequences for the perpetrator as well as the victim. The perpetrator is likely to spend a long time in custody, even if the setting is a secure hospital rather than a prison. The perpetrator will have to come to terms with having caused serious injury to another person, often a loved one, and suicide is not uncommon. The perpetrator may have to live with lifelong restrictions on his or her freedom. The violent act may split up a marriage or cause a rift within a family.

These dire consequences for the perpetrator amount to one of the most negative of all negative outcomes in mental illness. Leaving aside concern for potential victims, doctors have an ethical duty to take reasonable steps to reduce the chances of such a disastrous complication of serious mental illness.

Summary

A proper concern with the safe management of violence risk is not in any sense anti-patient. Risk management is an essential part of medical care, and the failure to manage violence risk properly can have devastating consequences for other people, for the patient, and for the public image of mental health.

THE ASSOCIATION BETWEEN MENTAL DISORDER AND VIOLENCE

Having dealt with the ethical aspects of violence risk management, it is appropriate to consider briefly the underlying science before moving on to the practicalities of managing risk.
One reason for the slow adoption of violence risk assessment in psychiatry is that, until recently, doctors were taught that violence was of little or no importance in mental illness. As recently as the late 1980s, the orthodox teaching within mental health was that there was no statistical association between mental illness and violence. Until then, most studies had methodological flaws that obscured the true picture. Only in 1990, with the emergence of large-scale epidemiological community studies, did it become apparent that there was a significant association. For example, Swanson and colleagues found self-reported violence during the past 12 months in 2 per cent of community respondents without a psychiatric diagnosis but in 8 per cent of community respondents with a diagnosis of schizophrenia.\(^1\)

The epidemiology of violence and mental disorder is now supported by a vast literature, and a review is beyond the scope of this chapter. It has been shown consistently that a diagnosis of schizophrenia is statistically associated with an increased risk of violence.\(^2\) The association with violence is even stronger for diagnoses such as substance misuse and antisocial personality disorder.

Apparent contrary findings, which show no statistical association between schizophrenia and violence, usually arise because the control group includes diagnoses such as personality disorder that carry an even higher risk. The true picture is summed up well in a paper by Shaw and colleagues, which showed a probability of schizophrenia of 5 per cent in men remanded on a charge of homicide compared with approximately 1 per cent in the general population.\(^3\)

The implication of these findings is inescapable. Once it has been demonstrated that some common mental disorders are associated at the population level with a significant increase in the risk of violence, their management becomes part of the core business of mental health services.

### APPROACHES TO RISK ASSESSMENT AND MANAGEMENT

#### Underlying principles

The awakening of interest in violence risk assessment has brought with it a range of methods, techniques and instruments. They can be helpful, but they can also be misleading; in order to use them sensibly, it is essential to be aware of their underlying assumptions and limitations. There is also a tendency for the debate to focus on which method or tool is ‘best’. The concept is meaningless unless we are clear about what we should expect from risk assessment. The underlying principles are helpful here because they show how much the various instruments have in common, and they help us to have realistic expectations of what they can do.

#### The past is the best guide to the future

The old clichés are the best, and it is impossible to overstate the value of this ancient one. It applies well beyond mental health and is the basis of aphorisms about learning from history, lest we be compelled to repeat it.

Critics point out that, if the cliché is taken at face value, then creativity could not exist and there would truly be nothing new under the sun. There would be no surprises. This criticism is valid but not fatal to a proper use of history. The future is similar to the past often enough to make it foolish in the extreme to ignore history. Also, surprises often come because somebody does something different; one of the things services can do differently is to improve treatment.

It is because of this principle that the management of violence risk begins with a careful description of the internal and external factors associated with previous violence. We hope to identify factors that we can change in order to influence the risk of future violence.

It is worth noting also that the principle of consistency is the basis of all science. Many scientific laws can be reduced to the formula: when \(x\) and \(y\) apply, \(z\) will follow. In most cases also, the scientific law originated from historical observations that, whenever \(x\) and \(y\) were observed together, \(z\) tended to follow. The next step is prediction based on a series of observations, which allows us to say how likely it is that \(z\) follows given that \(x\) and \(y\) are both present.

For our purposes, \(z\) is violence, or a particular type of violence. Risk assessment is the process of identifying the variables (internal and external) associated with previous violence and making predictions about the likely circumstances in which violence will recur.

Psychiatry is not physics. We will never have the luxury of precise formulae to link violence to its antecedents. The practical problem is that mental health services have to contend with variables \(a\) through to \(w\) as well as \(x\), \(y\) and \(z\). Nevertheless, the principle is sound. We should not neglect \(x\) and \(y\) just because there are other factors that we cannot influence.

#### There are fewer than 20 common indicators of risk

On the other hand, psychiatry has more of a scientific basis than we sometimes admit. Most management of violence risk deals with a surprisingly limited range of variables. They include non-compliance with medication, relapse, lack of insight, intoxication and psychopathy. The Historical Clinical Risk 20 (HCR-20) is so-called, rather than HCR-2000, for a reason: namely, that 20 variables cover most general indicators of violence risk.\(^4\) The Violence Risk Appraisal Guide (VRAG) has 12 items, as does the Hare Psychopathy Checklist: Screening Version (PCL-SV),\(^5\) whereas the full Hare Psychopathy Checklist Revised (PCL-R) has 20.\(^6\)
Standardized measures of risk in sex offending also tend to concentrate on a small number of variables, including psychopathy, non-sexual offending, victims unknown to the perpetrator, paraphilias, male victims, and inability to establish stable relationships. Of course, it would be ridiculous to suggest that such a small amount of information is all you need to know about a case, but the fact remains that a handful of variables tell us a great deal about the background risk of violence.

In summary, a small number of variables can account for much of the variance in the risk of re-offending. There is often overlap between the items used in different standardized measures. Once the basic list of variables is covered, little added value results from extending the list. Other, more idiosyncratic risk factors are best included as part of the overall clinical formulation rather than trying to develop a standardized measure that includes everything.

**Violence risk is multidimensional**

Violence risk is not like height and weight: it cannot be reduced to a score on a single dimension or number. Instead, it needs to be measured in a way that includes qualitative and descriptive factors.

The various facets of violence risk include nature, severity, immediacy and likely victims. A probability can be attached to any one of these dimensions. For example, a man with morbid jealousy may be very likely to attack his partner, moderately likely to attack a member of her family, and unlikely to attack a member of the general public. A predatory sexual offender may present a high risk of sexual assault to women but a low risk of violence to other groups of people.

The other difference from height and weight is that violence risk is not simply an inherent property of the individual. It depends also on external circumstances and contingencies, which make the description even more complicated. The use of alcohol and drugs increases most violence risks and, it may be more or less likely in the individual patient. Non-compliance with medication is one of the most important risk factors associated with violence in schizophrenia, so a patient on effective medication may present very different risks from the same patient when untreated.

A comprehensive assessment is therefore a detailed description, taking into account the history, present state and likely future conditions, and including an account of factors likely to increase and decrease risk. It is relative rather than absolute, and attempts to reduce risk to a number or percentage are misleading.

As a result, the quality of a risk assessment cannot be judged simply by its predictive ability. Testing of predictions lends itself readily to statistical analysis, but it should never be seen as the whole story. The true test of a risk assessment is the extent to which it aids treatment by improving risk management – which is much more difficult to measure but also much more important and useful than prediction.

If this sounds impossibly complicated, then we can take comfort from the fact that clinicians routinely juggle multifaceted risks. We are used to trading different dimensions off against each other. We decide almost automatically that a significant risk of minor physical assault can be tolerated and defended, whereas we have a very low tolerance when dealing with life-threatening assaults or potential risk to vulnerable groups such as children. The formal process of violence risk management simply makes these considerations more explicit and transparent – and therefore more defensible.

**Individual consistency helps clinical prediction**

Doctors have an advantage over physicists because doctors are concerned in clinical practice with risk prediction in the individual patient rather than in all patients or in the average patient. So, a rule about the relationship between delusions and violence may be impossible to formulate in a general sense for all patients, but a specific patient whose delusions have been associated with violence in the past will probably exhibit violence when deluded in the future. The greater accuracy is possible because, in scientific terms, many of the variables associated with the individual patient are controlled; they remain constant over time.

For this reason, statistical studies may underestimate the extent to which we can predict violence in association with mental illness. As a general rule, a patient who has been violent during a previous psychotic episode should be assumed to be likely to behave violently during a future episode, all other things being equal.

**The main priority is to prevent repetition**

It is much more difficult to foresee a first act of violence than it is to predict a repetition. Although this fact is rarely stated explicitly, it is implicit in any risk-management tool that relies on history. It follows from the first principle – that the past is the best guide to the future: when there is no history, it is difficult to say much about the likely future.

The same principle shapes expectations and criticisms of mental health services. The most critical homicide inquiries condemn failure to manage a patient who has already behaved violently, rather than failure to predict a first act of serious violence. In this sense, the attitude of the public is consistent with the science. One can understand and sympathize with professionals when a serious act of violence comes out of the blue, but there is less sympathy when there has been previous violence in similar circumstances. The more serious the previous violence, and the greater its similarity to the present act, the less any failing will be understood or tolerated.

This principle is also a powerful response to those who oppose risk management as ‘locking up people who have not done anything’. If a risk-management system works properly, then it should give priority to those cases in which
there has been previous violence. It is almost impossible for any patient to be rated as presenting a high risk of violence without a history of violence.

**Psychopathy is a risk factor for violence**

Many risk-assessment instruments incorporate items related directly or indirectly to psychopathy because psychopathy has consistently shown a positive association with violence risk. One can accept this association without necessarily accepting psychopathy as a diagnostic entity. For example, features such as lack of empathy and callous unconcern for others are likely to increase violence risk, whether they derive from schizophrenia, autism or a personality disorder. It may also be the case that the value of such a measure derives from a careful recording of the range and extent of previous antisocial behaviour rather than the diagnosis of any underlying personality disorder.

An elevated psychopathy score increases violence risk, irrespective of other diagnoses, but the reverse is not true. It is a serious mistake to assume that the absence of features of psychopathy necessarily means a low risk of violence, and this mistake is made most easily when dealing with mental illness. Schizophrenia and other serious mental illness can result in a high risk of violence, even in the absence of all other historical indicators of violence risk. Hence, standardized instruments that rely heavily on indicators of psychopathy can be misleading in mentally ill people.

**THREE APPROACHES TO RISK ASSESSMENT**

Having set out some principles of violence risk assessment, we turn to attempts to apply them in clinical practice. The three approaches considered here are unstructured clinical assessment, actuarial or standardized assessment, and structured clinical assessment. The evidence strongly favours a structured clinical approach, so the other two approaches are given only brief consideration. See Maden\(^7\) for a more detailed discussion.

**Unstructured clinical assessment**

As the title suggests, there are no rules other than the basic rules of good clinical practice. Until recently, this was probably the most common method of assessing violence risk in the UK. It has the virtue of being used widely and flexible. It can be adapted endlessly to fit any clinical case.

The disadvantage is that there is wide variation in individual practice, and standards vary widely according to the skill and experience of the practitioner. It is also difficult to challenge the opinion or to communicate the basis of the assessment to others. These are serious criticisms in an era when mental health services are often criticized for apparent discriminatory practice. A more structured approach to assessment could be justified solely on the grounds that it helps to reduce discriminatory practice, even if it made no other contribution to improving risk management.

**Actuarial or standardized risk assessment**

This term is derived from the insurance industry, in which a small number of facts are gathered and then combined according to a strict formula in order to estimate the level of risk associated with life insurance. Actuarial risk assessment lies at the opposite end of the spectrum from the unstructured clinical method. There are fixed rules about the data that must be gathered, and about the way in which data are used to arrive at an assessment of violence risk.

The link with the insurance industry is a key to both the strengths and the weaknesses of this method. The strengths are that it is systematic, eliminates variation between individual practitioners and excludes clinical judgement. Statistical evaluation shows that such methods are reliably better than chance in predicting violence.

Of course, such statistical evaluations are done on populations rather than individuals. The insurance industry requires only that its methods work for populations and has no interest in individual prediction. By contrast, clinical risk management deals with individuals. When dealing with individual patients, the inflexibility of the actuarial method becomes a major drawback. For example, an individual may have a single, idiosyncratic problem (e.g. morbid jealousy) that leads to a high risk of violence. In the absence of other generic risk factors, an actuarial assessment would be misleading, with potentially disastrous consequences.

VRAG is one of the most widely used actuarial scales.\(^8\) Its authors won notoriety by claiming it could and should supplant clinical estimation of risk. The scale was developed on 600 adult male patients followed up after release from a high-security hospital in Ontario, Canada, with violent reoffending as the outcome measure. From a mass of data, 12 items were found to predict reoffending (Box 79.1).

The claimed strength of actuarial instruments such as the VRAG is that they express risk in simple percentage terms. Put in 12 variables and the VRAG gives a risk of violent reoffending between, for example, 10 per cent and 20 per cent. Such precision would be wonderful if it were valid but, as we have seen above, violence risk is multifaceted and cannot be reduced to a single number.

A further problem is that the percentages are derived from groups and cannot be applied directly to an individual patient. We gain some useful information from knowing that an individual patient closely resembles a group with a particular risk of reoffending, but it is misleading to assume that all members of the group will behave in the same way. Idiosyncratic features and events may lead to a very different outcome. A simplistic example is the highrisk offender who is incapacitated by a broken leg or a serious physical illness; the VRAG score does not change, but the actual risk may be very different.
Incidentally, none of this matters in large groups, where the oddities cancel each other out. Actuarial measures such as the VRAG are useful and valid for commissioners and planners who may wish to compare services or allocate resources, but the clinician dealing with individuals needs to be more cautious in interpreting scores.

The other problem of the actuarial approach is that it is relevant only for patient groups very similar to the group on which it was developed. One of the oddities of the VRAG is the negative effect on risk of a diagnosis of schizophrenia. This anomaly arises because the personality-disordered patients in the original study group presented even higher risks. The research literature would not support the downgrading of risk because the diagnosis is schizophrenia.

Structured clinical assessment of violence risk

The structured clinical method represents a compromise between actuarial or standardized assessment on the one hand and the unstructured clinical method on the other (Box 79.2). A structured clinical assessment requires the collection of a certain amount of standard data about the individual (the small number of standard variables mentioned above), but there is flexibility in the use of additional data and in the way data are used to draw conclusions. In the example given above, morbid jealousy would simply be included as an additional variable, and the shrewd clinician would give it appropriate weight in the risk assessment, unconstrained by any of the rules that apply in actuarial assessments.

The best-known example of structured clinical risk assessment is the HCR-20. The HCR-20 requires the collection of 20 data items: ten items are historical and refer to the past; five items are clinical and relate to present state; and five risk-management items relate to the future (Box 79.3).

Each of the 20 items is scored as definitely present (2), probably or partially present (1) or absent (0). The definitions for each item are described by Webster and colleagues, and they are a major part of training in the use of the HCR-20. They are intended to be not operational but ostensional – that is, they provide only examples of the

**Box 79.1 The 12 items of the Violence Risk Appraisal Guide**

- PCL-R score
- Problems at junior school
- Personality disorder
- Alcohol abuse
- Separated from parents before age 16 years
- Failure on prior conditional release
- History of non-violent offending
- Never married
- Schizophrenia*
- Extent of victim injury*
- Age*
- Female victim*

*Negative correlation with risk of violence.

Total scores on the instrument have been divided into nine bins, along a spectrum of violence risk. Each bin has an attached probability of violence, expressed in percentage terms and relating to a 7-year timeframe.

---

**Box 79.2 Structured clinical management of violence risk**

- **Step 1:** Collection of data from records, patient interview and informants.
- **Step 2:** Standardized assessment of static and dynamic risk factors.
- **Step 3:** Consideration of idiosyncratic risk factors.
- **Step 4:** Description of violence risks, including nature, likely victims, and factors increasing and decreasing the risk.
- **Step 5:** Description of plans to address the risks, including contingency plans.
- **Step 6:** Assign priorities.

---

**Box 79.3 The 20 items of the Historical Clinical Risk 20 (HCR-20)**

**HISTORICAL ITEMS**

- H1: previous violence
- H2: young age at first violent incident
- H3: relationship instability
- H4: employment problems
- H5: substance use problems
- H6: major mental illness
- H7: psychopathy
- H8: early maladjustment
- H9: personality disorder
- H10: prior supervision failure.

**CLINICAL ITEMS**

- C1: lack of insight
- C2: negative attitudes
- C3: active symptoms of major mental illness
- C4: impulsivity
- C5: unresponsive to treatment.

**RISK-MANAGEMENT ITEMS**

- R1: plans lack feasibility
- R2: exposure to destabilizers
- R3: lack of personal support
- R4: non-compliance with remediation attempts
- R5: stress.
type of behaviour that should receive a particular rating. Other examples are always possible. Therefore, the rating requires judgement and the exercise of discretion.

With the basic data in place, the clinician is then required to add any idiosyncratic variables and to make an assessment of risks. There is complete freedom to interpret the data as seems appropriate in the individual case.

So far, the method appears to be no more than a flexible form of standardized risk assessment, with allowances for the exercise of clinical discretion. But there is one further stage to the HCR-20 that turns it from a risk-assessment instrument into a tool for risk management. The second stage of the HCR-20 is to formulate feared scenarios of violence based on the available data. For each scenario, the assessor is required to describe factors that will increase or decrease the risk, leading to the formulation of interventions and the assignment of priority to the case.

The three steps to developing a risk management plan in the HCR-20 are:

1. Description of feared scenarios of violence.
3. Prioritization of the case and arrangements for review.

The task may seem daunting because the number of scenarios is potentially infinite. In practice, the same scenarios and circumstances recur frequently – sometimes in a way that is embarrassing to mental health services because we fail to deal with them adequately.

Examples of common scenarios include the following:

- A patient stabilized on depot changes to oral medication.
- A patient stabilized on depot changes to oral medication.
- A non-compliant patient relapses, takes drugs and then assaults a family member, friend or fellow hostel resident.
- A male patient attacks his partner when he is unwell, because of his jealousy or her infidelity.
- A decrease in monitoring or support (e.g. discharge or transfer from hostel to the community) leads to non-compliance or drug-taking, relapse and violence.

The familiar themes of non-compliance, relapse and intoxication occur repeatedly. Common warning signs of an increased violence risk in mentally ill patients include relapse and non-compliance, from which case-management strategies follow automatically. Victim safety planning is often forgotten, but it is well known that relations and carers are disproportionately likely to be the victims of violence by mentally ill patients.

Protective factors tend also to be neglected, but they should be part of any risk-management plan.

**STRENGTHS AND WEAKNESSES OF THE HCR-20**

The HCR-20 and other structured clinical methods have become popular because they help clinicians without telling them what to do. They inform and can improve clinical judgement without attempting to substitute for it. The clinical team makes the final decisions.

This strength of the HCR-20 is potentially also its main weakness. Clinicians may feel disappointed that the final decisions and judgements remain with them. Unfortunately, there is no escape from this reality. Violence risk management involves making choices in a complicated situation in which conflicting values have to be balanced against each other and there is a range of possible right answers rather than a single one. It is unrealistic to expect any standard formula to come up with the ‘right’ answer, because the single right answer does not exist.

The structured clinical method goes beyond assessment into risk management. Violence is not a neutral occurrence. It is always a bad outcome. Good assessment automatically implies management aimed at avoiding the negative outcome.

A potential source of error in the HCR-20 is to add up the scores and use it as an actuarial instrument. In fact, this practice may be adopted as a way of measuring the predictive validity of the HCR-20’s items; it is difficult to think of any other way of measuring its predictive abilities.

Statistical evaluations of this type have value, and they suggest that the HCR-20 is comparable to actuarial measures of violence risk. We can derive comfort from that finding – the HCR-20 has indeed chosen 20 of the right variables – while also bearing in mind that it does not reflect best clinical use of the HCR-20.

It is interesting to reflect on how the HCR-20 can be better evaluated. It allows for idiosyncratic variables that, by definition, apply only to the individual patient and so cannot be included in statistical analysis. It also allows for the use of discretion, and so a high score need not imply a clinical judgement of high risk.

The point of the HCR-20 is to formulate a good risk management plan rather than to make a precise prediction. It is against that standard that it should be judged. In other words, it is judged against the standards of clinical practice, and not by the standard (predictive accuracy) of the fortune-teller or the actuary. The problem is that we do not have good ways of measuring standards of clinical practice; the task of the profession is to develop them rather than to allow ourselves to be judged by inappropriate statistical measures.

Meanwhile, the HCR-20 and other structured clinical approaches fit easily into the care programme approach (CPA), which is based on planning for the future and includes regular reviews. The HCR-20’s three strands relating to past, present and future are ideally suited to the CPA framework.

**RISK-SHARING AND OWNERSHIP**

Accurate prediction is never possible in the individual, and we can never eliminate violence risk entirely. Therefore, we
have to confront the problem of dealing with uncertainty, and we have to manage negative outcomes. It is inevitable that things will go wrong sometimes, and preparation for a bad outcome is part of risk management.

The first step is to clarify one’s responsibilities. Risk assessment and management can be considered as a three-stage process that addresses the following questions.\(^9\)

- **What are the risks associated with treatment of this mental disorder?** Mental health professionals should be able to give a reasonable answer, whether the issue concerns general risks or a specific patient. Professional expertise is relevant.

- **How can the risks be reduced?** Again, professional expertise is relevant, and so this is a reasonable question to address to mental health professionals. We may not be able to implement the measures concerned, but we can give an opinion on the likely effects of particular interventions or non-interventions.

- **Are the residual risks acceptable?** Unlike the previous two questions, the answer to this is to be found not in professional expertise but in moral, social or philosophical considerations. As it is not a technical question, mental health professionals have no claim to special expertise. There are also risks for the profession because, if we take on this responsibility, then we are held to account when things go wrong.

These considerations may seem abstract, but they underpin measures such as the restricted hospital order. Mental health services give their opinions on the risks and the effects of treatment, but the decision on discharge, which is effectively a consideration of whether the risk is acceptable, rests with the Ministry of Justice or with a tribunal.

Similar considerations should apply when dealing with risk in other contexts. At the lowest level, it is essential to involve relations and carers in decisions. The views of other members of the multidisciplinary team should always be sought. When dealing with mentally disordered offenders, there may be joint working with the probation service or the involvement of a multi-agency public protection panel. The common theme is a wider sharing of risks.

It is wrong to dismiss this approach as defensive practice. Once the issues involved go beyond technical questions, the quality of decision-making is improved by the involvement of other perspectives.

## THE SECOND OPINION

Risk assessments are rarely right or wrong in categorical terms, but they vary in quality. Similarly, there is usually room for discretion in the way risks are managed. The final arbiter is almost always a matter of clinical judgement. The preceding section stressed the importance of multidisciplinary and multi-agency approaches as a way of sharing risks and improving the quality of decision-making.

In particularly difficult cases, the best course of action is to seek a second opinion. Greater use should be made of forensic services in this respect. There may be no expectation that the service will take over the patient or suggest anything new, but the endorsement of current treatment can be invaluable. When there is no absolute right or wrong answer, it is reassuring to know you have the support of others. After all, a homicide inquiry is nothing more than a second opinion delivered with the benefit of hindsight; it is far better to have the benefit of all that wisdom before the event rather than after it.

### KEY POINTS

- Violence risk assessment always requires a detailed history of previous violence and the circumstances in which it occurred.
- Violence risk is multidimensional, and so a comprehensive assessment can never be reduced to a number or percentage on a single measure.
- Structured risk assessment enhances but can never replace clinical judgement.
- The best risk assessments are relative rather than absolute. They facilitate risk management by describing factors that will increase or decrease risk.
- Clinical and non-clinical factors contribute to violence risk. Multi-agency working allows better management and appropriate sharing of risk.
- Decisions on the acceptability of risk are social and political rather than medical. High-risk cases often involve courts and tribunals. Clinicians should take all reasonable steps to involve relatives and carers.
- Violence risk can never be eliminated, and so comprehensive risk management includes planning for a negative outcome.
- There are few absolutes in risk management. There is usually a spectrum of reasonable decisions rather than a single right answer. In doubtful and high-risk cases, the best protection is a second opinion.

APPENDIX I

Domestic Violence, Crime and Victims Act 2004

Provisions for unfitness to plead and insanity

1. Judge rather than jury will determine fitness to plead.
2. Secretary of State loses role in deciding whether defendant is admitted to hospital. Now a matter for Court.
3. Court can no longer order psychiatric hospital admission without medical evidence that justifies detention on grounds of mental state.
4. New range of disposals.
   (a) S. 37 Mental Health Act 1983 with or without a Restriction Order under S. 41.
   (Also S. 38 Interim Hospital Order).
   N.B: Court can now require a hospital to admit.
   (b) Supervision Order for physical and/or mental disorder, but not as inpatient without consent.
   (c) Absolute Discharge.

Extension of Victim Contact Scheme to victims of Mentally Disordered Offenders.
Includes offenders:
• Transferred from prison to hospital.
• Subject to Hospital Orders with Restriction Orders.
