A number of important laboratory measurements can be made on the cerebrospinal fluid: suspected bacterial, mycobacterial or fungal infection may be confirmed by immediate microscopy; evidence of viral or partially treated bacterial infection may be inferred from the type and density of white cells present; malignant cells may be identified in cases of central nervous system lymphoma or malignant meningitis; a translucent yellow tinge due to the breakdown products of haemoglobin (xanthochromia) forms 12 h after leakage of blood into the subarachnoid space and persists for at least 2 weeks, allowing a diagnosis of subarachnoid haemorrhage to be made even if blood was not, or is no longer, visible on CT; elevated protein content suggests acute or chronic inflammation, and the appearance on a cerebrospinal fluid electrophoresis of immunoglobulin bands that are not matched by similar patterns in a serum specimen in a vertical glass tube and measuring the height of the column. A low-pressure headache (relieved by lying down) occurs in up to a third of patients due to continued cerebrospinal fluid leakage after withdrawal of the needle. It normally settles spontaneously within days but sometimes necessitates infusion of a sample of venous blood obtained from the patient to seal the defect (blood patch).

**Tissue biopsy**

**Muscle and nerve**

Nerve and muscle biopsy are minor procedures carried out under local anaesthetic in order to obtain diagnostic information that cannot be acquired by less invasive means. Almost all patients with clinical and electrophysiological evidence of myopathy will be submitted to muscle biopsy, allowing degenerative, metabolic, dystrophic and inflammatory conditions to be identified from typical histological features. The large bulk and easy identification make deltoid or quadriceps the usual muscles of choice, though there may be clinical reasons for targeting other specific muscles.

Nerve biopsies are typically taken from the ankle (sural) or wrist (radial), since at these sites the nerve bundles consist of sensory fibres, restricting the inevitable postoperative deficit to a small and non-disabling area of anaesthesia. Nerve histology enables a firm diagnosis of vasculitic neuropathy to be established or excluded, the former justifying prolonged use of powerful immunosuppressive drugs. Rarer infiltrative causes, such as amyloid or lymphomatous neuropathy, will also become evident on biopsy.

**Brain**

The hazardous nature of brain biopsy, and its obvious potential for causing permanent functional disability, means that a decision to perform it is restricted to those cases in which there is high clinical suspicion of either (i) a potentially treatable but otherwise unprovable pathological process or (ii) a condition that, for prognostic purposes, is important to demonstrate.

**TREATMENT OF NEUROLOGICAL DISEASE**

Many chronic neurological conditions are amenable to specific therapies, although most of these act by relieving symptoms. Those that ameliorate the clinical course of the disease (disease-modifying agents) are unfortunately few and far between. The main groups of symptomatic treatments are anticonvulsant drugs (which raise the epileptic seizure threshold, reducing the likelihood of an episode); anti-migraine drugs (particularly of the triptan group, which stimulate serotonin receptors in the brain and cranial blood vessels); dopamine analogues and agonists (which partially compensate for the dopaminergic neuron deficit that underpins the movement disorder in Parkinson’s disease); and (underpinned by a similar principle) cholinergic agents in AD. Specific treatments for neuropathic pain include those with anticonvulsant and antidepressant properties, which may act by inhibiting overactivity in nociceptive fibres. Corticosteroids, usually in the form of intravenous methylprednisolone, are used to encourage

**Part 4 :Mental health problems and mental illness**
resolution in acute exacerbations of relapsing conditions with an inflammatory basis, including MS. Immune-suppressant drugs, such as methotrexate and cyclophosphamide, have a role in reducing the frequency of relapses and hence the need for repeated steroid doses. A selection of the important symptomatic agents, together with their indications, modes of action and important adverse effects, is provided in Table 36.7.

TIA, transient ischaemic attack.

Drugs that act on the underlying mechanisms of disease, and either reverse or modify the process, would be of enormous public health benefit and greatly welcomed by patients. Unfortunately, such agents remain largely an aspiration rather than a reality. One exception is interferon beta, which has been shown to reduce the relapse rate and long-term disability in some patients with relapsing–remitting MS, although its precise mechanism of action remains poorly understood.

**KEY POINTS**

- A clear history of the onset (sudden or gradual), pattern (variable, stuttering, progressive) and time course (static, improving, worsening) of a patient’s symptoms is the single most important neurological investigation: diagnosis can often be confidently based on this information alone; without it, the result of the most sophisticated laboratory tests are often uninterpretable.
- Neurological symptoms can be thought of as disturbances of (i) sensation (including pain), (ii) balance, (iii) consciousness, (iv) muscular control and (v) cognitive function.
- Headache is the most common neurological symptom and rarely has a sinister underlying cause. Subarachnoid haemorrhage, giant cell arteritis (in patients aged over 60 years) and raised intracranial pressure should, however, not be missed, as the consequences of delaying treatment may be devastating.
- Muscular weakness due to a lesion in the cerebral hemisphere, brainstem, spinal cord, lower motor neuron, neuromuscular junction or muscle are each associated with distinctive combinations of clinical features.
- Movement disorders can be classified into diagnostically helpful categories (tremor, chorea, myoclonus, hemiballismus, tic) on the basis of history or observation.
- A witness’s description is essential to the evaluation of a first suspected ‘fit’. Home video recordings are becoming more common as clinical evidence and are to be encouraged.
- An informative analysis of the nature of cognitive decline is possible using careful history-taking and a battery of simple neuropsychological instruments adapted for use in the clinic or at the bedside.
- Contrary to popular belief, many neurological illnesses, both acute and chronic, are amenable to effective symptomatic treatment. Drugs for modifying the course of chronic disease, however, remain a largely unachieved aspiration.
INTRODUCTION

This chapter describes the following groups of organic disorders, all of which are of importance in clinical neuropsychiatry: neurodegenerative and movement disorders; vascular disorders; trauma; hypoxic disorders; nutritional, toxic and metabolic disorders; infectious and related disorders; prion diseases; endocrinological disorders; immune-related disorders; and brain tumours and hydrocephalus. Psychiatric assessment is covered in Chapter 48.

NEURODEGENERATIVE AND MOVEMENT DISORDERS

Alzheimer’s disease, Lewy body disease and frontotemporal dementia are detailed in Chapter 72.

Parkinson’s disease

Parkinson’s disease, also known as idiopathic parkinsonism and paralysis agitans, is common, with a prevalence of roughly 0.2 per cent. The male/female ratio is about 1.5 : 1.

Clinical features

The onset is gradual and insidious, with symptoms generally first appearing in the mid-50s. The range is from 20 years to 80 years.

It initially manifests with parkinsonism:1-12 patients typically present with asymmetrical tremor or rigidity affecting an upper or, less commonly, lower extremity. Over time, the opposite side becomes involved, and eventually all four limbs are affected.

Once fully established, Parkinson’s disease leaves a stamp on patients that is, once recognized, almost unforgettable. Patients stand in a stooped ‘flexion’ posture, with their arms and knees in flexion. A rhythmic (3–7 cycles/s – cps, hertz, Hz) rest tremor is present, most noticeably in the hands but also evident, when seated, in the feet; the jaw is also often tremulous. Of note, although the tremor typically resolves with sleep, in a minority of patients it may persist.3,4 The face is often ‘masked’ and expressionless, and there is a reduced frequency of blinking; there may also be copious drooling. Speech is hypophonic, soft, monotonous and lacking in emotional inflection. Handwriting undergoes a micrographic change, producing scratchy, small letters. Passive extension of the limbs reveals the rigidity, which, although often ‘cogwheel’, may at times be ‘lead pipe’ in character.

While walking there is reduced arm swing, and patients often display marche à petit pas, wherein they take small, shuffling steps; furthermore, they often display festination, in which, as they walk, their steps become ever more rapid and closely spaced, to the point at which a catastrophic fall forward seems almost inevitable. Upon evaluating the station of these patients, one typically finds retropulsion, wherein a gentle push on the patient’s chest will induce a gradual toppling backward that the patient cannot keep up with by backward steps. Bradykinesia manifests as slowness in virtually any activity. For example, even in the absence of tremor or significant rigidity, it may take many minutes to fasten a button. A related phenomenon is bradyphrenia, in which thoughts, although coherent and logical, move very slowly.

Another curious phenomenon is freezing: in this, patients on the brink of an intentional act suddenly become frozen and unable to move at all.5 A patient standing in a doorway and desirous of walking down the hall may be unable to lift a foot, take a step or move at all. Amazingly, such freezing may be prevented by providing appropriate visual cues. For example, if the hallway is marked off with pieces of tape set about one footstep apart, the patient may well be able to begin and finish the walk down the hall without difficulty; furthermore, in some cases, patients may be able to lyse their own frozen state by simply imagining such cues.6

Akathisia may occur and may appear early in the course of the disease, before any pharmacological treatment.7 Autonomic symptoms such as dysphagia, constipation, urinary frequency or incontinence, and nocturia are common, occurring in over one-half of patients after 10 years or more of disease.8

Parkinson’s disease is associated with dementia,9 with overall reported prevalence figures ranging from 11 per cent10 to 41 per cent.11 Its prevalence rises with age: Mayeux and colleagues noted a prevalence of 0 for people under 50 years and 69 per cent for those over 80 years.11 Similarly,
over an 8-year follow-up, Aarsland and colleagues noted that 78 per cent became demented.12 It also appears that dementia is more likely in patients with more severe motor symptoms. Importantly, the dementia does not appear until after the motor symptoms have been well established: one study found that the onset of dementia occurred at a mean of 13 years after the appearance of motor symptoms, with a range of 6–21 years.13 The dementia is fairly non-specific: patients may experience difficulty with memory and concentration; less commonly, focal deficits such as aphasia or apraxia may appear.

Major depression has been reported in 3 per cent,14 5 per cent15 and, in two separate studies, 21 per cent of patients.16,17 Minor depressive symptomatology may be found in other patients15 – indeed, up to 20 per cent.17,18 The presence of depression worsens the cognitive deficits in patients who are also demented.19 In patients with primarily unilateral motor symptomatology, depressive symptoms are more likely when the right side of the body is affected compared with the left, indicating an involvement of the left hemisphere in the genesis of depression.17

Rapid-eye-movement (REM) sleep behaviour disorder is fairly common.

Course
Untreated, most patients become incapacitated within 8–10 years, with death often from pneumonia. With treatment, survival of 15 years or more may be expected.

Pathology
Macroscopically, there is depigmentation of the substantia nigra and the locus coeruleus. Microscopically, neuronal loss is present not only in these structures but also in the dorsal raphe nucleus, the pedunculopontine nucleus, the dorsal motor nucleus of the vagus, the thalamus, hypothalamus, nucleus basalis of Meynert, the amygdala, and in various areas of the cortex, including the temporal, insular, and cingulate cortices. Remaining neurons typically display the hallmark of Parkinson’s disease, namely the Lewy body, which is an intracytoplasmic inclusion, composed of alpha-synuclein, neurofilaments and ubiquitin.

Motor symptoms correlate with cell loss in the substantia nigra and generally do not appear until 60 per cent or more of these cells have been lost. Dementia correlates with cell loss and Lewy bodies in the cortex,13 and depression with greater cell loss and Lewy body pathology in the striatum of patients but also a reduced uptake in their clinically unaffected co-twins, suggesting that the co-twins had asymptomatic disease.23 Environmental toxins have long been suspected, and suspicion has focused on exposure to pesticides.24 Cigarette-smoking appears to reduce the risk of developing Parkinson’s disease.25

Interest in genetic factors has been stimulated by the investigation of cases having a clear-cut, unequivocal familial basis. These constitute only a small percentage of cases, no more than 10 per cent, and the pattern of inheritance may be either autosomal dominant or autosomal recessive. Table 37.1 lists the various forms that have been discovered.

Psychiatric side effects of medication
Most patients treated with levodopa or dopamine agonists eventually develop significant neuropsychiatric side effects. The most common of these are visual hallucinations; others include psychosis, anxiety (during wearing-off of levodopa) and certain other, much less common phenomena, including impulsive behaviours, stereotypies, euphoria (with, rarely, mania) and delirium.

Visual hallucinations are very common with prolonged treatment with either levodopa or dopamine agonists: in one 6-year study, the percentage of patients with hallucinations increased gradually until, at the end of the study, 62 per cent of patients were experiencing them.26 The hallucinations are typically complex, involving scenes, animals or people, and may last from minutes to hours or even days; importantly, early on, patients retain insight into the hallucinatory nature of these experiences and recognize that they are not real. Auditory hallucinations, or even olfactory or gustatory hallucinations, may also occur, but these are much less common.26,27 Of note, in a very small minority of patients, visual hallucinations may occur before any treatment is administered. Furthermore, it appears that patients with greater cell loss and Lewy body pathology in the amygdala are more likely to develop hallucinations when treated with levodopa.28 It may well be that amygdalar pathology not only renders patients more sensitive to the hallucinogenic effects of levodopa and dopamine agonists but may also, if severe enough, independently cause hallucinations.

Psychosis is said to be present when patients either experience hallucinations without insight or develop delusions. As noted above, visual hallucinations with preserved insight are very common; however, over a matter of several
years, the majority of patients who do have hallucinations will lose insight and begin to react to the visual hallucinations as if they were real. Delusions, often of persecution, may also occur but are much less common.

Treatment of hallucinations or psychosis should generally involve an attempt at reducing the dose of levodopa and/or dopamine agonists. These side effects are generally dose-responsive and in some cases it may be possible to reduce the dose sufficiently to allow for a substantial resolution of them without sacrificing control of the parkinsonism. When dose reduction is either ineffective or impractical, consideration may be given to treatment with an antipsychotic. Of the various second-generation antipsychotics that have been used, clozapine is the most successful; however, its side effects may make one hesitant to use it and, in such cases, consideration may be given to low-dose risperidone.

Anxiety may be seen during motor fluctuations of the ‘wearing-off’ type, and full anxiety attacks may occur; other symptoms seen during the ‘off’ period include depressed mood, irritability and sweating.

Impulsive behaviours, including pathological gambling, compulsive shopping and hypersexuality, may occur as side effects of treatment in a small proportion of patients and appear more likely in those treated with dopamine agonists; with discontinuation of treatment with the offending medication, symptoms resolve within days to months.

Stereotypes seen with treatment may be complex and socially disabling. Known as ‘punding’, these may include repeatedly taking apart and putting together machinery or engaging in other purposeless behaviours.

Euphoria may occur, and some patients may escalate the dose in order to achieve this side effect. In some cases, albeit rarely, a manic episode may occur.

Delirium has been noted as a side effect but is rare.

### Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS), first clearly delineated by the French neurologist Jean-Martin Charcot in 1874, is classically characterized by a combination of upper and lower motor neuron signs; there is additional involvement of the frontal and temporal cortices in this disease, with, in a substantial minority of patients, the development of a dementia. Also known as Charcot’s disease, motor neuron disease and Lou Gehrig’s disease (after the famous
American baseball player who suffered from it), ALS has a lifetime prevalence of roughly 4–6 per 100,000 and is more common in men than women by a ratio of approximately 1.5 : 1.

Clinical features
Onset is gradual, most patients falling ill between the ages of 40 years and 70 years. Classically, patients present with weakness in one of the upper extremities, often in the hand, and there may be difficulty buttoning clothes or using small tools; over time, other limbs become involved. Eventually, with involvement of both upper and lower neurons, brisk deep tendon reflexes are found, with atrophic muscular weakness and fasciculations. With involvement of the upper motor neurons destined for the cranial nerve nuclei, a pseudo-bulbar palsy may appear, with dysarthria, dysphagia, and ‘emotional incontinence’, with forced laughter and crying; the jaw-jerk reflex tends also to be brisk. With involvement of the lower motor neurons in the cranial nerve nuclei, the tongue may become atrophic and demonstrate fasciculation. Sensory changes are generally absent.

Subsequent to the onset of the upper and lower motor neuron symptoms, dementia may gradually appear in up to one-quarter of all patients; in a significant minority of others, there will be a cognitive decrement of less severe degree, characterized by poor short-term memory and judgement.

Although most patients present with a combination of upper and lower motor neuron signs and symptoms, in a small minority the presentation is weighted heavily towards either the upper motor neuron (producing primary lateral sclerosis) or the lower motor neuron (producing progressive muscular atrophy). Primary lateral sclerosis is characterized clinically by a progressive spastic paresis, accompanied in roughly one-half of patients by a pseudo-bulbar palsy. Progressive muscular atrophy, in contrast, presents with progressive weakness, atrophy and fasciculations. In most cases, patients with progressive lateral sclerosis or progressive muscular atrophy go on to develop clear clinical evidence of involvement of both upper and motor neurons, thus leaving no doubt as to the correct diagnosis.

Electromyography (EMG) typically reveals evidence of denervation, and nerve condition velocity studies are typically normal.

T2-weighted or fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) may reveal increased signal intensity bilaterally in the centrum semiovale, corresponding to the corticospinal tracts. Rarely, atrophy may be noted in the prefrontal gyrus.

Course
ALS is almost invariably progressive, with death, often from respiratory failure or intercurrent pneumonia, generally occurring within about 3 years; survival past 5 years is uncommon.

Aetiology
Ninety per cent of cases are sporadic; roughly 10 per cent are inherited in an autosomal dominant fashion, secondary to mutations in the gene for superoxide dismutase on chromosome 21, and there are very rare cases of inheritance on a recessive basis. Although the mechanism underlying cell loss in ALS is not known, excitotoxicity is strongly suspected.

Progressive supranuclear palsy
Progressive supranuclear palsy, or the Steele–Richardson–Olszewski syndrome, is characterized by an atypical parkinsonism, usually accompanied by supranuclear ophthalmoplegia and, in about half of cases, dementia. It is uncommon and occurs somewhat more frequently in men than women.

Clinical features
The onset is insidious and generally occurs in the sixth decade. The disease typically presents with frequent unexplained falls owing to postural instability. An atypical parkinsonism then gradually appears, characterized by a more or less symmetrical onset of rigidity, generally without tremor, and an abnormal gait typified by a wide-based stance with short, shuffling steps. Importantly, rather than the typical flexion posture seen in most cases of parkinsonism, patients with progressive supranuclear palsy typically display a dystonic axial rigidity, which may also affect the neck. Dystonic rigidity also affects the facial musculature, at times creating an ‘astonished’ appearance.

Classically, 1–3 years after the parkinsonism is established, one also sees a supranuclear ophthalmoplegia for vertical gaze, wherein patients have difficulty voluntarily looking down, a difficulty that may make walking down stairs particularly treacherous. This feature, however, may be delayed for many years and in some cases may never appear.

Dementia occurs in about one-half of all patients, generally well after the parkinsonism has become established: patients have difficulty with concentration and memory, and there may be elements of a frontal lobe syndrome with prominent apathy. Rarely, dementia may constitute the presenting symptom of progressive supranuclear palsy. Over time, pseudo-bulbar palsy with emotional incontinence may occur, and seizures may occur in a small minority. Aphasia, agnosia and apraxia are rare.

MRI may reveal atrophy of the midbrain and, in some cases, of the frontal and temporal cortices.

Course
The disease is progressive, with death within 5–7 years.

Pathology
Macroskopically there is atrophy of the midbrain, globus pallidus and, in some cases, the frontotemporal cortex.
Microscopically, cell loss is noted in the mesencephalic tectum, periaqueductal grey matter, locus coeruleus, substantia nigra, dentate nucleus, red nucleus, thalamus (especially in the caudal intralaminar nuclei), globus pallidus, subthalamic nucleus, and the temporal and inferior frontal cortices. This is accompanied by gliosis and, in surviving neurons, one finds neurofibrillary tangles dissimilar to those of Alzheimer’s disease.36

Aetiology
Although definite autosomal dominantly inherited cases have been identified, the vast majority of cases appear to be sporadic. There does, however, appear to be a ‘susceptibility genotype’, composed of normal variants in the gene for tau, which predisposes to classic progressive supranuclear palsy.37,38

Corticobasal ganglionic degeneration
This rare disorder, apparently equally common in men and women, is characterized by atypical parkinsonism or dementia, or both.

Clinical features
The onset is gradual, usually in the sixth or seventh decade. Most patients present with a strikingly asymmetrical rigid akinetic parkinsonism affecting an upper limb; dystonic rigidity may also be present. Cortical sensory loss, apraxia and myoclonus are common. Dementia occurs in about one-half of patients and, although this usually follows the motor disturbance by years, it may at times be the presenting feature;39,40 indeed, in two series, the majority of patients presented with dementia.41,42 In patients who do develop dementia, depression is common; apathy and irritability may also occur.41

Corticobasal ganglionic degeneration may rarely present with primary progressive aphasia43,44 or with a personality change with frontal lobe features.44 Although the alien hand sign is said to occur, this sign is not in fact well described in this disorder: rather, patients display such purposeless movements as grasping, ‘wandering’ or levitation.

MRI may reveal asymmetrical cortical atrophy affecting primarily the parietal and frontal cortices.

Course
Over a long period of time, the parkinsonism gradually becomes bilateral; in some cases, cerebellar signs may appear and, rarely, supranuclear ophthalmoplegia has been noted. Death typically occurs within 6–10 years, generally secondary to aspiration pneumonia.

Pathology
Macroscopically there is asymmetrical cortical atrophy, affecting primarily the parietal lobe and the posterior portion of the frontal lobe; over time, the atrophy may spread to the contralateral side, and the temporal lobes and anterior portions of the frontal lobes may become involved. Microscopically, changes are seen in these areas and in the basal ganglia and substantia nigra, consisting of neuronal loss and astrocytosis; surviving neurons are large, ballooned and achromatic and contain tau-positive filaments.

Aetiology
The vast majority of cases are sporadic.

Multiple system atrophy
Three variants are generally recognized: the striatonigral, olivopontocerebellar and Shy–Drager variants. It is uncommon and somewhat more frequent in men than women.

Clinical features
The onset is gradual and typically occurs in the sixth decade.

The striatonigral variant, seen when the striatum and substantia nigra are most involved, is characterized by the gradual onset of parkinsonism, which is similar to that seen in Parkinson’s disease, with the exceptions that the flexion posture is often extreme and tremor is seen in only a minority of patients and is typically not of the classic pill-rolling type. Furthermore, patients may have other signs not typical of Parkinson’s disease, such as hyperreflexia and extensor plantar responses, myoclonus and, rarely, supranuclear ophthalmoplegia for downward gaze.

The olivopontocerebellar variant, seen with involvement of the inferior olives, basis pontis and cerebellar cortex, is characterized by the gradual onset of ataxia, intention tremor, dysarthria and scanning speech; reflex myoclonus is also commonly seen and emotional incontinence occurs in roughly one-third of cases.46

The Shy–Drager variant, seen when the intermediolateral grey matter of the spinal cord is heavily involved, is characterized by evidence of autonomic failure, such as urinary retention or incontinence, postural dizziness or syncope, erectile dysfunction and, rarely, faecal incontinence.

Dementia may occur in a minority of patients with multiple system atrophy and may be distinguished by elements of a frontal lobe syndrome.47 Rarely, multiple system atrophy may present with a personality change and dementia, as has been noted in a case of the olivopontocerebellar variant.48

Regardless of which variant the disease presents with, over a matter of years most patients will eventually display features of all three variants. Many patients also eventually develop laryngeal stridor.

There is a strong association with REM sleep behaviour disorder:49 one report noted that the vast majority of patients with multiple system atrophy had this disorder, which could precede the development of typical symptomatology by years.50

MRI may reveal atrophy of the striatum, pons, inferior olives and cerebellum. In some cases, especially in patients
with the striatonigral variant, the putamen displays decreased signal intensity on T2-weighted scanning but laterally has a surrounding rim of increased signal intensity. In other cases, especially those with the olivopontocerebellar variant, the basis pontis will display the ‘hot-cross bun sign’ on axial T2-weighted images, wherein the base of the pons is marked by lines that give it the appearance of a hot-cross bun seen from above.

**Course**

It is gradually progressive, with death, often from aspiration pneumonia, generally within 6–9 years.

**Pathology**

Macroscopically, there is variable atrophy of the cerebral cortex (particularly the frontal area), striatum (more so the putamen than the caudate), pons, inferior olives and cerebellum. Microscopically, cell loss and astrocytosis are seen not only in these areas but also in the substantia nigra, locus coeruleus, ventrolateral medulla and intermediolateral gray matter of the spinal cord. Cytoplasmic inclusions containing alpha-synuclein are seen in oligodendroglia and in surviving neurons.

**Aetiology**

This is a sporadic disorder of unknown cause.

**Huntington’s disease (chorea)**

The lifetime prevalence is 0.004–0.008 among white populations, one-third of that in black populations and one-tenth among Japanese populations.

**Clinical features**

The onset is generally highly insidious and may occur anywhere from childhood to the eighth decade, with most patients falling ill in their thirties. The presentation may be with either chorea or a personality change; over time, in the vast majority of patients, both these syndromes will become present and be joined by the gradual development of dementia. Exceptions to this rule do occur, especially in people with late onset in the sixth decade or beyond, when one may see primarily chorea, with little or no cognitive deficit.

Chorea may initially present as fidgetiness, clumsiness or a tendency to drop things; obvious choreiform movements are generally first visible on the face (including the forehead), from where they spread to involve the trunk and extremities. There may be facial grimacing, brow-wrinkling and blinking; upper extremity involvement may lead to shoulder-shrugging, abrupt flinging of the arms, or purposeless ‘piano-playing’ movements of the hands. In shaking the patient’s hand, one may note the classic ‘milkmaid grip’, wherein the patient’s grasping of the examiner’s hand feels as if the patient is attempting to milk a cow. Lower extremity involvement may lead to a lurching, staggering or ‘dancing and prancing’ gait, which in some cases may so resemble the gait seen in alcohol intoxication that patients have been arrested for public intoxication. Importantly, these choreiform movements are quite brief, appearing and disappearing on a random basis from one location to another with lightning-like rapidity. Interestingly, although some patients seem fully aware of their chorea, it is not at all uncommon to find patients with obvious chorea denying that anything is amiss.

Early on, patients may attempt, with varying degrees of success, to disguise the choreic movements by merging them with purposeful movements: for example, a choreic fling of the arm up to the head may be purposefully extended to draw the fingers through the hair, as if the purpose had all along been to straighten the hair. Dysarthria often occurs, as does dysphagia, which may lead to aspiration. The chorea eventually makes almost all purposeful activity, whether eating, dressing or walking, almost impossible, and patients eventually become chair-bound or bedridden. At the end, the chorea may gradually disappear, to be replaced by a rigid, akinetic state. In advanced cases, seizures may also occur.

The personality change presents with poor judgement, impulsivity, irritability and an overall coarsening of behaviour. Over time, dementia develops, characterized by deficits in memory, concentration, calculation and abstraction; focal signs, such as aphasia and apraxia, are generally not seen. Associated symptoms are found in the vast majority of patients, including depression of variable severity in roughly half, agitation, irritability, apathy and anxiety and, in a minority, euphoria or, rarely, mania. Delusions, generally of persecution, and, less commonly, hallucinations may be seen in a small minority; rarely, Huntington’s disease may present with a psychosis. Suicidal ideation is common, and suicide itself occurs in a significant minority.

When Huntington’s disease presents in childhood or adolescence, one often sees the Westphal variant, in which, rather than chorea, there is a rigid, akinetic state generally accompanied by severe dementia, often with seizures, myoclonus and ataxia; in other cases, rather than parkinsonism, the presentation may be with chorea, myoclonus or dementia.

Structural neuroimaging may be normal early in the course; over time, however, because of atrophy of the caudate nuclei, there is a characteristic dilation of the frontal horns of the lateral ventricles, yielding a characteristic ‘butterfly’ configuration. Cortical atrophy, especially of the frontal lobes, may also be seen.

A positive family history is found almost universally. Exceptions may occur secondary to rarely occurring spontaneous mutations or, more commonly, to uncertain parentage.

**Course**

Huntington’s disease is relentlessly progressive: most patients die within 10–30 years of onset, with an average
life expectancy of about 15 years. Those with an earlier age of onset experience a more rapid course, with death within about 10 years; conversely, those with a late onset, in the fifth decade or beyond, typically experience a longer course.

**Pathology**
Macroscopically, atrophy is noted in the caudate, less so in the putamen, and to a degree in the frontal and parietal cortices. Neuronal loss and reactive astrogliosis are noted in these areas; in the caudate nucleus in particular, spiny neurons are lost first. Surviving neurons may display intranuclear inclusions, which contain huntingtin.

**Aetiology**
Huntington's disease is a fully penetrant autosomal dominant disorder. The affected gene, at 4p16, codes for huntingtin; in Huntington’s disease there are increased CAG repeats (36 or more) at this locus.

**Choreoacanthocytosis**
This rare disorder is a member of the neuroacanthocytoses.

**Clinical features**
The onset is generally in the late twenties or early thirties but may occur anywhere from late childhood to the seventh decade. Clinically, most patients present with gradually progressive chorea, which, over time, is often joined by other abnormal movements, such as tics, dystonia or mild parkinsonism. A classic symptom, seen in only a minority, is self-mutilating lip- or tongue-biting, which is outside the patient’s control: one patient despite attempting to ‘restrain herself ... by placing her fingers or a folded towel in her mouth ... nevertheless had bleeding and scarred lesions of her oral mucosa and lips’.58 Most patients will also develop a sensorimotor peripheral polyneuropathy and, in a minority, seizures may occur. Roughly half of all patients will also develop personality change or dementia, or both.

Acanthocytic erythrocytes, to a degree of 10 per cent or more, are seen on peripheral smears; importantly, the smears must be fresh wet preparations and, given the chance of false negatives, at least three smears should be examined. Genetic testing is available.

**Course**
The disease is gradually progressive, with death, on average, after 14 years.

**Pathology**
Macroscopically, there is atrophy of the caudate, putamen and, to a lesser degree, the globus pallidus. Microscopically, neuronal loss and gliosis are seen in these structures and in the substantia nigra. Axonal loss occurs in the peripheral nerves.

**Aetiology**
Choreoacanthocytosis is an autosomal recessive condition occurring secondary to mutations in the VPS13A gene at 9q21 (formerly known as CHAC), which codes for chorein. There may be considerable phenotypic heterogeneity in the same family.

**Fragile X-associated tremor/ataxia syndrome**
Fragile X-associated tremor/ataxia syndrome (FXTAS) is far more common in men than women.

**Clinical features**
Although the age of onset ranges from the fourth to the ninth decade, most patients fall ill in the seventh decade, with the gradual onset of ataxia and tremor. The tremor, although typically of the intention type, may also have a rest or postural component. Over time, mild parkinsonism may also accrue, with rest tremor, rigidity and bradykinesia. Peripheral neuropathy is common, and some patients may experience autonomic symptoms, such as erectile dysfunction.

Cognitive deficits eventually appear, and anywhere from one-quarter to one-half of patients may eventually become demented: short-term memory loss, poor concentration, concreteness and poor judgement are common. Frontal lobe symptomatology may also be seen, with disinhibition, perseveration and inappropriate jocularity, and mood changes are common, with agitation, irritability, apathy or depression.59,60

MRI may reveal both cerebral and cerebellar cortical atrophy. The most characteristic finding, however, is the ‘middle cerebellar peduncle’ sign: on T1-weighted scans these peduncles show decreased signal intensity, and on T2-weighted scans there is increased signal intensity.61 This sign, although not universally present, becomes more likely later in the course of the disease. Genetic testing is available.

**Course**
Symptoms progress very slowly.

**Pathology**
Macroscopically, there is cerebral and cerebellar cortical atrophy. Microscopically, there is neuronal loss in these regions, and status spongiosus in the cerebellar white matter and the middle cerebellar peduncles. Intranuclear inclusions are found in both astrocytes and surviving neurons.

**Aetiology**
Like fragile X syndrome, FXTAS occurs as the result of a mutation in the fragile X mental retardation 1 (FMR1) gene, located on the long arm of the X chromosome, with an increase in the number of CGG repeats up into the premutation range of from 55 to 200.
Dentatorubropallidoluysian atrophy (DRPLA)

Clinical features
The onset of dentatorubropallidoluysian atrophy (DRPLA) is gradual and the clinical features are strongly influenced by the age of onset. Early-onset cases are characterized by ataxia, myoclonus, seizures and dementia.62 Late-onset cases are typified by chorea or ataxia, or a combination of these; in a minority of cases, one may also see a mild degree of dystonia or parkinsonism.62 In adults one also sees the eventual development of dementia, which may be accompanied by prominent hallucinations and delusions; rarely, DRPLA may present with a psychosis in adult years.63 A small minority of adults may also have seizures. MRI may reveal superior cerebellar peduncular atrophy and, on T2-weighted scans, increased signal intensity in the globus pallidus.

Course
DRPLA is a gradually progressive disorder.

Pathology
Neuronal loss is found in the dentate nucleus, red nucleus, globus pallidus, subthalamic nucleus, striatum, substantia nigra, inferior olive, thalamus and cerebral cortex. In surviving neurons, intranuclear inclusions, formed of abnormal atrophin-1, may be found.

Aetiology
DRPLA is an autosomal dominantly inherited disorder: mutations exist in the gene for atrophin-1, on chromosome 12, which consist of an expansion of a normally occurring CAG repeat. There is considerable phenotypic heterogeneity within and between families.

Wilson’s disease
Wilson’s disease (hepatolenticular degeneration) occurs in around 1–2 per 100 000 of the general population.

Clinical features
The onset is typically between late childhood and early adulthood, although the range is wide, from early childhood to the sixth decade. The presentation may be with movement disorder, psychosis, personality change or dementia; over time, most patients eventually develop a combination of these. Other features include seizures, a Kayser–Fleischer ring, hepatitis and anaemia.

The movement disorder may consist of dystonia, chorea, tremor or parkinsonism; dysarthria may also appear. Dystonia may present with torticollis, dystonia of the upper or lower extremity, oculogyric crisis or facial dystonia; classically, there is a fixed, vacuous, wide-mouthed dystonic smile. Chorea may involve either the upper or the lower extremities. The tremor may be rhythmic or irregular; at times, one may see the classic ‘wing-beating’ tremor in which a rhythmic elevation and lowering of the upper extremities, combined with flexion at the elbows, gives an overall appearance of a frightened bird flapping its wings.

Personality change is generally characterized by lability, disinhibition and, at times, bizarre behaviour.65–67 Psychosis is characterized by hallucinations and delusions and may be bizarre, with Schneiderian first-rank symptoms. Indeed, one of Wilson’s patients heard ‘God and the devil talking to him simultaneously’ and said that he was ‘influenced, willed or hypnotized to do certain things’.69 In one case, stuporous catatonia dominated the presentation.70 Seizures may occur but are rare, occurring in about 5 per cent of patients.

The Kayser–Fleischer ring is a golden-brown discolouration of the corneal limbus, visible either on slit-lamp examination or to the naked eye. Although present in the overwhelming majority of patients, cases of unequivocal Wilson’s disease (with a movement disorder) without a Kayser–Fleischer ring do occur.

Hepatic damage may lead to clinical hepatitis, with fever, malaise, abdominal pain and elevated transaminase levels. With significant hepatic dysfunction, hepatic encephalopathy may occur.

A Coombs-negative haemolytic anaemia may occur.

The caeruloplasmin and total serum copper levels are both low, but the serum free copper is elevated, as is the 24-h urinary copper; in a small minority of patients, the caeruloplasmin level may be normal. Liver biopsy reveals an elevated copper level.

MRI may reveal characteristic findings.71 On T2-weighted scans, increased signal intensity may be seen in the head of the caudate and lateral aspect of the putamen, with decreased signal intensity in the globus pallidus; in the midbrain, the ‘face of the giant panda’ sign may be seen, with increased signal intensity in the tegmentum and decreased signal intensity in the red nuclei. On T1-weighted scans, increased signal intensity may be seen in the caudate and putamen.

Given the large number of possible mutations, genetic testing is not practical.

Pathology
Biliary excretion is deficient and copper accumulates, first in the liver, where it causes hepatitis, and then, once it spills over into the systemic circulation, in the brain, where copper deposition occurs primarily in a pericapillary distribution. Macroscopically, there is atrophy and a brownish discolouration of the striatum, with, in advanced cases, cavitation and a mild degree of cortical atrophy. Microscopically, there is neuronal loss and astrocytosis in the striatum (more so in the putamen than in the caudate) and to a lesser degree in the globus pallidus; other affected structures include the cerebral cortex (especially the frontal lobes), thalamus, red nucleus, substantia nigra, dentate nucleus and cerebellar cortex. Copper deposition in Descemet’s membrane produces the Kayser–Fleischer ring.
Aetiology
Wilson’s disease is an autosomal recessive disorder resulting from mutations in the \( {\text{ATP7B}} \) gene on chromosome 13 that codes for the copper-binding ATPase; multiple different mutations have been identified.

Spinocerebellar ataxia
Spinocerebellar ataxia (SCA) is also known as autosomal dominant cerebellar ataxia.

Clinical features
The clinical hallmark is the appearance of gradually progressive cerebellar ataxia generally accompanied by dysarthria and nystagmus. The onset, although generally in the early to mid-adult years, may occur anywhere from childhood to senescence. With disease progression, almost all patients also develop one or more of the following associated features: hyperreflexia and extensor plantar responses; decreased vibratory sense, atrophy and fasciculations; supranuclear ophthalmoplegia; tremor (including titubation), dystonia, chorea, myoclonus or parkinsonism; or pigmentary retinopathy. Seizures are uncommon and may be grand mal, simple or complex partial in type.

Dementia may occur in a minority of patients, as may personality change (often frontal lobe type). Some patients may develop delusions and hallucinations. Rarely, SCA may present with dementia, personality change or psychosis.

Genetic testing is available.

MRI may reveal atrophy of the cerebellum, pons and inferior olives.

Pathology
There is atrophy of the cerebellum, pons and inferior olives. Associated atrophy may also be found in one or more of the spinocerebellar tracts, Clarke’s column, globus pallidus, subthalamic nucleus, substantia nigra and cerebral cortex.

Aetiology
SCA is an autosomal dominantly inherited syndrome, and approximately 26 different loci have been identified. For example, SCA19 (genetic locus 1p21–q21) is associated with cognitive impairment, while SCA13 (19q13.3–q13.4) is associated with early onset and developmental delay.

Pantothenate kinase-associated neurodegeneration
This disease was formerly known as Hallervorden–Spatz disease, but the use of this name is now discouraged, given the participation of Hallervorden and Spatz in the obscene Nazi ‘euthanasia programmes’ of the Third Reich.

Clinical features
The onset is typically gradual and, although most patients fall ill in childhood or adolescence, adult-onset cases may occur. The clinical symptomatology is heavily influenced by the age of onset.

Childhood-onset cases are generally characterized by slowly progressive dystonic rigidity, prominent in both the extremities and the face; although this dystonia may be unilateral initially, bilateral involvement eventually occurs. Over time, other abnormal movements may appear, including tremor or choreoathetosis; tics have also been noted in a small minority of patients, as have obsessions and compulsions. Dementia occurs gradually.

Adult-onset cases may present with parkinsonism, dystonia or athetosis. Over time, and with progression of the abnormal movements, dementia may occur. Rarely, the presentation may be with dementia, followed years later by a movement disorder. In some cases depressive symptomatology may occur or, rarely, delusions and hallucinations.

In addition to the abnormal movements, many patients may also develop signs of spasticity, with hyperreflexia and the Babinski sign; in a minority, pigmentary retinopathy may occur.

MRI generally reveals the distinctive ‘eye of the tiger’ sign. On T2-weighted scans, increased signal intensity is seen in the lateral aspect of the globus pallidus, whereas on the inner aspect there is a gross loss of signal intensity: the overall effect, seen on axial imaging, is of looking a tiger in the eye.

Course
Childhood-onset cases show gradual progression, with death occurring within 10–15 years; adult-onset cases tend to pursue a longer course, and some patients may remain ambulatory for decades.

Pathology
Macroscopically, the globus pallidus is atrophic and exhibits a yellow–brown discolouration. Microscopically, iron deposition and axonal spheroids are seen in the globus pallidus, cerebral cortex and pars reticulata of the substantia nigra.

Aetiology
This is a recessively inherited disorder, and mutations are found in the gene for pantothenate kinase, \( {\text{PANK2}} \), on chromosome 20.

Dopa-responsive dystonia
It is important not to miss this diagnosis in clinical practice because, although dopa-responsive dystonia is uncommon, the dystonia tends to respond to levodopa.

Clinical features
The classic onset is in childhood, but later onsets in adolescence and adulthood have also been reported. Regardless of the age of onset, symptoms generally both appear and accrue gradually.
Childhood-onset cases generally present with an intermittent dystonia of one foot; over time, the dystonia spreads, eventually involving the other lower extremity and then the upper extremities; truncal and cervical dystonia may also eventually appear. A characteristic feature of the dystonia has been termed ‘sleep benefit’: after a good night’s sleep, the dystonia may be very mild, or even absent, only to reappear gradually and worsen as the day wears on. In some cases, mild parkinsonism may appear; myoclonus has also been noted. The movement disorder may be accompanied by depression or obsessions and compulsions.

Later-onset cases may also be marked by more prominent parkinsonism. In some cases, the syndrome may present with depression or obsessions and compulsions without any abnormal movements.76,77

Course
In childhood-onset cases the dystonia eventually generalizes over about 3–4 years, after which it remains static.

Pathology
Reduced neuromelanin has been reported in the substantia nigra, without cell loss, in both DYT5a and DYT14 (see below).

Aetiology
Dopa-responsive dystonia is a genetically heterogeneous syndrome. The following diseases have so far been described: DYT5a, DYT5b and DYT14.

DYT5a (Segawa syndrome) is autosomal dominant and constitutes the most common cause of dopa-responsive dystonia. There is a mutation in the guanosine triphosphate cyclo-hydrolase 1 (GCH1) gene on chromosome 14. GCH1 is the rate-limiting enzyme for the synthesis of tetrahydrobiopterin, which is an essential co-factor for tyrosine hydroxylase. Hence, there is a reduction in dopamine production.

DYT5b is an autosomal recessive disorder caused by a mutation in the gene for tyrosine hydroxylase on chromosome 11.

DYT14 is an autosomal dominant disorder linked to a site on chromosome 14.

Tourette’s syndrome
Described by Georges Gilles de la Tourette in 1885, this classic cause of chronic tics is also known as Gilles de la Tourette syndrome, maladie des tics and tic convulsiv. It has a lifetime prevalence of about 0.05 per cent and is about three times more common in males than females.

Clinical features
The onset is typically with a simple tic, more often motor than verbal, and more often on the head or face than elsewhere. Although the age of onset may be anywhere from infancy to the early adult years, most patients fall ill in childhood, around the age of 7 years.

In its fully developed form, both motor and verbal tics are present; these may be either simple or complex. Sensory tics are also usually present.

Motor tics are usually the first to appear. Simple motor tics include blinking, brow-wrinkling, grimacing and shoulder-shrugging; complex motor tics may include touching, smelling, hopping, throwing, clapping, bending over, squatting, or even such very complex acts as echopraxia or copropraxia (making obscene gestures). Motor tics usually appear first in the face or head and then spread in a caudal direction. In most cases, before having a tic, patients first experience an urge to tic,79 an urge that may at times be resisted, albeit with difficulty. Some patients are able to abort a motor tic with a geste antago- niste, such as placing a hand under the chin to prevent the emergence of a tic of the head.79

Simple vocal tics include snorting, hissing, coughing, throat-clearing, grunting and, classically, barking. Complex vocal tics include uttering words, simple phrases or entire sentences. Echolalia or pallilalia may occur; in a minority of patients, classic coprolalia, or involuntary swearing, may occur.

Sensory tics appear to exist in two forms. In one form, there is simply the experience of an itch or a tingle,80 this is seen in perhaps one-quarter of patients. In the other form, the sensory tic appears more as a premonitory urge to a motor tic;81,82 this has been reported in over 90 per cent of cases.82 Remarkably, in one case a premonitory urge to itch was experienced by a patient as residing in another person, whom the patient then proceeded to scratch.83

Rarely, dystonic movements, especially cervical or facial dystonias, may appear, but not until 10–38 years have passed.84

Obsessions and compulsions are common, eventually appearing in nearly one-half of all patients.85,86 They typically begin to appear about 5 years into the course. The compulsions often centre on getting things ‘just right’.87

Attention-deficit hyperactivity disorder (ADHD) very commonly accompanies Tourette’s syndrome. When this occurs, the hyperactivity usually precedes the tics by a little over a year.88

Course
In most cases, symptoms gradually worsen over a matter of a few years, peaking in severity around the age of 10 years; subsequently there is a gradual and progressive remission of symptoms, such that by the age of 18 years roughly one-half of patients are left with either no or only trivial tics.89,90

In those cases where full remissions do occur, relapses may appear, sometimes decades later.

Pathology and aetiology
Tourette’s syndrome is familial, with concordance rates rising from about 5 per cent in siblings to approximately 10 per cent in dizygotic twins and 50 per cent in monozygotic twins; indeed, if one accepts the presence of simple tics as
evidence of the disorder, then the monozygotic concordance rises to over 75 per cent. It is a complex genetic disorder.

MRI studies strongly suggest a reduced size of the basal ganglia. Although neuropathological studies have not revealed distinctive microscopic findings, immunological studies have shown a decreased number of dopamine reuptake sites in the striatum and a decrease in dynorphin staining in fibres coursing from the striatum to the globus pallidus. Some research suggests that, at least in a certain minority of cases, Tourette’s syndrome may be an autoimmune disease, triggered, in turn, by a preceding beta-haemolytic streptococcal infection. Swedo and colleagues considered Tourette’s syndrome to be part of a syndrome that they named paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). In this condition, similar to Sydenham’s chorea, a preceding group A beta-haemolytic streptococcal pharyngitis triggers an immune response that cross-reacts with the basal ganglia, leading to, among other symptomatologies, tics; increased levels of anti-streptococcal antibodies in patients support this notion. Furthermore, most studies have also found an increased incidence of serum anti-basal ganglia antibodies.

Myotonic dystrophy type 1
The lifetime prevalence of myotonic dystrophy type 1 (DM1) is around 5 per 100 000. It is equally common in males and females.

Clinical features
The onset is gradual and insidious. Most patients fall ill in their late teens or early twenties, but the age of onset ranges from childhood to the sixth decade.

The cardinal symptoms are myotonia and weakness. Myotonia may go unnoticed or manifest in difficulty in, for example, letting go of a doorknob or disengaging from a handshake. Myotonia may be elicited by tapping the thenar eminence with a percussion hammer and observing for the characteristic muscle dimpling. Weakness is eventually accompanied by atrophy, which is more prominent distally, being seen first in the upper extremities. Other signs may also accrue. Many patients have a distinctive ‘myopathic facies’, with frontal balding, ptosis, and wasting of the face and neck musculature; the voice often becomes nasal and monotone. Cataracts occur in over 90 per cent of patients, and some children may be born with ‘congenital’ myotonic muscular dystrophy, characterized, among other symptoms, by mental retardation.

Aetiology and pathology
DM1 is inherited in an autosomal dominant fashion with almost 100 per cent penetrance but a quite variable expressivity, even within the same family. Mutations consist of an expansion of a normally occurring CTG triplet in the myotonic dystrophy protein kinase (DMPK) gene on 19q13.3. ‘Anticipation’ may occur, in which in succeeding generations, and with expansion of the triplet repeat, the disease becomes more severe and has an earlier onset. Anticipation is more likely with maternal transmission than paternal cases.

Dystrophic muscle shows characteristic changes, including internal nuclei in muscle fibres. Neuronal heterotopias have been noted in the cerebral cortex and neurofibrillary tangles in the hippocampus. In cases characterized by hypersomnolence, cell loss was noted in the midbrain superior central nucleus; in cases marked by alveolar hyperventilation, cell loss was seen in the medullary reticular formation.

Other rare disorders
Cerebrotendinous xanthomatosis
This recessively inherited lipid storage disease (mutations in CYP27, a gene on chromosome 2 coding for sterol 27-
hydroxylase) may cause dementia. The onset is very gradual and, although most patients begin to have symptoms in late childhood or early adolescence, the range in age of onset is wide. The fully developed disease is characterized by dementia, seizures, long-tract signs, ataxia, peripheral sensorimotor polyneuropathy, gross tendon enlargement, especially evident in the Achilles tendon, cataracts and chronic diarrhoea. Although the disease may present with any one of these various features, in most cases the presentation will be with juvenile cataracts or with chronic, intractable diarrhoea.

Thalamic degeneration
This is characterized clinically by dementia and pathologically by relatively selective degeneration of the thalamus, in the absence of known causes such as Creutzfeldt–Jakob disease. This syndrome probably subsumes several or more different disease processes. The age of onset may range from adolescence to the seventh decade, and the mode of onset from subacute to insidious. Dementia may be accompanied by apathy and somnolence, emaciation or myoclonus.

Metachromatic leucodystrophy
This is a recessively inherited disorder, secondary to any of a large number of mutations in the chromosome 22 gene for arylsulfatase A (which normally converts sulfatides into cerebroside, a normal constituent of myelin). Demyelination and accumulation of sulfatides in the brain, peripheral nerves, kidneys and gallbladder result. When appearing in adolescents or adults, it may present with a psychosis, personality change or dementia.

Adrenoleucodystrophy
This X-linked disorder (mutations in the \( ALD \) gene) is characterized pathologically by the accumulation of very-long-chain fatty acids in the brain, spinal cord, peripheral nerves and adrenal glands, and clinically by a variable combination of dementia, spasticity and adrenal failure.

Kufs’ disease
This typically presents in early adult years in one of two fashions. Type A patients present with grand mal and myoclonic seizures and dementia, often accompanied by ataxia or abnormal movements, such as athetosis or parkinsonism. Type B patients typically present with personality change or dementia, which may also be accompanied by ataxia and other abnormal movements. The disease is relentlessly progressive, with death occurring on average after 12 years.

Vascular (arteriosclerotic) parkinsonism
This disorder, which is probably uncommon, is characterized by atypical parkinsonism occurring on the basis of lacunar infarctions in either the mesencephalon or the basal ganglia.

Clinical features
The onset is generally in the seventh or eighth decade. Clinically, the parkinsonism is characterized by bradykinesia, lead-pipe rigidity, instability and a tendency to fall. The posture may or may not be in flexion; the gait is either shuffling or ‘magnetic’, in that the feet seem ‘stuck’ to the floor. Overall, these parkinsonian features may be symmetrical or asymmetrical. Notably, both tremor and cogwheeling are generally absent, and the response to levodopa is generally poor. Vascular (lacunar) dementia may occur, and typically there is damage to corticospinal tracts (e.g. spasticity) and corticobulbar tracts, with pseudo-bulbar palsy.

MRI reveals multiple lacunes, with at least some of them involving either the basal ganglia or the mesencephalon.

Course
The overall course is generally one of progression and may be either stepwise or more or less gradual.

Aetiology and pathology
In most patients, vascular parkinsonism occurs in the setting of multiple lacunes affecting not only the basal ganglia or substantia nigra but also the corticospinal and corticobulbar tracts as they course through the internal capsule.

Binswanger’s disease
First described by Otto Binswanger in 1894, this is characterized by a slowly progressive dementia occurring in elderly people on the basis of a diffuse microangiopathic ischaemic leucoencephalopathy or leuкоaraiosis. It is considered to be one of the vascular dementias.

Clinical features
The onset is generally gradual, occurring in the sixth or later decades. Clinically, as described by Binswanger, there is a ‘slow development of the deterioration of the intellectual capacities’, and patients present with a non-specific dementia, with slowness of thought, decreased short-term memory, disorientation and concreteness. In advanced cases, a pseudo-bulbar palsy may occur. Minor focal signs, such as asymmetrical deep tendon reflexes or a Babinski sign, may be seen, but in uncomplicated Binswanger’s disease major clear-cut syndromes such as aphasia or apraxia do not occur.

CT reveals widespread areas of radiolucency in the periventricular white matter and centrum semiovale. MRI is more sensitive and on FLAIR or T2-weighted images one finds multiple patchy and confluent areas of increased signal intensity in the periventricular region and the cen-
trum semiovale, extending close to the cortex but sparing the U-fibres. In advanced cases, these patchy areas may coalesce to the point of creating a virtual ‘white-out’.

**Aetiology and pathology**

At autopsy, the small penetrating medullary vessels display lipohyalinosis and, in some cases, the lumens are obliterated. There is widespread demyelination, with some associated axonal loss; in severe cases, cystic changes may occur. Although it is suspected that these microangiopathic changes occur on the basis of long-standing hypertension, other factors are probably also at work, asBinswanger’s disease may occur in normotensive individuals.

**Cranial arteritis**

Cranial arteritis is also known as giant-cell arteritis and temporal arteritis. In people over 50 years of age, it is a not uncommon disorder; it is seen primarily in white people, especially those of Nordic descent.

**Clinical features**

The symptomatology varies according to which arteries are inflamed.

Branches of the external carotid artery are commonly involved, and inflammation of the temporal artery is classic, causing a severe headache in the temporal region, which, although generally unilateral, can be bilateral. If the occipital artery is involved, the headache may be localized to the neck. Involvement of the facial artery may lead to jaw claudication, with facial pain upon chewing; involvement of the lingual artery may cause tongue necrosis. Of the branches of the internal carotid artery, the ophthalmic artery is classically involved; in such cases, unilateral blindness may occur, which may or may not be preceded by episodes of amaurosis fugax.

In about 10 per cent of cases, strokes or transient ischaemic attacks (TIAs) may occur; this may be seen with involvement of either the vertebral artery or the internal carotid artery. With vertebral artery involvement, clots may form, which may then embolize further downstream, for example to the posterior cerebral artery. Small branches of the vertebral arteries may also be occluded, leading to medullary infarction. With involvement of the internal carotid artery, clots may also form, with embolization downstream, causing occlusion of the middle or anterior cerebral arteries or their branches. Small penetrating arteries may be involved, causing multiple lacunes. In some cases, if the number and location of infarctions are appropriate, vascular dementia may ensue.

Most cases are further characterized by constitutional symptoms such as malaise, fatigue, anorexia and a low-grade fever. Most patients also have an associated polymyalgia rheumatica, with muscle aching and stiffness, which, although diffuse, is most prominent in the neck and shoulders.

With rare exceptions the erythrocyte sedimentation rate (ESR) is elevated, generally above 50 mm/min and often above 100 mm/min. Mild anaemia is common, and the alkaline phosphatase may also be elevated. The diagnosis is confirmed by biopsy of an involved artery, such as the temporal artery; given the segmental nature of the inflammation, however, false negatives are possible and multiple biopsies may be required.

**Aetiology and pathology**

Involved arteries show a granulomatous inflammation characterized by the presence of giant cells. The inflammation is segmental, and between the involved segments the artery may become occluded. Although the mechanism underlying the inflammation is not known, an autoimmune process is suspected.

**Cerebral amyloid angiopathy**

Also known as congophilic amyloid angiopathy, this a not uncommon disorder characterized by amyloid angiopathy.

**Clinical features**

Onset is typically in the seventh or later decades. The disorder may present with either spontaneous lobar intracerebral haemorrhages or gradually progressive dementia.

The lobar intracerebral haemorrhages present with a gradual evolution, over perhaps half an hour, of headache, nausea and vomiting, and a focal deficit appropriate to the location of the haemorrhage. Classically, the haemorrhage occurs spontaneously and recurrences are the rule. With multiple recurrences, a stepwise accrual of cognitive deficits may occur, eventually leading to a picture of multi-infarct dementia.

Dementia may also be of gradual onset and progression, and in this instance it is non-specific in character, with decreased short-term memory, variable disorientation, and deficits in abstracting and calculating ability.

Cerebral micro-haemorrhages may occur; these may be silent or present with relatively minor focal findings that, in most cases, resolve over time. Residual deposits of haemosiderin may serve as seizure foci, and partial seizures may also occur.

MRI will reveal evidence of any old intracerebral haemorrhages; in cases with a leucoencephalopathy, T2-weighted or FLAIR images reveal bilateral, more or less symmetrical, patchy or confluent areas of increased signal intensity that spare the U-fibres. Gradient echo images may reveal punctate areas of decreased signal intensity, corresponding to old micro-haemorrhages. In some cases, one finds large asymmetrical areas of increased signal intensity on T2-weighted or FLAIR imaging in the subcortical white matter, which fail to enhance and which may represent vasogenic oedema.
This depends on the preponderance of the underlying pathology. With repeated intracerebral haemorrhages, a stepwise course may occur, whereas cases with leucoencephalopathy are characterized by a gradual progression of cognitive deficits. The combination of these two courses may also occur and is distinctive for this disease.\textsuperscript{113}

Aetiology and pathology
Amyloid deposition occurs in the walls of small and medium-sized cortical arterioles, resulting in fibrinoid degeneration and the formation of microaneurysms.\textsuperscript{114} Affected vessels are congophilic, staining well with Congo red dye, thus accounting for the alternative name for this disorder, ‘congophilic amyloid angiopathy’. The aneurysmal dilations of these vessels are fragile and account for both spontaneous lobar intracerebral haemorrhages and microhaemorrhages. Within the areas of distribution of the affected arteries, rarefaction of the white matter occurs, probably on an ischaemic basis.

Although the vast majority of cases are sporadic, cerebral amyloid angiopathy may also occur on an autosomal dominant basis as hereditary cerebral haemorrhage with amyloidosis, of either the Dutch or Icelandic type.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is a rare autosomal dominantly inherited arteriopathy.

CADASIL is characterized by the onset of recurrent migraine headaches, typically with aura, in the third or fourth decade, followed by recurrent strokes or TIAs in the fourth or fifth decade, and a dementia in the sixth or seventh decade. A pseudo-bulbar palsy may occur and, in a small minority of patients, seizures may appear. The strokes are typically of the lacunar type, reflecting infarcts that occur primarily in the basal ganglia. The dementia, although generally reflecting the effects of multiple lacunar infarctions, at times may also be caused by progressive leukoencephalopathy, and in rare instances CADASIL may present with dementia secondary to the leukoencephalopathy in the absence of stroke.\textsuperscript{115,116}

Two unusual manifestations of CADASIL must also be kept in mind, namely intracerebral haemorrhage and reversible delirium. Intracerebral haemorrhage, primarily of the thalamus or basal ganglia, may occur but is uncommon. Delirium is rare. Patients present with a subacute delirium, often accompanied by seizures and fever, which may progress to coma; recovery is spontaneous and occurs after 1–2 weeks.\textsuperscript{117}

MRI reveals prior lacunar infarctions. Most patients also have diffuse leukoencephalopathy and, indeed, this may be present early on, even before the first stroke. The leukoencephalopathy is evident on either T2-weighted or FLAIR imaging: patchy, confluent areas of increased signal intensity are seen in the centrum semiovale and the periventricular white matter and also, classically, in the external capsule and, most notably, in the white matter of the anterior temporal lobe. Gradient echo imaging has also identified evidence for old micro-haemorrhages in the thalamus and basal ganglia.

Diagnosis may be made by genetic testing. Skin biopsy may also be performed, but false negatives are common.

Course
The course is described above. Death occurs in the seventh to ninth decade, often from pneumonia.

Aetiology and pathology
In this autosomal dominant disorder mutations are found in the \textit{Notch3} gene on chromosome 19. Pathologically, there is concentric fibrous thickening of small penetrating arteries, leading to both subcortical infarcts and widespread leucoencephalopathy.

Granulomatous angiitis of the central nervous system
This rare disorder is also known as primary angiitis of the central nervous system (PACNS).

Clinical features
Although the disease may present at any age, most patients are in their thirties or forties. The onset is generally subacute, spanning a few weeks. Clinically, patients typically have severe, generalized headache, and in this setting they develop delirium, which may be accompanied by focal deficits or, uncommonly, seizures. Although focal deficits such as hemiparesis may have a stroke-like onset, in most cases they appear gradually. Sometimes the spinal cord may be involved.

The ESR is generally either normal or only mildly elevated. MRI may initially be normal; however, over time areas of increased signal intensity on FLAIR or T2-weighted imaging appear in the cerebrum or cerebellum. Angiography may be normal or may disclose typical beading. Lumbar puncture should be performed in all suspected cases: there is typically a lymphocytic pleocytosis, an elevated protein and a normal glucose.\textsuperscript{118} Brain biopsy, sampling both the leptomeninges and the cerebrum from the tip of the non-dominant temporal lobe, is the gold standard; however, even this may be falsely negative, missing affected tissue.

Course
Untreated, progressive deterioration occurs in almost all cases and perhaps half of all patients will die within months, with the remainder surviving for up to 2 years or more.
Aetiology and pathology
The cause is unknown. A granulomatous angiitis affects both small leptomeningeal vessels and small or medium-sized parenchymal vessels. The cerebrum is most commonly affected, although the cerebellum, brainstem and even the cord may be involved.

Polyarteritis nodosa
Also known as periarteritis nodosa, this is a rare systemic vasculitis.

Clinical features
The onset is generally subacute or gradual in middle years with constitutional symptoms and evidence of involvement of the kidneys, gastrointestinal tract or muscles; renal disease may lead to hypertension or renal failure. The respiratory tract is not involved.

Nervous system involvement generally occurs only after other evidence of the disease is well established. Peripheral nervous system involvement, which is most common, typically involves a mononeuritis multiplex. In a minority of patients, central nervous system (CNS) involvement may occur, most commonly presenting with lacunar strokes; larger territorial infarctions and intracerebral haemorrhages are rare. In a very small minority of patients, delirium or dementia may occur; seizures have also been noted.

Both the white cell count (WCC) and the ESR are elevated. Anti-neutrophil cytoplasmic antibodies (ANCA), especially perinuclear ANCA (pANCA), are found in the majority of cases. The Venereal Disease Research Laboratory (VDRL) test may be falsely positive. MRI will reveal infarctions. Definitive diagnosis is made by biopsy of an affected muscle or peripheral nerve.

Course
Although spontaneous remissions do occur, they are rare, and most cases are characterized by relentless progression, with only about 10 per cent of patients surviving past 5 years.

Aetiology and pathology
There is a systemic, segmental panarteritis affecting medium and small arteries, with, at times, extension into arterioles. With intimal proliferation, thrombosis and occlusion of arteries may occur; with involvement of the muscular layer, microaneurysms may form. These microaneurysms may rupture occasionally; however, they typically undergo fibrosis, thus creating nodules along the course of the artery, thereby providing the characteristic that gives the disease its name.

Involvement of the peripheral vasa nervorum leads to the mononeuritis multiplex. Within the CNS, involvement of small perforating arteries leads to lacunar infarctions; in uncommon cases involving larger arteries, territorial infarctions may occur and, with rupture of an aneurysm, intracerebral haemorrhage may be seen.

Although the mechanism underlying the arteritis is not known with certainty, deposition of immune complexes probably plays a role, and in this regard there is an association with hepatitis B antigenaemia.

Behçet’s disease
This was first described in 1937 by the Turkish dermatologist Hülsi Behçet. There is evidence of CNS involvement in one-tenth to one-third of patients. Although not uncommon in Japan and the eastern Mediterranean region, Behçet’s disease is rare in Europe and the USA.

Clinical features
Behçet’s disease typically presents in the twenties or thirties, and almost all patients have oral aphthous ulcers and some form of uveitis. Genital ulcers are somewhat less common. Another distinctive sign, not seen in all patients, is pathergy: here, within 1–2 days of minor skin trauma, for example phlebotomy, a large pustule forms at the site of the trauma. Other symptoms include furuncles, erythema nodosum, migratory thrombophlebitis and a non-deforming polyarthritis. Within the context of these symptoms, evidence of CNS involvement may appear.

When the CNS is involved, a wide variety of symptoms may appear, including delirium, dementia, pseudo-bulbar palsy with emotional incontinence, hemiplegia, ataxia, cranial nerve palsies, abnormal movements (e.g. chorea), personality change of the frontal lobe type and, rarely, seizures. In addition to vasculitis, both meningitis and dural sinus thrombosis may occur, and in such cases one may see headache; in cases of dural sinus thrombosis, one may also see signs of increased intracranial pressure, with nausea, vomiting and papilloedema.

T2-weighted or FLAIR MRI may reveal areas of increased signal intensity in the brainstem, cerebellum or, less commonly, cerebrum; these areas may demonstrate enhancement with gadolinium. MR venography may be required to demonstrate dural sinus thrombosis. The CSF may be abnormal, with an elevated total protein and/or a pleocytosis, which is generally lymphocytic. The ESR and WCC may be elevated.

Course
Most cases demonstrate an episodic course. The first attack tends to occur in the twenties or thirties, and most attacks last in the order of weeks or a month or more, after which there is a spontaneous remission. These remissions, however, are generally not complete, and most patients are left with residual symptoms. Recurrent attacks are the rule, and after each attack the overall burden of residual symptoms increases. In some cases, this typical episodic course may evolve into one of steady, waxing and waning progression; rarely, Behçet’s disease may pursue a chronic, non-episodic course from the outset, as was seen in a case of progressive dementia with aphthous and genital ulcers.
Aetiology and pathology
The aetiology is unknown, but an autoimmune process is suspected.
CNS perivenular vasculitis occurs. Meningeal inflammation may also occur, possibly accompanied by dural sinus thrombosis.

Hypertensive encephalopathy
This relatively common disorder is sometimes subsumed under the syndrome reversible posterior leucoencephalopathy.

Clinical features
In the setting of sustained diastolic pressure elevations, often 130 mm Hg or higher, delirium and headache evolve over a matter of 1–3 days. Most patients also experience nausea and vomiting, and a majority experience bilateral visual blurring, which may progress to cortical blindness. Seizures may also occur and, in a minority of patients, focal signs such as aphasia or hemiplegia may occur. Untreated, patients may become comatose. Fundoscopy may reveal papilloedema or retinal haemorrhages. Acute cardiac and renal failure may accompany the cerebral symptomatology.

CT may reveal bilaterally symmetrical areas of hypodensity in the occipitoparietal white matter. MRI is more sensitive and, on T2-weighted or FLAIR imaging, increased signal intensity will be seen in the same areas; gradient echo imaging may reveal evidence of petechial haemorrhages. Rarely, these MRI findings may be found in the brainstem and cerebellum.

Course
Untreated hypertensive encephalopathy may be fatal. In cases in which the blood pressure is corrected, symptoms gradually resolve over a matter of days, and white-matter abnormalities seen on CT/MRI typically clear within a week or so. In those cases in which focal findings were noted, these may persist, and MRI will show persistent abnormalities consistent with infarction. With a sufficient number of strategically placed infarctions, patients may be left with vascular dementia.

Aetiology and pathology
As blood pressure rises above a critical level, autoregulation of small and medium-sized cerebral arteries fails and there is extravasation of proteinaceous fluid into the surrounding white matter; some vessels may also rupture, causing petechial haemorrhages, and others may undergo fibrinoid necrosis and occlusion, causing infarction.

Reversible posterior leucoencephalopathy syndrome
Clinical features
The syndrome presents acutely, over hours, and manifests with delirium or lethargy, accompanied typically by headache, nausea or vomiting, and grand mal seizures, which may have a focal onset. Cortical blindness is common. Other symptoms may also occur, such as hemianopia, hemiparesis, abulia or asterixis.

T2-weighted or FLAIR MRI reveals areas of increased signal intensity bilaterally in the white matter of the occipital and parietal lobes, with similar findings, in many cases, noted in the posterior aspects of the temporal lobes.

Course
With prompt and adequate treatment, clinical findings resolve within days to weeks.

Aetiology and pathology
This syndrome has been noted secondary to treatment with a variety of chemotherapeutic and immunomodulatory agents, including tacrolimus, ciclosporin, vincristine, methotrexate, bevacizumab, cyclophosphamide, asparaginase, cisplatin, cytarabine, interferon-alpha, and immunoglobulins. Although the mechanism of toxicity is not clear, it probably involves damage to the vascular endothelium. Vasogenic oedema is seen within the white matter. In cases with an unfavourable outcome, white-matter infarction occurs.

Other uncommon vascular disorders
Thrombotic thrombocytopenic purpura
This typically occurs in young or middle-aged adults. It is marked by the subacute onset of delirium and thrombocytopenia. The delirium is marked by a pronounced fluctuation in the severity of symptoms throughout the day. Other symptomatology includes focal signs, such as hemiparesis or aphasia, which are typically transient, and seizures, with, in a small minority, complex partial status epilepticus.

The platelet count is generally reduced below 30 000/mm³, and there is an accompanying microangiopathic haemolytic anaemia with schistocytes or Burr cells. Renal failure with proteinuria and azotaemia is common, as are fever and purpura.

Fat embolism syndrome
This syndrome represents an uncommon complication of fractures or surgery to the long bones, or trauma to fatty tissues, in which showers of fat globules pass to and through the lungs, leaving the patient in respiratory distress and with delirium.

Anywhere from 1 to 3 days after relevant trauma or surgery, patients develop dyspnoea and confusion; there may also be seizures and strokes and, in severe cases, coma. In some cases, a petechial rash may appear on the trunk.

Diffusion-weighted MRI reveals multiple punctate areas of increased signal intensity, primarily scattered throughout the white matter, with variable involvement of the cortex or subcortical structures. Chest radiography reveals bilateral
Transient global amnesia
The first episode of transient global amnesia generally occurs in the sixth or seventh decade. Episodes are generally of abrupt onset and may be associated with various precipitating events, such as strong emotion, sexual intercourse, pain, physical exertion, the Valsalva manoeuvres or even immersion in cold water. Whether or not a precipitating event is present, the patient suddenly experiences amnesia that has retrograde and anterograde components. The retrograde component covers at least the previous few hours and in many cases may stretch much further into the past: typically, this retrograde amnesia displays a temporal gradient, such that, whereas the amnesia may be quite dense for events of the very recent past, it becomes patchy for events further back. The anterograde component is fairly dense, and patients are unable to keep track of any ongoing events during the episode. Most patients, although not confused, are more or less alarmed at their state, and may will anxiously and repeatedly ask where they are and how they got to be where they are. Formal mental status testing reveals that patients are coherent, alert and not confused. Although digit span is intact, patients are unable to recall any of three words after 5 min; furthermore, they will be unable to recall events of the recent past leading up to the onset of the episode. In essence, cognitive ability, other than memory, remains normal, and indeed some patients may engage in quite complex activity, such as playing an organ piece, during the episode itself. Neurological examination is generally normal. The episode generally lasts 4–18 h, averaging about 6 h, and terminates gradually.

After the episode has cleared, patients are once again able to keep track of ongoing events, and their ability to recall words after 5 min is fully restored. When they try to recall what happened, however, they often find an ‘island’ of amnesia that covers not only the duration of the event itself but also any events that occurred anywhere from a few minutes to an hour or so just before the onset of the episode. Although clinically patients are thus fully restored, detailed testing may reveal some subtle decrements in memory.

Although the aetiology of this disorder is unknown, it is included here because of the strong suspicion that it may result from either transient ischaemia or venous congestion of medial temporal structures.

TRAUMA

Subdural haematoma
Clinical features
Acute subdural haematoma typically occurs following traumatic brain injury and is often accompanied by other intracranial injuries, such as diffuse axonal injury, contusions, intracerebral haemorrhages and subarachnoid haemorrhage. Patients may develop delirium or may present in stupor or coma.

Subacute subdural haematoma tends to present with drowsiness and delirium, and symptoms may fluctuate for days; when the haematoma occurs secondary to trauma, the latent interval between trauma and onset of symptoms may last from days to around a week. Focal signs such as hemiparesis may or may not be present. With progression, uncal herniation may occur, with the development of ipsilateral third nerve palsy and hemiparesis.

Chronic subdural haematoma may be caused by trivial head injury and, indeed, anywhere from one-quarter to one-half of patients may not recall any head trauma. After a latent interval of months to years, patients gradually develop dementia, often accompanied by headache; personality change may occur; rarely, chronic subdural haematoma may present with depression. Focal signs such as hemiparesis may or may not be present; when present, they may be mild. Rarely, seizures may occur.

CT/MRI is diagnostic. In the case of acute and subacute haematomas, blood may be demonstrated for a week or two, after which, with haemolysis, a proteinaceous fluid remains. In chronic cases, the fluid has the same imaging characteristics as CSF. Most cases of subdural haematoma occur over the frontal or parietal convexities, and the haematoma itself has a convex shape; in a minority of patients, haematomas may also be found in the interhemispheric fissure or layering on top of the tentorium cerebelli.

Course
Acute subdural haematomas tend to enlarge rapidly and may become immediately life-threatening. Subacute subdural haematomas tend to evolve over a matter of weeks and may either progress to stupor or coma or may stabilize, after which there may be a greater or lesser degree of gradual improvement. Chronic subdural haematomas tend to undergo very gradual progression.

Aetiology and pathology
Most cases occur secondary to trauma, either a blow to the head or an acceleration–deceleration injury. This may be obvious and severe, for example in a motor vehicle accident; however, in elderly patients, the trauma need not be severe and indeed may appear trivial. Acute subdural haematomas generally occur secondary to arterial bleeding, which explains their rapid evolution and grave prognosis. Subacute and chronic subdural haematomas, however, typically appear secondary to venous bleeding owing to rupture of the delicate bridging veins that span from the surface of the cortex to the overlying dural sinuses. Regardless of the source of the bleeding, blood accumulates in the virtual space between the dura and the arachnoid. Haemolysis occurs and, within a week or two of the initial bleed, a relatively clear fluid remains. The further evolution
may then take one of two paths. In cases in which the haematoma is relatively small, the fluid may simply be resorbed, with little in the way of anatomical sequelae. However, in cases of larger fluid collection, fibroblastic activity may either create a fibrotic scar that replaces the fluid, or one may see the creation of a pseudo-membrane that encapsulates the remaining fluid. The appearance of a pseudo-membrane sets the stage for the clinical occurrence of a chronic subdural haematoma. These encapsulated fluid collections tend to enlarge very gradually, probably as a result of bleeding from fragile capillaries found in the pseudo-membrane itself, which accounts for the gradual progression of symptoms.

Chronic subdural haematomas are more likely in patients who are prone to falls, such as those with alcoholism or epilepsy, and in those on anticoagulants or with blood dyscrasias. Old age also increases the risk of a chronic subdural haematoma, perhaps because normal atrophy with ageing leads to stretching of the bridging veins, making them more vulnerable to rupture.

**Diffuse axonal injury**

With a sudden and severe acceleration–deceleration injury, axons and arterioles are subjected to substantial shearing and rotational stresses, leading to widespread damage typically accompanied by other traumatic lesions such as contusions and intracerebral haemorrhages.

**Clinical features**

Typically, patients are rendered immediately unconscious at the moment of injury. Some may never regain consciousness; those that do may develop a persistent vegetative state or may emerge into delirium, which, upon clearing, typically leaves the patient with significant cognitive deficits, in some cases amounting to dementia. Other sequelae may include agitation and personality change.

CT may demonstrate multiple petechial haemorrhages, typically in the centrum semiovale or corpus callosum; however, in many cases the scan may look unremarkable. MRI is more sensitive and typically displays multiple abnormalities in the centrum semiovale, corpus callosum, internal capsules, dorsolateral quadrants of the brainstem, and the superior cerebellar peduncles; gradient echo imaging enables identification of micro-haemorrhages.

**Course**

Most improvement is seen over the first 6 months post-injury, with some further, but less substantial, progress over the following 6 months. After a year, however, little further spontaneous improvement may be expected.

**Aetiology and pathology**

With either sudden impact or severe whiplash injury, the head undergoes an acceleration–deceleration injury and tremendous shearing and rotational forces are exerted intracranially, resulting in immediate damage to long axons and penetrating arterioles. Axons acutely display retraction balls and microglial clusters and, over time, microglial scars appear. Damage to arterioles leads to petechial haemorrhages of various sizes. Certain areas of the brain are more susceptible to such injuries, including the corpus callosum, the white matter of the centrum semiovale near the grey–white junction, the internal capsules, the dorsolateral quadrants of the brainstem, and the superior cerebellar peduncles.

**Dementia pugilistica**

This disorder is also known as punch-drunk syndrome, punch-drunkenness and chronic traumatic encephalopathy.

**Clinical features**

Onset of symptoms is gradual and occurs 5–40 years after there has been an accumulation of a sufficient number of blows to the head, which, in the case of professional boxers, equates to perhaps a dozen or so knockouts. Thus, in most cases, symptoms are delayed until long after the boxer has left the ring.

When the syndrome is fully developed, patients present with dementia, ataxia, some dysarthria and parkinsonism. The presence of ataxia and dysarthria often gives the impression of alcohol intoxication ('punch drunk'). The dementia is non-specific, except perhaps for an undue amount of irritability.

CT/MRI typically displays an enlarged cavum septi pellucidi, cerebral cortical atrophy and ventricular dilation.

**Aetiology and pathology**

The cause is repeated blows to the head. Although the disorder is found most commonly in boxers, other individuals may also be at risk, for example professional jockeys. The cavum septi pellucidi and ventricles are enlarged, and the cerebral cortex and cerebellum are atrophied.

Microscopically, there are widespread neurofibrillary tangles, identical to those found in Alzheimer's disease. Neurotic (senile) plaques are also present; however, in contrast to Alzheimer's disease, they are diffuse. Cell loss occurs in the substantia nigra and locus coeruleus, but Lewy bodies are absent.

**Post-concussion syndrome (post-concussional disorder)**

**Clinical features**

Concussion may be associated with loss of consciousness that generally lasts only a minute or so; in other cases, patients may remain conscious but appear dazed and mildly confused, with these symptoms resolving quickly. The amnesia following concussion extends in a retrograde fashion for up to hours and in an anterograde fashion from minutes to, in rare cases, hours. In a very small minority of
cases, concussion may be associated with a grand mal seizure occurring within seconds of the impact; also known as ‘concussive convulsions’, these events do not recur and do not portend the development of epilepsy. Although the grosser aspects of concussion clear immediately, there may be some subtle and mild difficulty with memory and concentration, which typically resolves gradually within a week;\textsuperscript{131} in patients with a history of prior concussion, however, these symptoms may take longer to resolve.\textsuperscript{132}

In a minority of patients, concussion may be followed by the post-concussion syndrome, in which, in addition to the above cognitive difficulties, other symptoms become evident within the first day and then persist. Headache tends to be severe and may be continuous or episodic; it may be dull and continuous, or throbbing, and may be exacerbated by loud noises, coughing or sneezing. Fatigue may be constant or may become evident only on exertion. Dizziness may consist of mere light-headedness, or there may be a true vertigo; when vertigo is present, patients may complain that it is exacerbated or precipitated by changes in position or by any sudden movements. Depression may occur and be marked by severe insomnia. Irritability may be prominent, and patients may complain of great difficulty controlling their temper. Less commonly, anxiety may also be seen. Other symptoms may occur, including photophobia, hyperacusis, and hyperhidrosis. Many patients report that alcohol exacerbates their symptoms.

**Course**

In most cases, a gradual remission of symptoms occurs from a few weeks up to 3 years after the concussion, with the majority of patients recovering in a matter of months. When symptoms persist for more than 3 years, a chronic, indefinite course may be anticipated.

**Aetiology**

Although concussion probably occurs secondary to a fully reversible disruption of axonal function, post-concussion syndrome probably occurs secondary to a mild degree of diffuse axonal injury, as indicated by MRI\textsuperscript{133} and in one autopsy case of a patient with the syndrome who died 7 months after the concussion of an unrelated cause.\textsuperscript{134}

---

**HYPOXIC DISORDERS**

**Post-anoxic (post-hypoxic, post-ischaemic or ischaemic–hypoxic) encephalopathy**

**Clinical features**

Among those patients who survive an ischaemic–hypoxic event and emerge from coma, some may be left in a persistent vegetative state; others emerge into a delirium of variable duration. After the delirium clears, some patients may recover entirely; however, most will be left with either dementia or amnesia. The dementia may or may not be accompanied by delusions and hallucinations; many patients will be restless, and in some cases there may be a significant degree of agitation. In some cases, rather than dementia, patients will be left with an isolated amnestic syndrome, with both anterograde and retrograde components.

Action (or intention) myoclonus may occur and may appear independently or in concert with dementia or amnesia. Parkinsonism, dystonia or athetosis (or a combination of these) may also appear.

MRI may reveal a variety of findings, including laminar cortical atrophy, ventricular dilation and, within the cerebral cortex, either a laminar or a multifocal pattern of cortical necrosis. In cases characterized by isolated amnesia, the temporal lobes, in particular the hippocampi, are heavily involved; in cases of parkinsonism or dystonia, the basal ganglia show similar changes. In some cases of global ischaemia, watershed infarctions and abnormalities in the basal ganglia.

**Course**

Dementia and amnesia may show some improvement over the first 6 months or so, after which these features tend to remain stably chronic. Parkinsonism and dystonia may show gradual progression over many years.

**Aetiology and pathology**

Common causes include cardiac arrest, haemorrhagic or septic shock, carbon monoxide (CO) poisoning, strangulation and drowning. After 5 min or more of global ischaemia or anoxia, permanent damage occurs. In patients who develop post-anoxic encephalopathy, one finds cortical atrophy, ventricular dilation and, within the cerebral cortex, either a laminar or a multifocal pattern of cortical necrosis. In cases characterized by isolated amnesia, the temporal lobes, in particular the hippocampi, are heavily involved; in cases of parkinsonism or dystonia, the basal ganglia show similar changes. In some cases of global ischaemia, watershed infarctions may also occur.

**Delayed post-anoxic leucoencephalopathy**

This may occur in a small minority of those patients who make a more or less complete recovery after emergence from coma following a global hypoxic or ischaemic insult.

**Clinical features**

The lucid interval averages about 2–3 weeks, ranging from 2 days to 2 months. The onset of the encephalopathy is fairly sudden, occurring over a matter of a day or two, and patients generally present with a combination of delirium and a movement disorder. Confusion, amnesia, apathy, irritability and incontinence are prominent, and some patients may become mute. Parkinsonism is the most common movement disorder, but some patients may develop dystonia and some may experience a combination of both syndromes. Spasticity is common, with hyperreflexia and extensor plantar responses. Delirium may occasionally be absent and patients may present only with a movement disorder, such as parkinsonism, dystonia or chorea.
T2-weighted MRI reveals increased signal intensity in the white matter in patients with delirium; acutely, diffusion-weighted imaging (DWI) shows increased signal intensity in the same area. In patients with a movement disorder, T1-weighted scanning may reveal decreased signal intensity in the striatum.

Course
In a small minority of patients the course is fulminant, with coma and death. In most, however, the course is favourable, with patients experiencing a more or less complete recovery of cognitive abilities over 6–12 months, with only a minority being left with residual dementia. The movement disorder, however, may persist and in some cases may progressively worsen.

Pathology
At autopsy there is a massive, symmetrical, diffuse demyelination of the white matter, with variable involvement of the basal ganglia.

Carbon monoxide poisoning
Clinical features
The onset of intoxication may be gradual or sudden. Given that CO is colourless and odourless, victims may be unaware of their plight. In general, although the correlation between carboxyhaemoglobin level and clinical symptomatology is only a rough one, headache and delirium appear at a carboxyhaemoglobin level of 10–30 per cent, worsening and being joined by nausea and vomiting as the level rises to 40 per cent. At levels of 40–50 per cent, stupor and ataxia appear, and cyanosis may be seen. When the level rises above 50 per cent, coma and convulsions occur. Levels over 60 per cent are often fatal. Although it is traditional to associate CO poisoning with a cherry-red discolouration of the lips, nails and skin, this is in fact rare; if anything, most patients display a degree of cyanosis.

In survivors, characteristic CT/MRI changes may be seen in the globus pallidus.

Course
In general, if intoxication ceases before the onset of stupor, recovery is typically complete within anywhere from hours to weeks. If coma occurs, and even in some cases in which only delirium has occurred, a minority of patients may experience significant sequelae, such as post-anoxic encephalopathy or delayed post-anoxic encephalopathy.

Aetiology and pathology
CO poisoning may be accidental, as may occur with poorly ventilated gas, wood or charcoal stoves, or by suicidal intent, such as when patients hook a hose to the car exhaust and then funnel it into the tightly windowed car or simply leave the car running in an enclosed garage. The affinity of CO for haemoglobin is over 200 times greater than that of oxygen and, when a high fraction of haemoglobin exists as carboxyhaemoglobin, tissue anoxia supervenes. CO also binds to mitochondrial cytochrome oxidase, thereby impairing cellular respiration; furthermore, CO also binds to iron-rich CNS areas such as the globus pallidus and substantia nigra. In fatal cases, widespread petechial haemorrhages are found throughout the cerebrum.

NUTRITIONAL, TOXIC AND METABOLIC DISORDERS

Wernicke’s encephalopathy and Korsakoff’s psychosis are considered in Chapter 69.

Vitamin B12 deficiency
Clinical features
Symptoms referable to the cerebrum or spinal cord tend to appear subacutely over weeks or months.

Cerebral involvement manifests most commonly with dementia, which may be marked by hallucinations and delusions. Personality change may also occur, and, rarely, depression or mania. Another rare manifestation is psychosis (‘megaloblastic madness’): in one case, a 46-year-old woman developed delusions of persecution and jealousy and was correctly diagnosed only when symptoms of subacute combined degeneration became evident; in another case, a 47-year-old woman became withdrawn, guarded and suspicious, heard the voice of God commanding her to board a spaceship, and prayed fervently, with all symptoms resolving upon vitamin B12 (cobalamin) administration.

Subacute combined degeneration reflects demyelination of the peripheral nerves, posterior columns and lateral corticospinal tracts. Patients present with acral paraesthesiae, followed by ataxia, a positive Romberg test and eventually spasticity. The plantar responses are generally extensor, but the deep tendon reflexes may be either increased or depressed, depending on the peripheral neuropathy severity.

Macrocytosis, with or without anaemia, is common; however, both of these findings may be absent. Indeed, in one large study, both the red blood cell count and the mean corpuscular volume were normal in approximately one-fifth of patients.

MRI reveals patchy, confluent areas of increased signal intensity in the centrum semiovale in patients with cerebral symptomatology, while electroencephalography (EEG) may show generalized slowing.

It is customary to obtain a serum B12 level; it is also appropriate to obtain levels of methylmalonic acid and homocysteine. In B12 deficiency, both methylmalonic acid and homocysteine levels are elevated, and this combination of findings is extremely sensitive and specific for B12 deficiency: when the serum B12 level is borderline, these two findings should be relied on when deciding whether intracellular B12 deficiency is present.
Course
Most cases are gradually progressive.

Aetiology and pathology
The most common cause of vitamin B12 deficiency is pernicious anaemia; anti-parietal cell antibodies lead to destruction of gastric parietal cells, with a consequent lack of intrinsic factor and deficient uptake of ingested B12 by ileal cells. Other patients also have anti-intrinsic factor antibodies. Other antibodies may also be present, including antibodies against the thyroid and adrenal/suprarenal gland, and patients may develop Hashimoto’s thyroiditis with hypothyroidism, or adrenocortical insufficiency.

Other causes of B12 deficiency include strict vegetarianism, severe malnutrition (e.g. in patients with chronic alcoholism), total or partial gastrectomy, inherited abnormalities of the R binder or intrinsic factor, achlorhydria, pancreatic insufficiency, steatorrhea or malabsorption of any cause, tapeworm infestation, bacterial overgrowth (e.g. after a Billroth II operation), ileal diseases (e.g. Crohn’s disease), ileal resection, and chronic treatment with omeprazole or metformin. All of these causes lead to intracellular B12 deficiency because of a failure of B12 absorption and are associated with decreased serum B12 levels. There are also some very rare diseases characterized by intracellular B12 deficiency or malutilization; in these disorders, the serum B12 level will be normal, but with elevated serum methylmalonic acid and homocysteine levels. Examples include inherited abnormalities in transcobalamin II and abnormalities in the intracellular metabolism of cobalamin. There may also be an association between acquired immunodeficiency syndrome (AIDS) and B12 deficiency.

Clinical B12 deficiency can be precipitated by inhalation of nitrous oxide, for example during dental procedures or in drug abusers. In cases in which there is already a subclinical B12 deficiency, nitrous oxide inhalation can acutely precipitate symptoms; in other cases, for example in young, well-nourished drug abusers, symptoms may not occur until nitrous oxide has been abused for a long time.

When B12 deficiency has been confirmed by elevated methylmalonic acid and homocysteine levels, efforts should be made to determine the cause of this deficiency. Given that pernicious anaemia is the most common cause, all patients should be tested for anti-parietal cell and anti-intrinsic factor antibodies. If these are absent, then the other causes noted above should be considered.

Neuropathologically, demyelination is seen within the centrum semiovale and in the posterior columns and lateral corticospinal tracts.

Folate deficiency
Clinical features
Reynolds and colleagues demonstrated an association of folate deficiency with dementia, and Strachan and Henderson described two convincing cases of dementia secondary to folate deficiency, one occurring in combination with a peripheral neuropathy and the other without any other symptoms. Folate deficiency is also a cause of megaloblastic anaemia. The serum homocysteine level is elevated.

Course
It appears that, in the absence of treatment, the course is progressive.

Aetiology
Folate is needed in DNA biosynthesis and is found in fresh green vegetables, some fruits, yeast, kidney and liver. Dietary deficiency, as in chronic alcoholism, is the most common cause of deficiency; intestinal malabsorption (e.g. in sprue) may also be a factor. Given the limited hepatic storage of folic acid, symptoms of deficiency may appear within a few months of poor oral intake or malabsorption. Medicines that reduce folate levels include oral contraceptives, phenytoin, primidone, phenobarbital, carbamazepine, pyrimethamine, trimethoprim, pentamidine, sulfasalazine and methotrexate. Marginal folic acid reserves may be depleted rapidly in conditions of increased metabolic demand, for example during pregnancy and lactation, and during the reticulocytosis seen with treatment of vitamin B12-induced anaemia.

Pellagra
This may occur clinically, as either acute (encephalopathic) or chronic pellagra.

Clinical features
Encephalopathic pellagra presents fairly acutely, over days to a week. When fully developed, it is characterized by delirium, dysarthria, cogwheel rigidity, gegenhalten and myoclonus.

Pellagra of gradual onset appears insidiously over many months. When fully developed, it is characterized by dementia, dermatitis and diarrhoea (‘3 Ds’). The dementia may present with apathy, depression or anxiety; however, over time, typical cognitive deficits, such as decreased memory and poor concentration, eventually appear. The dementia at times may also be marked by delusions or hallucinations. The dermatitis is characterized initially by erythematous lesions in sun-exposed areas. Eventually, the skin becomes hyperpigmented and roughened, and it is from the Italian for ‘rough’ (pelle) ‘skin’ (agra) that the disease gains its name. Diarrhoea may be severe and the fluid blood-tinged. Most cases of pellagra do not, however, present with the full ‘3 Ds’: some patients with pellagrous dementia may have only one of the other ‘Ds’, and in some cases there may only be dementia, without any rash or diarrhoea.

EEG shows generalized slowing.
Although the serum niacin level is low, a more reliable test is a 24-h urine test for niacin metabolites.

Course

The encephalopathic form may be rapidly progressive, and coma and death may occur in a matter of weeks. The chronic form pursues a slower course, with death in a matter of years.

Aetiology and pathology

Niacin deficiency occurs most commonly as a result of dietary deficiency. In developed countries, this is seen primarily in malnourished patients with alcoholism as the encephalopathic form. The chronic form was endemic in the American south among people subsisting primarily on corn. As corn contains niacin in a bound, biologically less active form, and also lacks tryptophan, these individuals very gradually became niacin-deficient. Since the introduction of corn flour enriched with niacin, the chronic form of pellagra has almost disappeared in the USA. Other causes of niacin deficiency include bowel resection, Crohn’s disease and anorexia nervosa.

Pellagra has also been noted in conditions in which the normal endogenous conversion of tryptophan to niacin is impaired, for example following isoniazid treatment. The normal enzymatic conversion of tryptophan to niacin is dependent on the activated form of pyridoxine (vitamin B6); isoniazid impairs the conversion of the inactive form of B6 to the active form and by this indirect mechanism reduces the endogenous production of niacin. Another example is in cases of carcinoid tumour, in which the gross overutilization of tryptophan by the tumour leaves less available for conversion to niacin.

Within the CNS, neurons are swollen and display chromatolysis, with eccentric nuclei and a loss of Nissl substance, seen particularly in neurons of the pontine nuclei, cerebellar dentate nuclei, cerebral cortex, basal ganglia and anterior horn of the spinal cord.

Manganism

Clinical features

The onset of symptoms is typically gradual, occurring after months or years of exposure to manganese. Patients may present with personality change or parkinsonism, or both.

The personality change typically consists of asthenia, fatigue, irritability, emotional lability, and a peculiar kind of ‘incongruous’ laughter, reminiscent of the emotional incontinence seen in pseudo-bulbar palsy: patients may smile without cause, or burst out in laughter, again for no apparent reason. Insomnia or hypersonmia may accompany these changes.

The parkinsonism is characterized by rigidity, bradykinesia, postural instability, and a tendency to ‘freeze’ and fall upon turning. Cogwheeling is often seen and, although tremor may also be present, it is generally not of the ‘pill-rolling’ type. The parkinsonism may also be accompanied by dystonia, often affecting the cervical musculature or face. The most characteristic feature is a distinctive dystonic gait abnormality known as ‘cock-walk’: patients walk on their metatarsophalangeal joints as if they were wearing high heels; at times, the elbows may be flexed, creating the overall appearance of the walk of a rooster.

Dementia may occur concurrent with the parkinsonism and may be characterized by a marked degree of memory loss.

Psychosis (‘manganese madness’) may occur and is characterized by excitation, hallucinations and delusions.

T1-weighted MRI may reveal increased signal intensity within the globus pallidus bilaterally. Manganese levels are increased in the serum, hair or 24-h urine sample.

Course

With ongoing exposure, symptoms gradually worsen. With cessation of exposure, however, rather than a gradual reduction of parkinsonian signs and symptoms, these actually continue gradually to worsen over the next 10 years or so, after which they persist in a stable chronicity. A similar progression has been noted for the ‘cock-walk’.

Aetiology and pathology

Most cases of chronic manganese exposure result from inhalation among manganese miners and people who work in steel or battery factories. Cases have also been reported secondary to drinking contaminated well water or, very rarely, to prolonged intravenous total parenteral nutrition with manganese-containing solutions.

Neuronal loss and gliosis, although most prominent in the globus pallidus, are also found in the putamen, pars reticulata of the substantia nigra, thalamus, hypothalamus and cerebral cortex.

Intoxication with other metals

Thallium intoxication

Although thallium can be absorbed through either the lungs or the skin, industrial exposure is rare and most cases of thallium intoxication are by ingestion. Since thallium was banned as a rodenticide, current cases generally represent a deliberate, often homicidal, poisoning.

Acute intoxication generally presents with abdominal pain, vomiting and diarrhoea. Within days or a week or so, patients develop delirium and painful peripheral sensorimotor polyneuropathy, which may progress to quadriplegia. Cranial neuropathies, with facial palsy or ophthalmoplegia, may also develop; rarely, grand mal seizures may occur. Within 1–3 weeks, patients develop severe, generalized alopecia.

Gradual intoxication presents with dementia, sensorimotor polyneuropathy and alopecia.

Thallium may be found in the urine and serum and, in long-standing cases, the hair.
Acute intoxication may be fatal in up to one-tenth of cases. In survivors, there is a gradual, more or less complete recovery; in some cases there may be persistent cognitive deficits (which may be severe enough to produce dementia) or personality change.

**Arsenic intoxication**

Although elemental arsenic causes relatively little CNS toxicity, arsenic salts are toxic. Arsenic salts are found in certain herbicides and rodenticides, and ingestion may occur accidentally or with suicidal or homicidal intent.

Acute ingestion is followed rapidly by delirium, nausea, vomiting and diarrhoea, which may be bloody; convulsions may also occur. Classically there is an odour of garlic on the breath. Arrhythmias, renal failure and hypotension may occur. Within 1–3 weeks, painful peripheral sensorimotor polyneuropathy appears.

Chronic exposure to small amounts of arsenic salts may cause both dementia and polyneuropathy. Hyperkeratosis of the palms and soles may occur, and Mees’ lines – transverse white discoloration of the nails – may appear. Occasionally there is mild alopecia.

Arsenic may be found in a 24-h urine sample and, within weeks of exposure, is also found in the hair and nails.

**Bismuth intoxication**

Bismuth is found in a number of preparations and is used for the control of diarrhoea and in the treatment of *Helicobacter pylori* infection.

The onset may be gradual or acute, depending on the dosage. Gradual onset is marked by insomnia and mood changes, with depression, irritability or, uncommonly, euphoria; rarely, delusions or hallucinations may occur. With high dosage, there may be an acute onset of delirium, accompanied by myoclonus, ataxia and, in a minority of patients, seizures.

CT may reveal patchy areas of cortical radiolucency in the cortex.

**Tin intoxication**

Exposure to tin compounds may occur in certain industries or by ingestion.

Delirium and seizures have been reported after intoxication with trimethyltin and triethyltin. With phenyltin ingestion, delirium and ataxia occur.

Although most patients survive trimethyltin intoxication, the mortality rate after triethyltin intoxication is approximately 50 per cent. Among patients who survive tin intoxication, residual symptoms are common and may be severe.

**Lead encephalopathy**

Toxic accumulations of lead may occur in a number of ways. Children may eat lead-based paint chips. Among adults, exposure may occur in certain occupations, for example in welders and in people who work in battery factories or lead smelters; ‘moonshine’ whiskey, made with the help of old car radiators, may also be a source. Other less common sources include lead-glazed pottery, certain alternative medications and retained bullets. Leaded petrol (gasoline) used to be a major source, but since lead additives were banned this has essentially ceased to be a problem.

In children, acute lead encephalopathy may be preceded by a prodrome of irritability, abdominal pain and lethargy that lasts for weeks. In both children and adults, the full syndrome is marked by delirium, which may be accompanied by excitation, hallucinations, delusions, ataxia and seizures; classically, patients complain of a metallic taste in the mouth. Haemolysis and renal failure may occur.

Chronic lead encephalopathy in children may present with very gradual cognitive decline, which may range in severity from a drop of a few intelligence quotient (IQ) points to dementia. There is also an association between lead exposure and the development of a syndrome virtually identical to attention-deficit hyperactivity disorder (ADHD). Occasionally seizures may occur.

Chronic lead encephalopathy in adults may present with either personality change or dementia of variable severity; patients also may complain of colicky abdominal pain and a metallic taste in the mouth. In some cases, depressive symptoms may be seen. Motor peripheral neuropathy may occur, with, classically, wrist- and foot-drop.

Whole blood lead levels of over 80 μg/dL are associated with an acute presentation, whereas levels of 10–20 μg/dL, if chronically maintained, produce chronic encephalopathy. The zinc protoporphyrin level is also increased. In both children and adults, ‘lead lines’ may be seen at the border of the gingiva and teeth; in childhood cases, lead lines may also be seen in radiographs of the tibia or other long bones.

Acute lead encephalopathy runs a rapid course, with mortality rates approaching 25 per cent. Survivors may be left with dementia, seizures or spasticity. Chronic lead encephalopathy shows little improvement over time.

**Mercury intoxication**

Three forms of mercury are potentially toxic to humans, namely elemental mercury (e.g. in gold miners), salts of mercury (in people employed in the manufacture of plastics, fungicides and electronics), and organic mercury as methylmercury (e.g. from contaminated fish and contaminated seed grain), ethylmercury and phenylmercury.

With acute exposure to elemental mercury via inhalation, a pneumonitis may occur. Acute exposure to either mercury salts or to organic mercury may cause vomiting, which may be quite severe in the case of mercury salts and may also be accompanied by renal failure.

Among patients who survive the acute exposure, and in cases of chronic, low-level exposure, various sequelae may gradually ensue, including personality change, dementia and abnormal movements. The personality change, erethism, is classically characterized by emotional lability,
Hypoglycaemia

Clinical features
As the blood glucose level falls below 2.5 mmol/L (45 mg/dL), autonomic symptoms appear fairly promptly, including anxiety, palpitations, tremulousness and diaphoresis; patients may also complain of hunger, nausea, headache and generalized weakness.

Neuropathic symptoms are associated with blood glucose levels of 1.67 mmol/L (30 mg/dL) or lower\(^{157,158} \) but, unlike the autonomic symptoms, tend to appear only after this degree of hypoglycaemia has been sustained for approximately 30 min. Initially, patients may experience light-headedness or depersonalization. Delirium is common and may be associated with unusual behaviour: in one case, the patient ‘was restless, opening and closing his eyes, and thrashing about with his arms and legs, occasionally hitting onlookers and spitting in their faces’\(^{157} \) in another case, the patient, a soldier, ‘walked into the mess hall ... [dressed] in his underwear’\(^{160} \). Partial or grand mal seizures may occur. A very small minority of patients also have focal findings such as hemiplegia or aphasia. With sustained hypoglycaemia, coma may ensue.

Although in most cases neuropathic symptoms are preceded by autonomic symptoms, exceptions occur, and some patients may present with neuropathic symptoms alone.\(^{158,161,162} \) This may occur in patients with diabetes who have developed a diabetic autonomic neuropathy or in patients being treated with beta-blockers, which mask autonomic symptoms. Such a scenario may also occur in patients in which the blood glucose level drops very slowly, for example as may occur with fasting.

Course
Whereas autonomic symptoms respond promptly to glucose treatment, delirium may take up to an hour to subside. Patients who have developed coma may not recover consciousness and those who do may be left with dementia. In cases characterized by a residual dementia, a greater or lesser degree of recovery may occur over the following year or two.

Aetiology
Symptomatic hypoglycaemia may occur in the fasting state, for example early in the morning before breakfast or in people who skip meals, or postprandially, several hours after a meal. Fasting hypoglycaemia is seen most commonly in people with diabetes on insulin or oral antidiabetic agents; it may also occur in patients with insulinomas or in those who undertake a prolonged fast, for example during a hunger strike or in patients with anorexia nervosa.\(^{163} \) Liver disease, by impairing gluconeogenesis, may also set the stage for fasting hypoglycaemia. Gluconeogenesis is also inhibited by alcohol and, after a bout of binge drinking when little food is consumed, hypoglycaemia is common. Postprandial hypoglycaemia may be seen in early type II diabetes; after vagotomy, gastrectomy, pyloroplasty or gastrojejunostomy; and rarely in functional or essential postprandial hypoglycaemia.

Hypoglycaemia may also be intentionally produced by malingerers who inject themselves with insulin or take high doses of oral antidiabetic agents. Whenever this is suspected, as well as checking the glucose level, one should also determine the insulin and C-peptide levels and obtain a toxicology screen for oral agents.

Central pontine myelinolysis
Originally described by Adams and Foley in 1953, this disorder is classically characterized clinically by the development of a combination of flaccid quadriplegia and delirium, and pathologically by demyelination in the central portion of the pons, all occurring within 2–3 days of overly rapid correction of chronic hyponatraemia.\(^{164} \) Exceptions to this classic picture do occur, with prominent demyelination in extrapontine sites associated with movement disorders or delirium in the absence of quadriplegia. The existence of these exceptions has led some authors to propose the
alternative names ‘central pontine and extrapontine myelinolysis’ or, more generally, ‘osmotic demyelination syndrome’.

**Uraemia**

**Clinical features**

When caused by severe renal failure, the onset reflects the rapidity with which the kidneys fail, and hence the onset of uraemic encephalopathy may range from acute to gradual. Patients may initially experience some lassitude or a mild degree of somnolence; however, eventually delirium appears that is often marked by visual hallucinations. Asterixis and multifocal myoclonus are common, and in some cases one may see diffuse multifocal muscle twitching; dysarthria may also occur. In a minority of patients, seizures, typically grand mal, may appear. In one rare case, uraemia presented with only mania.165

A sensorimotor polyneuropathy may occur and may be acute or gradual in onset; the motor component may be severe and patients may become quadriparetic. In a little under 50 per cent of patients with a polyneuropathy, there may be prominent dysaesthesiae and restlessness, similar to that seen in the restless legs syndrome.

The severity of the encephalopathy correlates with the level of blood urea nitrogen (BUN) and also with the rapidity with which the BUN rises. For example, although in cases of acute renal failure levels of 35.7 mmol/L (100 mg/dL) are typically associated with delirium, in renal failure of very gradual onset levels of 71.4 mmol/L (200 mg/dL) may be tolerated with few if any symptoms. The EEG typically shows generalized slowing; triphasic waves may also be seen.

**Course**

Typically the symptoms of delirium show marked fluctuations throughout the day. The overall course parallels that of the renal failure, and in some progressive cases coma may ensue.

**Aetiology and pathology**

Urea itself is not the cause of the CNS dysfunction, and the delirium probably results from an ‘auto-intoxication’ by as yet unidentified substances. In chronic cases that come to autopsy, an excess of protoplasmic astrocytes has been found.

**Hepatic encephalopathy**

**Clinical features**

Acute-onset cases typically present with delirium. In gradual-onset cases, although delirium eventually occurs, it is often preceded by a prodrome characterized by impaired judgement, difficulty with abstracting, and mood changes, often tending toward euphoria. The delirium is characterized by confusion, drowsiness, sleep reversal, asterixis and myoclonus. A small minority of patients may have seizures, which may be partial or grand mal, and a minority may also have focal signs such as hemiparesis. Rarely, catatonic symptoms such as waxy flexibility may occur. Fetor hepaticus occurs in about half of cases. With progression of hepatic failure, stupor and coma may occur, accompanied by rigidity and bilateral Babinski signs.

The EEG shows generalized slowing, often accompanied by triphasic waves; interictal epileptiform discharges may occasionally be seen. Although the blood ammonia level is elevated in most cases, there is only a rough correlation between the degree of elevation and the severity of the encephalopathy.

**Course**

Without treatment, the course mirrors the severity of the underlying hepatic failure. With treatment, provided that coma has not supervened, recovery is generally good; in cases that have progressed to coma, the mortality rate is high.

With repeated episodes, patients may develop acquired hepatocerebral degeneration (see below).

**Aetiology and pathology**

With significant disease or dysfunction of hepatocytes, or with significant shunting of blood past the liver and directly into the systemic circulation, toxins normally removed by the liver reach the brain. In chronic cases, there may be an increased number of Alzheimer type II astrocytes. In acute cases characterized by coma, cerebral edema occurs, sometimes with transtentorial herniation.

The most common causes of hepatic failure are viral hepatitis and alcoholic cirrhosis. Often the onset of delirium may be traced to an event that increased the nitrogenous load in the gut beyond the diminished detoxifying capacity of the liver. Examples include high-protein meals, blood (as may occur with bleeding oesophageal varices or peptic ulcer disease), constipation, infection, anaesthesia, hypokalaemia, uraemia, and exposure to alcohol or sedative-hypnotics, especially benzodiazepines.

**Acquired hepatocerebral degeneration**

**Clinical features**

The onset is typically gradual and often punctuated by repeated episodes of hepatic encephalopathy. Cognitive deficits may occur and range from mild to dementia. The movement disorder is often complex, with variable admixtures of chorea, facial grimacing, postural tremor, parkinsonism and ataxia. Chorea, when present, often affects the head and neck, and the resulting movements may be tic-like in character.

T1-weighted MRI typically reveals increased signal intensity in the globus pallidus; similar changes may be seen in the striatum and in the substantia nigra.
Course
In general, the overall course is marked by slow progression.

Aetiology and pathology
This rare disorder occurs secondary to repeated or prolonged bouts of hepatic encephalopathy.

At autopsy, spongiform change or laminar cortical necrosis may be found in the cerebral and cerebellar cortices; spongiform change is also noted in the basal ganglia, and this may be accompanied by microcavitation. Alzheimer type II astrocytes are present in the cortex and basal ganglia.

Hepatic porphyria
Of the hepatic porphyrias, four can cause delirium. Acute intermittent porphyria may be found in Sweden and among white people in South Africa. Hereditary coproporphyria is rare and delta-aminolaevulinic acid (ALA) dehydratase deficiency extremely rare.

From a clinical viewpoint, the first three hepatic porphyrias are essentially the same, with the exception that both variegate porphyria and hereditary coproporphyria may cause a photosensitive rash, a symptom not seen in acute intermittent porphyria.

Of interest, it appears that the periodic ‘madness’ of King George III represented attacks of hepatic porphyria.

Clinical features of the first three porphyrias
These are episodic disorders; the first episode usually occurs in late adolescence or early adulthood. The attacks tend to present fairly acutely and are often precipitated by one of the factors mentioned below.

Classically, episodes are characterized by abdominal pain with vomiting, constipation or diarrhoea, accompanied, in about half of cases, by delirium, which is often marked by affective lability, delusions of persecution and visual hallucinations, which may be quite compelling; in some cases, stupor or coma may supervene. Uncommonly, rather than delirium there may be psychosis with auditory hallucinations, delusions of persecution and bizarre behaviour, all occurring in a clear sensorium without confusion or cognitive deficits. Other symptoms, seen in a minority of patients, include a primarily motor polyneuropathy (which may progress to quadriplegia), cranial neuropathy (most commonly with ophthalmoplegia or facial palsy), partial or grand mal seizures, hypertension, tachycardia and fever. A small minority of patients may also have significant hyponatraemia, which in turn may form a syndrome of inappropriate antidiuretic hormone (ADH) secretion or intestinal or renal sodium loss.

During episodes, a 24-h urine test shows elevated levels of porphobilinogen and ALA in all three of these porphyrias. In addition, patients with variegate porphyria and hereditary coproporphyria also display elevated urinary coproporphyrin; distinguishing between these two requires a 24-h stool collection for protoporphyrin and coproporphyrin. In variegate porphyria, protoporphyrin levels are higher than those of coproporphyrin; in hereditary coproporphyria, the converse holds true. Importantly, in between episodes all these measurements may be normal.

Course
The duration of episodes usually ranges from days to weeks. Although most patients recover completely, death may occur as a result of respiratory failure owing to motor neuropathy or an arrhythmia. Repeat episodes are common and typically occur in response to a specific precipitating factor.

Aetiology
The first three porphyrias are inherited in an autosomal dominant pattern; acute intermittent porphyria occurs secondary to mutations in the gene for porphobilinogen deaminase (chromosome 11); variegate porphyria to mutations in the gene for protoporphyrinogen oxidase (chromosome 1); and hereditary coproporphyria to mutations in the gene for coproporphyrinogen oxidase (chromosome 3). When the haem biosynthetic pathway becomes stressed in the presence of these mutated proteins, upstream proteins accumulate and an episode occurs. The fourth porphyria, ALA dehydratase deficiency, is an autosomal recessive disorder.

Precipitating factors include infection, menstruation, pregnancy, fasting (or a low-carbohydrate diet), surgery, and many drugs, including barbiturates, phenytoin, valproic acid, carbamazepine, nortriptyline, sulphonamides, griseofulvin, meprobamate, ergot derivatives, synthetic oestrogens and progestins, danazol, alpha-methylidopa, chlorpropamide and alcohol. Importantly, the following drugs appear to be safe: phenothiazines, opioid analgesics, chloral hydrate, gabapentin, levetiracetam, diazepam, diphenhydramine, aspirin and paracetamol (acetaminophen).

Fahr's syndrome (idiopathic striopallidodentate calcinosis, idiopathic calcification of the basal ganglia)
Clinical features
The presentation is generally gradual and may be characterized by either a movement disorder or a neuropsychiatric syndrome. Over long-term follow-up, most patients display a combination of these symptoms.

Of the movement disorders seen, the most common is parkinsonism; choreoathetosis or dystonia may also occur, and in a small minority of patients there may be ataxia or dysarthria.

Neuropsychiatric syndromes most commonly include...
Personality change, which may be of the frontal lobe type,
may also occur. Psychosis, similar to that of schizophrenia,
has been reported, especially in elderly patients.182 Other presentations include depression or mania183 and obsessions and compulsions.184 Seizures have also been noted.

CT displays bilateral basal ganglia calcification. One also sees bilateral calcification in other structures, such as the dentate nuclei, the thalamus and the grey–white junction of the cerebral and cerebellar cortices.

Aetiology

The calcification may either be secondary to some other disorder, such as hypoparathyroidism, or occur on a primary basis as an idiopathic or inherited disorder, in which case one speaks of ‘Fahr’s disease’.

Cytomegalovirus encephalitis

The great majority of adults show evidence of prior infection with cytomegalovirus (CMV). In immunocompromised patients, for example those with AIDS or those undergoing transplantation, the virus may reactivate and, among other syndromes, produce delirium. Autopsy studies have demonstrated evidence of CMV infection of the CNS in approximately one-third of patients with AIDS, making it one of the most common opportunistic infections seen in this condition. The delirium typically presents subacutely and is of variable severity; in some cases, however, the onset may be fulminant and the delirium quite severe, and in such cases there are often signs of brainstem involvement, such as nystagmus, ophthalmoplegia and ataxia. Some patients may also have cord involvement or a peripheral neuropathy.

Progressive multifocal leukoencephalopathy

In almost all cases patients have depressed cell-mediated immunity, most commonly owing to AIDS, in which 2–5 per cent of patients are afflicted.

Clinical features

The onset is typically subacute, generally over approximately 2 weeks. In most cases, patients present with a slowly progressive focal sign, such as hemianopia, aphasia, apraxia, hemisensory loss or hemiplegia; rarer focal findings such as Balint’s syndrome have also been reported. Over time, these initially unilateral deficits become bilateral, and many patients then go on to develop personality change, dementia or, rarely, delirium. Seizures may occur in up to 20 per cent of patients and may be simple partial, complex partial or grand mal. Rarely, the disorder may present with dementia,185 delirium186 or personality change.187 Cerebellar signs are uncommon. Other rare signs include quadriplegia secondary to brainstem involvement, dystonia, chorea and parkinsonism.

The EEG may show diffuse or focal slowing.

MRI reveals one or more focal lesions, generally in the subcortical white matter (signal intensity decreased on T1 and increased on FLAIR).

The CSF, although characteristically normal, may occasionally reveal a mild lymphocytic pleocytosis. The polymerase chain reaction (PCR) assay for JC virus is generally, but not always, positive. Serum testing for antibodies to JC virus is not helpful, given that most adults will be positive. In doubtful cases, brain biopsy may be required.

Course

The disorder is generally relentlessly progressive, with death occurring after about 4 months on average. Rarely, the course may stretch out for years; even more rarely, there may be spontaneous remissions.

Aetiology

The disorder occurs secondary to a CNS opportunistic infection by the JC virus. Approximately 80 per cent of the adult US population have latent JC virus infection. In a very small minority of patients with depressed cell-mediated immunity, this virus reactivates and spreads to the brain. Although the most common cause of immunoincompetence in these patients is AIDS, progressive multifocal leukoencephalopathy has also been noted in Hodgkin’s disease, other lymphomas, leukaemia, other cancers, tuberculosis, sarcoidosis, systemic lupus erythematosus (SLE), post-transplantation therapeutic immunosuppression and natalizumab pharmacotherapy. Very rarely, it may occur in otherwise healthy individuals.

Pathology

Within the CNS, oligodendrocytes and, to a lesser degree, astrocytes are infected by the JC virus. With destruction of oligodendrocytes, demyelination with only relative axonal sparing occurs and foci of demyelination begin to appear. Within and surrounding these foci there is a variable, and typically slight, degree of inflammation. At least initially, these foci are generally few in number and confined to one hemisphere; most commonly, they are seen in the subcortical white matter and the centrum semiovale; however, rarely, they may be prominent in the cerebellar white matter or the brainstem. Over time, the foci increase in size and number, and bilateral involvement occurs.
Herpes simplex encephalitis

Clinical features
Herpes simplex encephalitis can occur at any age, but most patients are middle-aged or older. The onset generally spans several days; however, the range is wide, from explosive onsets over several hours to gradual onsets lasting weeks or more. In some cases the onset may be preceded by a prodrome, lasting several days, of malaise, headache, irritability and mild fever.

Typically, patients present with fever, headache and delirium. Most also develop focal signs, such as hemiparesis or aphasia, and approximately two-thirds have complex partial or grand mal seizures. Although meningeal signs, such as a stiff neck or photophobia, are common, they are generally not severe. Notably, bizarre behaviour is common and, although this usually occurs in the context of the delirium, there are rare reports of the encephalitis presenting with either mania or psychosis. Untreated, coma develops in about one-third of patients.

CT scanning may show radiolucent areas in the medial aspects of one or both temporal lobes, but it may be normal for up to a week. MRI is much more sensitive, showing increased medial temporal lobe signal intensity on FLAIR or T2-weighted scanning, although this too may be normal for the first few days. DWI may show increased signal intensity in the same regions, which may be evident earlier than that seen on T2-weighted or FLAIR imaging. Gadolinium enhancement may also occur.

The EEG is usually normal for the first few days but will eventually show delta slowing in one temporal area, which may be accompanied by periodic complexes; with progression of the disease, bilateral involvement may be seen.

PCR assay of the CSF is almost 100 per cent sensitive for herpes simplex DNA and is the diagnostic procedure of choice. The CSF itself may be normal during the first few days but will in most cases show an elevated total protein with a lymphocytic and polymorphonuclear pleocytosis; red cells may also be present, reflecting the haemorrhagic nature of the inflammatory process. Although the glucose level is typically normal, it may rarely be reduced.

If lumbar puncture is not possible, brain biopsy may be necessary in order to make a definitive diagnosis; however, treatment should rarely await such a procedure.

Course
Untreated, over 50 per cent of patients die within days or a few weeks. In survivors, the clinical picture usually stabilizes in a matter of weeks; exceptionally, the acute illness may be prolonged for months or even longer.

Although most patients have only one episode, recurrences may occur occasionally.

Among survivors, the vast majority are left with significant sequelae, most commonly a chronic amnestic syndrome, dementia or personality change. Other sequelae include focal signs (e.g. aphasia, hemiplegia) or epilepsy; rarely, there may be a Kluver-Bucy syndrome. There is also a case report in which complex motor and vocal tics occurred.

Aetiology
Although most cases are caused by type 1 herpes simplex virus (which usually causes orolabial infections), type 2 virus may be causative in a small minority. Most adults have at some time been infected with herpes simplex type 1, and the virus may remain in a latent state in various sites, including the trigeminal ganglion.

Pathology
There is intense inflammation (which may progress to haemorrhagic necrosis) affecting initially the medial portions of the temporal lobe, with, in most cases, eventual spread to other regions, including the lateral aspects of the temporal lobe, insula, inferior portions of the frontal lobes, and cingulate cortex. Although involvement is typically unilateral early on, with time both temporal lobes become involved. There may be substantial oedema, and both uncal and subfalcine herniation may occur. In survivors, scarring, cavitation and cystic change are seen in affected regions.

Encephalitis lethargica
Also known as von Economo’s disease and European sleeping sickness, this was first described by Baron Constantin von Economo at a meeting of the Vienna Psychiatric Society in 1917. It swept the world in an epidemic during 1917–28, and sporadic cases still occur.

Clinical features
Acute encephalitis lethargica is characterized by headache, fever, sleep reversal (nocturnal wakefulness and diurnal somnolence), delirium, various oculomotor paresis and, classically, oculogyrig crises; some patients also display euphoria, psychosis or stuporous catatonia.

The CSF may be normal or may reveal a lymphocytic pleocytosis and an elevated total protein; oligoclonal bands may also be present.

Course
The mortality rate for acute encephalitis was about 25 per cent; among survivors, the encephalitis gradually cleared over about a month.

Post-encephalitic parkinsonism occurred in over 50 per cent of survivors after a latent interval of 1–20 years. Patients gradually developed a syndrome similar to that seen in idiopathic Parkinson’s disease. In addition, other motor abnormalities, including dystonia, blepharospasm and oculogyric crises, were often present. Interestingly, these transient oculogyric crises could also be accompanied by classic obsessions or compulsions; in some cases, palilalia or agitation and excitation were noted to accompany the oculogyric crises. Oculogyric crises, although most
commonly seen in conjunction with post-encephalitic parkinsonism, at times occurred independently.

Other sequelae, seen in a minority of patients, included dementia, narcoleptic and cataplectic attacks and, in children, restlessness and inattentiveness.

Pathology and aetiology
Autopsies of patients dying in the acute stage revealed inflammation with a perivascular accumulation of lymphocytes and plasma cells in the midbrain, basal ganglia, and cortex. In patients with sequelae, autopsy studies have revealed neuronal loss, gliosis and, in the remaining neurons, neurofibrillary tangles similar to those of Alzheimer’s disease, in the substantia nigra, locus coeruleus, hippocampus, basal ganglia, thalamus and cerebral cortex. Macroscopically, there was cortical atrophy and depigmentation of the substantia nigra and locus coeruleus.

Given that the pandemic of encephalitis lethargica coincided with the Spanish influenza epidemic, it was long suspected that encephalitis lethargica was secondary to influenza. Work on archived specimens, however, has failed to find any evidence of influenza RNA.193

Infectious mononucleosis
In about 5 per cent of cases of infectious mononucleosis, the central or peripheral nervous system may be involved, producing, variably, delirium, seizures, meningismus, ataxia, a cord syndrome, or a cranial or peripheral neuropathy. The disorder is caused by the Epstein–Barr virus and is transmitted primarily via oral secretions passed during intimate contact such as kissing. The virus gains access to the bloodstream and infects lymphocytes, spreading later to various other organs, including the brain. Although mononucleosis may occur in adults, it is most commonly seen in children and adolescents. Typically there is a prodrome, lasting for 1–2 weeks, of fatigue, malaise and headache, after which one sees the classic development of sore throat, fever and cervical adenopathy; splenomegaly and hepatomegaly may also occur.

Rabies
Rabies typically occurs after a patient is bitten by a rabid animal, for example a dog, cat, wolf, fox, skunk, raccoon or vampire bat; cases have also been reported secondary to respiratory transmission in spelunkers within bat-infested caves and in a veterinarian who was working with the homogenized brain of a rabid animal; more recently, rabies has been reported secondary to solid-organ transplantation from a donor with an unsuspected case.194 Although rabies is very rare in developed countries, it remains a significant problem in India and parts of Asia.

After the patient is bitten by an infected animal, there is a latent, asymptomatic period, generally of 1–3 months, with a range of weeks to a year or more; the duration of the latency appears related not only to the severity of the bite but also to the distance from the bitten area to the brain, with bites on the feet having the longest latency and facial bites the shortest.

With resolution of the latent interval, there is usually a prodrome, lasting days, characterized by headache and malaise; pain or paraesthesiae may also develop at the site of the original bite. Subsequently, the illness may evolve in one of two forms, namely furious rabies or dumb (or paralytic) rabies.

Furious rabies is seen in perhaps 80 per cent of cases and is characterized by restlessness, agitation, excitability, excessive startability and convulsions; delirium is typical, and patients may engage in bizarre behaviour, including biting. The combination of excessive salivation and dysphagia caused by pharyngeal spasm may literally cause the patient to foam at the mouth. Pharyngeal spasm may also be provoked by swallowing water or even by the sight of water, giving rise to the classic symptom of hydrophobia. Dumb rabies is characterized by a flaccid paralysis that typically begins in one limb and rapidly becomes generalized and symmetrical.

Subacute sclerosing panencephalitis
Subacute sclerosing panencephalitis (SSPE) occurs in 5–10 out of 1000 000 people with a history of measles and in approximately 1 out of 1 000 000 people who receive the measles immunization. It is three to four times more common in males than females.

Clinical features
The vast majority of cases occur in children. In these cases, the average latency from the preceding infection or immunization is about 8 years and the average age of onset about 13 years. In adults, the latency ranges from 8 years to 33 years, and the average age of onset is in the early twenties.

The onset is generally gradual, even insidious, and typically the disease evolves through three stages. In the first stage, the patient may become restless, distractable and forgetful; irritability and moodiness may be noted. In some cases, particularly in those with adult-onset disease, this first stage may be characterized by a psychosis that may mimic schizophrenia, with delusions (including Schneiderian first-rank symptoms) and stuporous catatonia. In the second stage, dementia evolves, accompanied by myoclonus, ataxia and partial or grand mal seizures; abnormal involuntary movements such as chorea, athetosis or dystonia are occasionally seen at this point. In the third and final stage, there is stupor and generalized rigidity, and eventually coma. There are many exceptions to this typical picture. In some cases, the onset may be relatively fulminating, with severe symptomatology seen in a matter of months. Furthermore, there may be considerable overlap among the various stages.

MRI may reveal cortical atrophy and, on T2-weighted...
imaging, multiple areas of increased signal intensity in the cerebral grey and white matter, with a predilection for the periventricular area.

The EEG in the second and third stages will display a classic burst-suppression pattern in the majority of cases.

The CSF is generally acellular, with a mildly elevated total protein. The immunoglobulin G (IgG) level is increased, sometimes greatly so, oligoclonal bands may be found, and, most importantly, anti-measles antibodies are present.

Course
Although the course is variable, most patients pass through the three stages and die within 1–3 years. In fulminant cases, however, a fatal outcome may occur within several months. Occasionally the course is prolonged, up to a decade or more, and there may at times be periods of relative stability, lasting many years; however, these inevitably give way to further progression.

Aetiology
SSPE occurs secondary to a reactivation of a dormant measles virus that lacks a normal M-protein; rather than undergoing ‘budding’, these defective viruses spread by means of cell fusion within the CNS.

Pathology
There is widespread perivascular inflammation accompanied by patchy demyelination and neuronal loss. Within surviving neurons, inclusions are found within nuclei, which, by electron microscopy, appear similar to measles nucleocapsids.

General paresis of the insane
Details of neurosyphilis, including neurological symptomatology, are given in Chapter 36. General paresis of the insane (GPI; also known as dementia paralytica and paretic neurosyphilis) is not necessarily associated with meningo-vascular syphilis and, indeed, it may be the only manifestation of tertiary neurosyphilis. GPI typically manifests with dementia of gradual onset and slow progression. Although the dementia may be non-specific, certain cases may be marked by frontal-lobe-type personality change; mood changes, tending towards either mania or depression; or delusions and hallucinations. Rarely, GPI may present with psychosis. Regardless of the typology of the dementia, other signs and symptoms gradually accrue. Seizures, either partial or grand mal, are common. Dysarthria and anomia may occur, and handwriting becomes very poor. Coarse tremor is common and may be present not only in the hands but also in the lips and tongue. Very typically the facial musculature loses its tone, giving the patient a vacant, dull facial expression. The Argyll Robertson pupil is present in most cases. With further progression, the gait becomes unsteady and a true ‘general paresis’ occurs, with profound widespread weakness of almost all of the voluntary musculature. The plantar responses become extensor and, unless tabes dorsalis is present, there is a generalized hyperreflexia.

Whipple’s disease
This is found mostly in white males.

Clinical features
The disorder typically presents in middle years. Migratory large-joint polyarthritis is common; patients also typically have abdominal pain, diarrhoea, weight loss and mild fever. In a minority of patients, the CNS is involved and, although such involvement generally occurs within the context of long-standing arthralgia or abdominal symptomatology, there are cases in which Whipple’s disease has presented with CNS involvement alone.

When the CNS is involved, patients typically present with gradually progressive dementia, delirium or personality change. In most cases, other symptoms are also present, including upper motor neuron signs, ataxia, nystagmus, myoclonus, seizures, supranuclear ophthalmoplegia, and various manifestations of hypothalamic dysfunction, including sleep disturbance (with either hypersomnolence or, less commonly, insomnia), hyperphagia, decreased libido or diabetes insipidus. A small minority of patients may also display oculomasticatory myorhythmia, in which pendular eye movements occur in concert with rhythmic jaw movements.

T2-weighted MRI may reveal multifocal areas of increased signal intensity within the cerebral cortex, basal ganglia, thalamus, midbrain and cerebellar cortex; in some cases, these lesions may show enhancement with gadolinium.

The CSF may show a lymphocytic pleocytosis or an elevated total protein, or both, with a normal glucose. In rare instances, some of the white cells may be periodic acid–Schiff (PAS)-positive. PCR assay is typically, but not always, positive for Tropheryma whippelii DNA.

The diagnosis may also be established by small-bowel biopsy, which may reveal not only PAS-positive macrophages but also a positive PCR assay; however, it must be kept in mind that, albeit rarely, CNS Whipple’s disease can occur with a negative small-bowel biopsy.

Course
CNS involvement is a grave sign in Whipple’s disease; in most cases, there is steady progression, with death occurring within 6–12 months.

Aetiology and pathology
The disorder occurs secondary to infection with the bacillus T. whippelii. Within the CNS, focal areas of inflammation and necrosis, with glial scars, are found in the cerebral cortex, basal ganglia, hypothalamus, brainstem (especially the periaqueductal grey matter) and cerebellar cortex.
PAS-positive macrophages are found in these regions, and electron microscopy may reveal the bacillus within the macrophage.

**Malaria**

Malaria occurs secondary to infection with any one of four species of the protozoon *Plasmodium*, including *P. malariae*, *P. vivax*, *P. ovale* and *P. falciparum*. Of these four, only *P. falciparum* invades the CNS, causing cerebral malaria. Malaria is endemic in Haiti, much of Asia and Oceania, and tropical and subtropical areas of Africa and South America; although it has been eradicated from most of North America and Europe, cases may still be seen in people returning from travel in endemic areas who did not take adequate prophylactic medication.

About 1–4 weeks after infection via the bite of an *Anopheles* mosquito, patients fall ill with fever, headache, malaise and myalgia. A small minority of those whose malaria has occurred secondary to *P. falciparum* may then develop cerebral malaria, with delirium, stupor or coma, and seizures. Focal signs such as hemiparesis may uncommonly occur. Diagnosis is by examination of peripheral blood smears.

**Toxoplasmosis**

Infection by *Toxoplasma gondii* is common in birds and mammals; cats serve as the definitive hosts and oocysts found in cat faeces may remain viable for up to a year. Primary infection in humans occurs secondary to eating contaminated food or undercooked lamb, pork or beef from infected animals and is very common: serological studies indicate that about one-third of adults in North America and Europe have been infected. In the vast majority, host defences are capable of rapidly controlling the infection and, during primary infection, patients are either asymptomatic or suffer a self-limited mononucleosis-like syndrome. Toxoplasma, however, may not be eradicated but remain latent in cysts, often in muscle.

CNS infection is very rare in immunocompetent adults. In immunocompromised patients, however, CNS toxoplasmosis does occur, either during a primary infection or, more commonly, with reactivation of a latent infection. In the pre-AIDS era this was noted in patients with cancer and in patients undergoing therapeutic immunosuppression, but it was rare; with the advent of AIDS, however, CNS toxoplasmosis has become common and indeed is the most common opportunistic infection in patients with AIDS, where it typically appears only when the CD4 count falls below 200/mm$^3$.

In most cases, CNS toxoplasmosis presents subacutely, over a matter of weeks. The presentation is variable, depending on the number and location of toxoplasma abscesses, and may include headache, fever, delirium, dementia, seizures and various focal signs, including hemianopia, hemiparesis, aphasia or, uncommonly, abnormal movements such as dystonia or chorea.

**PRION DISEASES**

**Creutzfeldt–Jakob disease**

Creutzfeldt–Jakob disease (CJD) occurs at an annual rate of 1–2 cases per 1 000 000 and is equally common in males and females. About 85 per cent of cases occur on a sporadic basis (sporadic CJD, sCJD), 10 per cent are inherited on an autosomal dominant basis, and the remainder represent iatrogenic infections (iatrogenic CJD, iCJD).

**Clinical features**

On average, sporadic cases appear in the early sixties, but the range is wide, from late teenage years to the tenth decade. Inherited cases tend to appear a bit earlier, mostly in the early fifties. Iatrogenic cases appear anywhere from 1 year to 30 years after the infectious event. Although most cases appear subacutely, over weeks to months, fulminant onsets spanning only a few days have been reported.

The presentation may be with dementia, personality change, psychosis, cerebellar ataxia, or visual symptomatology such as hemianopia or cortical blindness; rare presentations include aphasia, the ‘alien hand sign’ or mania. With progression, almost all patients become profoundly demented, and the dementia is accompanied by myoclonus (which may be stimulus-responsive) in almost 90 per cent of cases. Parkinsonism of the rigid, akinetic variety may occur, as may upper motor neuron signs; in a small minority of patients, evidence of lower motor neuron dysfunction, such as fasciculations, may be seen. Seizures occur in a small minority of patients.

MRI generally discloses cortical atrophy, the progression of which may be monitored with registration of serial scans. T2-weighted, FLAIR imaging and DWI may display increased signal intensity in the striatum and cerebral and cerebellar cortices; within the cortex, the increased signal intensity follows the cortical ribbon, displaying a gyriform pattern.

The EEG may show generalized slowing, and in some cases frontal intermittent rhythmic delta activity (FIRDA) has been noted. The most characteristic EEG findings, however, are periodic triphasic spike-and-slow-wave complexes at around 1 Hz, which are eventually seen in the majority of cases of sCJD and in some cases of genetic CJD and iCJD. The EEG may become abnormal only as the disease progresses; consequently, when the initial EEG fails to reveal this finding, it may be appropriate to perform serial EEGs.

The CSF is acellular with a normal glucose; in a very small minority of patients, the total protein level may show a mild elevation. Most importantly, the 14-3-3 protein is found in 50–95 per cent of cases.
Course

CJD progresses rapidly, and often one may see a decline from week to week, with death occurring within about 6 months on average. The overall range is relatively wide, with some patients dying in as little as a month and others surviving for up to 3 years.

Pathology and aetiology

Microscopically there is widespread spongiform change within the grey matter of the cerebral cortex, basal ganglia, thalamus and cerebellar cortex, which in turn is accounted for by grossly swollen dendrites and axons. In perhaps 5–10 per cent of cases, plaques may be found, which are, at least in part, composed of prions. There is also neuronal loss and astrogliosis but very little, if any, inflammation. Prions are also found in peripheral nerves, olfactory neuroepithelium, spleen and muscle.

The prion protein is a normally occurring cellular protein coded for by the PRNP gene on chromosome 20. The agent responsible for CJD is a pathological form of the prion protein.

The aetiology of sCJD is not clear. Some authors think there may be spontaneous, age-related transformations of normal cellular prion proteins into pathogenic prion proteins, whereas others suspect that sCJD may represent infections with a long incubation period.

Inherited cases occur secondary to any one of a large number of mutations in PRNP. Mutations may occur spontaneously, in which case the family history will be negative.

iCJD has occurred upon inadvertent exposure to tissue from patients with CJD via the following procedures: corneal transplants, dura mater grafts, the use of contaminated electrodes during neurosurgical procedures, injections of human growth hormone, and the injection of human pituitary gonadotropins. Interestingly, a case also occurred secondary to the use of lyophilized dura mater in the treatment of a nasopharyngeal angiofibroma, a procedure in which the dura mater remained extracranial. The persistence of prions cannot be overemphasized; in one case, electrodes that had been used during neurosurgery on a patient with CJD 2 years earlier were cleaned three times and repeatedly sterilized in ethanol and formaldehyde vapour and yet were still able to transmit the disease to a chimpanzee.

New-variant Creutzfeldt–Jakob disease

New-variant CJD (nvCJD; also known simply as variant CJD) is a very rare infectious prion disease acquired by eating meat derived from cows that had bovine spongiform encephalopathy (BSE), or ‘mad cow disease’. Currently, most cases have occurred in the UK (Table 37.2).

Clinical features

The incubation period between ingestion of contaminated meat and disease development is probably less than 20 years. Disease onset is subacute and, although most patients have been in their late twenties, the range of age of onset is wide, from early adolescence to the eighth decade.

Most patients present with behavioural changes such as depression or, less commonly, personality change, withdrawal, agitation, insomnia, apathy, emotional lability

or psychosis, which in turn may comprise visual and auditory hallucinations and Schneiderian first-rank symptoms.\textsuperscript{205–207} The remainder of patients present with ataxia, dysesthesiae or memory loss, or a combination of these and behavioural changes. With progression, dementia eventually appears, which is often accompanied by myoclonus.\textsuperscript{206–209}

FLAIR MR scanning displays a distinctive pulvinar sign in approximately three-quarters of all patients, characterized by increased signal intensity in the pulvinar of the thalamus. In addition, increased signal intensity may occur in the basal ganglia and cerebral and cerebellar cortices. The EEG may demonstrate generalized slowing.\textsuperscript{206} With rare exceptions, periodic spike-and-slow-wave complexes are absent.

The CSF is acellular, with a normal total protein. The 14-3-3 protein is found in about 50 per cent of cases. Tonsil biopsy appears to be sensitive and specific.\textsuperscript{210}

Course
nvCJD is relentlessly progressive, with most patients dying within a little over a year, with a range of 18 months to 3 years.

Aetiology and pathology
nvCJD occurs secondary to eating beef from cows that had BSE; in turn, cows contract the disease by eating meal made from the offal of sheep that had the transmissible spongiform encephalopathy scrapie. Almost all patients have been homozygous for methionine at codon 129 of \textit{PRNP}.

Within the thalamus, basal ganglia, and cerebral and cerebellar cortices, there are widespread prion plaques surrounded by spongiform change. Prions are also found in tonsils, lymph nodes and the spleen. It also appears that prions are present in the blood, and there have been cases of nvCJD occurring secondary to blood transfusion.\textsuperscript{211}

Fatal familial insomnia
Onset is typically subacute or gradual and occurs in middle years, with a wide range from late adolescence to the seventh decade. In general, patients develop intractable insomnia, followed in many cases by oneiroid states in which they appear confused, experience visual hallucinations, and behave as if they were acting out dreams. In one case, ‘the patient performed movements of sawing with a virtual saw and stopped bewildered when told there was no saw.’\textsuperscript{212} Rarely, the presentation may be with a psychosis coupled with insomnia.\textsuperscript{213} Paroxysms of autonomic disturbance often occur, with hyperhidrosis, tachycardia, hypertension and irregular respiration. Over time, dementia appears, accompanied, variously, by ataxia, myoclonus and spasticity. Although insomnia is the initial hallmark of this disease, in some cases it may appear late in the course and, rarely, it may be absent.

The EEG shows slowing, but there are no periodic complexes. The CSF is generally normal, although in a small minority of patients the 14-3-3 protein may be found. Most cases occur on an autosomal dominant basis, with mutations found at codon 178 of \textit{PRNP}.

Kuru
Kuru is a unique human prion disease, spread by ritual cannibalism that included ingestion of brain, and present only in the Fore people of New Guinea. With the elimination of cannibalism in the 1950s, new infections stopped, but, given the long incubation period, the disease itself is still present. After a long incubation period, spanning 4–50 years or more, patients gradually develop ataxia and tremor, followed, in a minority, by dementia.

Pathologically there is atrophy of the cerebellar vermis and flocculonodular lobe. Microscopically there is widespread spongiform change, neuronal loss and astrocytosis, together with kuru plaques, which are distinguished from the amyloid plaques of Alzheimer’s disease, for example, by the presence of spikes radiating out around the plaque circumference.

Other prion diseases
Gerstmann–Sträussler–Scheinker disease
Gerstmann–Sträussler–Scheinker disease (GSS) is a very rare, autosomal dominantly inherited prion disease occurring secondary to any one of several mutations in the \textit{PRNP} gene. The onset is subacute or gradual, and usually in the sixth decade, with a wide range from the third to the eighth decades. Classically, patients present with progressive ataxia, with the eventual development of dementia; in some cases, parkinsonism or long-tract signs may also occur. Death occurs, on average, after 5–6 years.

The EEG may show generalized slowing, but there are no periodic complexes. The CSF is normal and the 14-3-3 protein is absent.

ENDOCRINOLOGICAL DISORDERS

Cushing’s syndrome
Clinical features
The mode of onset is dependent on the underlying cause. Cases caused by exogenous steroid use are of the most rapid onset and may appear within days. Cushing’s disease secondary to a pituitary adenoma may present very gradually, over years, and cases of Cushing’s syndrome secondary to ectopic adrenocorticotropic hormone (ACTH) production may present over months.

Neuropsychiatric features include depression, mania or hypomania, anxiety, psychosis, dementia and/or delirium.
Depression is the most prominent neuropsychiatric feature; it occurs in one-half to three-quarters of patients with Cushing’s syndrome and may be the presenting feature. Anxiety commonly accompanies the depression, as agitated depression. The depression at times may be severe, with psychotic features, which may be either mood-congruent or mood-incongruent, with Schneiderian first-rank symptoms of thought broadcasting and thought insertion. Both suicide attempts and completed suicides may occur.

Mania is less common than depression in Cushing’s syndrome of endogenous origin, but the converse holds true in exogenous cases, in which mania is common. Anxiety of pathological degree has been noted in about one-tenth of patients but is most often seen in the context of depression.

Psychosis, although rare, can occur secondary to Cushing’s syndrome. One patient presented with delusions of persecution, auditory and visual hallucinations, and bizarre behaviour, which all cleared with adrenalectomy; another patient experienced agitation, auditory hallucinations, and religious and grandiose delusions, which again cleared with adrenalectomy.

Delirium may occur but is rare, being noted in only about 1 per cent of cases. Dementia is rare and is often characterized by prominent memory loss.

These neuropsychiatric features classically occur in the setting of a Cushingoid habitus, with moon facies, truncal obesity and violaceous abdominal striae. Other features include acne, hirsutism, proximal myopathy, easy bruising, hypertension, diabetes mellitus, amenorrhoea and, rarely, pseudo-tumour cerebri. All these features, however, take time to develop and thus may not be present in cases of Cushing’s syndrome secondary to exogenous steroid use, which may develop over days. Furthermore, in cases of Cushing’s syndrome secondary to ectopic ACTH secretion by an oat-cell carcinoma, one may see emaciation rather than obesity.

When Cushing’s syndrome occurs secondary to exogenous steroid administration, the diagnosis is fairly obvious, as symptoms appear within days of using high-dose steroids, for example more than 60 mg/day of prednisone. However, when endogenous steroid overproduction is suspected, laboratory testing is essential to confirm the diagnosis. Confirmation of suspected endogenous hypercortisolism is sought via a 24-h urine test for free cortisol. Serum cortisol levels show pulsatile fluctuations during the day and hence should not be relied on. If the 24-h urine free cortisol level is normal, the diagnosis is effectively ruled out.

In cases in which the 24-h urinary free cortisol level is elevated, further testing is required to determine the cause. The first step is to obtain an ACTH level. In hypercortisolism secondary to an adrenal tumour the ACTH is low, whereas in all other cases it is elevated. If the ACTH is elevated, the next step is to determine whether the ACTH is derived from an ectopic source, for example lung carcinoma, or from a pituitary tumour, and this is accomplished with the high-dose dexamethasone suppression test. In this test, patients are given 2 mg of dexamethasone orally every 6 h over 2 days; during the second day, a 24-h urine sample is collected for measurement of free cortisol. In cases of ectopic ACTH production, the tumour secreting the ACTH is not sensitive to the feedback of dexamethasone and hence continues to secrete ACTH, resulting in an increased free cortisol level in the 24-h urine sample; in such cases, one speaks of ‘non-suppression of cortisol by dexamethasone’. By contrast, pituitary adenomas do remain sensitive to dexamethasone and, in these cases, ACTH output falls with a resulting fall in the 24-h urine free cortisol level; in such cases, one speaks of ‘suppression of cortisol by dexamethasone’. An alternative, or supplementary, test is the corticotrophin-releasing hormone (CRH) stimulation test: ectopic ACTH-secreting tumours are not sensitive to CRH, and cortisol and ACTH levels do not rise significantly; pituitary adenomas, however, are sensitive, and here cortisol and ACTH levels do rise.

In some cases, the dexamethasone test may be equivocal, and differentiating between an ectopic ACTH-secreting tumour and a pituitary tumour may depend on sampling venous blood flow from the pituitary using sampling from the superior petrosal sinus or internal jugular vein.

If a pituitary tumour is suspected, MRI with gadolinium enhancement is in order, and, if positive, may obviate the need for superior petrosal or internal jugular sampling. Unfortunately, however, most ACTH-secreting pituitary tumours are microadenomas and about 50 per cent will escape detection by MRI.

Course
This depends on the underlying cause. Once cortisol levels are returned to normal, either by stopping exogenous steroids or by virtue of treatment of endogenous causes, neuropsychiatric features gradually resolve; although such resolution may occur within weeks to days in cases secondary to relatively short-term treatment with high-dose exogenous steroids, months may be required in endogenous cases.

Aetiology
There are various causes for endogenous hypercortisolism. Adrenal tumours, which may be either adenomas or carcinomas, account for about 15 per cent of cases. Ectopic ACTH-secreting tumours likewise account for about 15 per cent; although small-cell lung cancer is the most common of these, other tumours may also be at fault, including cancer of the thymus, pancreas or thyroid, and phaeochromocytoma. Pituitary adenomas are by far the most common cause, accounting for about 70 per cent. There are also very rare reports of CRH-secreting tumours, which may be located in the hypothalamus or ectopically, as for example in thyroid cancer.
Adrenocortical insufficiency

Clinical features
Acute adrenocortical insufficiency presents with nausea, vomiting and abdominal pain, with rapidly falling blood pressure, postural dizziness and eventually hypovolaemic shock. Delirium develops, followed by stupor and coma.

Chronic adrenocortical insufficiency presents gradually with fatigue, listlessness, poor concentration, anorexia, nausea, diarrhoea or constipation, and abdominal pain. Depression may occur; rarely, there may be delirium or psychosis. Blood pressure is low and postural dizziness common. In primary cases, with a lack of cortisol feedback on the pituitary, excessive stimulation of melanocytes by ACTH may lead to hyperpigmentation, especially prominent in sun-exposed areas and on the buccal and gingival mucosa. Chronic adrenocortical insufficiency may also be complicated by an acute episode, as may occur when chronic patients are subjected to a significant physiological stress such as surgery.

Serum cortisol is reduced. In primary cases ACTH levels are increased because of a lack of feedback inhibition on the pituitary, whereas in secondary cases the ACTH level is low. In cases in which ACTH levels are equivocal, further testing may be conducted with a synthetic ACTH analogue to determine whether such cases are primary or secondary; in primary cases there is little or no rise in ACTH, whereas in secondary cases, presuming that the adrenal/suprarenal glands have not atrophied owing to chronic non-stimulation, there should be a robust rise in ACTH.

Further laboratory abnormalities may be seen in primary cases in which destruction of the adrenal/suprarenal glands causes decreased mineralocorticoid levels, with resulting hyponatraemia and hyperkalaemia.

Course
Acute adrenocortical insufficiency is a life-threatening emergency. The course of chronic adrenocortical insufficiency is determined by the underlying cause: in the case of primary chronic adrenocortical insufficiency resulting from autoimmune destruction of the adrenals, there is a gradual progression of symptoms, with death occurring in perhaps 2 years.

Aetiology
Primary adrenocortical insufficiency is most commonly caused by autoimmune destruction of the adrenal/suprarenal glands. In this disorder, other endocrine glands may also be targeted by the autoimmune process, and patients may develop Hashimoto’s thyroiditis (with either hyperthyroidism or hypothyroidism), pernicious anaemia with vitamin B12 deficiency, hypoparathyroidism with hypocalcaemia, or diabetes mellitus. Other causes of primary adrenocortical insufficiency include adrenoleucodystrophy, tuberculosis, CMV infection (e.g. in AIDS), sarcoidosis, amyloidosis, metastatic disease and haemorrhagic infarction (e.g. during sepsis or overvigorously anticoagulated). With the exception of haemorrhagic infarction, all of these forms of primary adrenocortical insufficiency cause a chronic presentation.

Secondary adrenocortical insufficiency most commonly occurs secondary to abrupt discontinuation of long-term corticosteroid treatment. Any patient taking supraphysiological corticosteroid doses for more than a month will have some suppression of ACTH output from the pituitary coupled with some atrophy of the adrenal cortex. Other causes of secondary adrenocortical insufficiency include infarction, and tumours or granulomas of the pituitary or, rarely, the hypothalamus. These secondary cases may present either acutely (e.g. with abrupt discontinuation of steroid treatment) or chronically (e.g. with slowly growing pituitary tumours).

Hyperthyroidism

Clinical features
The age of onset varies according to the underlying aetiology: Graves’ disease typically appears in the twenties or thirties, while toxic multinodular goitre generally has an onset in old age. Although symptoms usually appear gradually, over weeks or months, subacute onsets may be seen, especially in relation to various physiological stressors.

Typically, patients are apprehensive and anxious and, although fatigued and tired, often experience restlessness and an inability to sit still. Anxiety often stands out and may represent the presenting complaint. Patients typically complain of diaphoresis, heat intolerance and an increased frequency of bowel movements; despite an often increased appetite with increased caloric intake, there may be substantial weight loss. On examination, one finds tachycardia, widened palpebral fissures and proptosis, a fine postural tremor, and generalized hyperreflexia; there may also be a proximal myopathy. Women may complain of menstrual irregularity and men may experience erectile dysfunction. Rarely, there may be chorea, grand mal seizures or a motor peripheral neuropathy.

Apathetic hyperthyroidism represents a variant of hyperthyroidism that is generally only seen in elderly people and that is characterized by apathy and, in some patients, lethargy. Remarkably, of the autonomic signs and symptoms seen in typical cases, only tachycardia is common in this apathetic variant: diaphoresis, tremor and hyperreflexia are generally absent. Many patients also develop atrial fibrillation and congestive failure.

Of the neuropsychiatric features seen in hyperthyroidism, depression is the most common and is seen in a substantial minority, especially in patients with apathetic hyperthyroidism, in whom the only clue to the correct diagnosis may be tachycardia or congestive heart failure. Depression may be accompanied by mood-congruent delusions or considerable agitation.
Mania is less common than depression\textsuperscript{232} and, in some cases, may be of the mixed variety.\textsuperscript{233}

Psychosis, although only rarely caused by hyperthyroidism, may occur: one patient developed a delusion of jealousy and, convinced that his wife was having an affair, had her followed; when his hyperthyroidism was treated, his psychosis resolved.\textsuperscript{234}

Dementia may occur in typical hyperthyroidism\textsuperscript{235} but is rare. By contrast, a significant minority of patients with the apathetic variant will develop cognitive deficits that may be severe enough to constitute dementia.\textsuperscript{236} Rarely, delirium may also occur.

Thyroid storm is a complication that typically appears in a patient with untreated hyperthyroidism who is subjected to some significant physiological stress (e.g., surgery, infection). There is a rapid escalation of all of the typical signs and symptoms, followed by hyperthermia, delirium, stupor and coma. In some cases, seizures may occur. Rarely, thyroid storm has presented with psychosis.\textsuperscript{237,238} Thyroid storm may also occur in the setting of apathetic hyperthyroidism and in such cases may present with coma in the absence of any autonomic features.\textsuperscript{239}

In almost all cases of hyperthyroidism the free thyroxine (T4) level will be elevated and the thyroid-stimulating hormone (TSH) level reduced. Exceptions occur in cases of triiodothyronine (T3) thyrotoxicosis, in which the free T4 level is normal; in cases in which the clinical suspicion of hyperthyroidism is high and the free T4 is normal, the free T3 level should be determined. Other exceptions include the very rare cases of a hypothalamic tumour secreting thyrotropin-releasing hormone (TRH) or a pituitary adenoma secreting TSH: in both cases, both the free T4 and the TSH levels are elevated.

**Course**

This is dictated by the underlying cause. Thyroid storm, regardless of the underlying cause, may pursue a fulminant course, with death in hours or days.

**Aetiology**

Most cases result from Graves’ disease. Other causes include toxic multinodular goitre, toxic solitary adenoma and the thyroiditides, including lymphocytic thyroiditis, subacute (De Quervain’s) thyroiditis and Hashimoto’s thyroiditis. The thyroiditides are characterized by ‘leakage’ of T4 from the inflamed thyroid and, typically, cause hyperthyroidism that is time-limited and that may, depending on the amount of inflammatory damage and scarring, be followed by hypothyroidism. Rare causes include hypothalamic tumours, pituitary adenomas, inherited pituitary resistance to T4, production of ectopic TSH by various tumours (hydatidiform mole, uterine choriocarcinoma, testicular choriocarcinoma), and production of T4 by various tumours (struma ovarii or metastatic follicular carcinoma of the thyroid). Finally, hyperthyroidism may occur as a side effect of amiodarone and may also be intentional, as in thyrotoxicosis factitia.

**Hypothyroidism**

**Clinical features and course**

The age of onset is determined by the underlying cause. Cases secondary to Hashimoto’s thyroiditis typically appear in the late thirties or early forties, and cases occurring after thyroidectomy may first appear within weeks postoperatively. The onset and evolution of symptoms are typically gradual.

Typically, patients develop psychomotor retardation, with slowed speech and movements; in some cases, lethargy and somnolence may occur. When asked a question, up to a minute may pass before the patient responds; the response itself, when it does come, is slow. Simple activities such as unfastening a button may take an inordinate amount of time to complete. Patients may appear apathetic and lacking in initiative, and often there may be difficulty with concentration and ‘fogginess’ of thought and memory.\textsuperscript{240} The overall appearance is often distinctive: skin becomes thickened, puffy and even boggy, and this is particularly obvious on the face, in the supraclavicular fossae, and on the dorsal surfaces of the hands and feet. The hair becomes thin and brittle, and there may be considerable hair loss, including the lateral thirds of the eyebrows. Other symptoms include a voice change towards hoarseness, cold intolerance, constipation, weight gain, decreased libido, erectile dysfunction and menorrhagia. Vibratory sense may be lost and the deep tendon reflexes are often reduced; the ankle jerk is often ‘hung up’, with a delayed relaxation phase. Cranial nerves may be involved, with partial deafness and, rarely, a peripheral facial palsy; cerebellar ataxia (‘myxoedema staggers’)\textsuperscript{241} occurs in up to 20 per cent. Very rarely, seizures may occur. Myxoedematous infiltration may cause carpal or tarsal tunnel syndrome; macroglossia may also occur and, if severe, may be followed by obstructive sleep apnoea. Bradycardia and hypotension are common, and there may be a degree of hypothermia; pericardial and pleural effusions may also occur. In a small minority of cases, a syndrome of inappropriate ADH secretion may occur, with hyponatraemia.

In severe cases, ‘myxoedema coma’ may develop. Typically this occurs in patients with long-standing hypothyroidism who are subjected to a physiological stress (e.g., surgery, infection) or who are given phenothiazines\textsuperscript{242} or any medications with prominent sedative effects. Stupor or coma develops, accompanied by hypothermia (which may be severe), significant bradycardia, respiratory depression and, in a significant minority, grand mal seizures.

Of the neuropsychiatric features seen in hypothyroidism, depression is most common; this may be severe and may be accompanied by hallucinations and delusions.\textsuperscript{243}

Psychosis occurring secondary to hypothyroidism has traditionally been referred to as ‘myxoedema madness’\textsuperscript{244}
and is often characterized by delusions of persecution and reference and auditory hallucinations.\textsuperscript{245,246}

Dementia may present with failing memory,\textsuperscript{247,248} followed by deficits in calculation and orientation; in some cases, the dementia may be accompanied by delusions of persecution and auditory hallucinations.

The EEG typically shows generalized slowing.

Free T4 is reduced in all cases. In primary hypothyroidism, the TSH is increased; in both secondary and tertiary cases, however, TSH is reduced. Distinguishing secondary from tertiary cases generally requires a TRH-stimulation test. In cases of secondary hypothyroidism, given a lack of pituitary cells capable of producing TSH, the TSH response to exogenous TRH is blunted. By contrast, in tertiary hypothyroidism, in which a chronic lack of endogenous TRH allows for an up-regulation of TRH receptors on pituitary cells, there is an enhanced response of TSH to TRH.

In subclinical primary hypothyroidism, although the free T4 level is within normal limits, the TSH level is mildly elevated. These indicate that, although the free T4 may be within broadly defined limits of normal, it is nevertheless below the individual patient’s ‘normal’ as indicated by the rise in TSH. Although patients may not have symptoms directly related to these findings, the findings are significant for two reasons. First, they may indicate that the patient is in the very early stages of what will become clinically evident hypothyroidism, and therefore close monitoring is required. Second, such subclinically reduced free T4 levels, although not causing symptoms per se, will nevertheless blunt the response to antidepressants or mood-stabilizing agents in patients with major depression or bipolar disorder.

Aetiology

Primary hypothyroidism accounts for over 90 per cent of cases. The most common cause is Hashimoto’s thyroiditis, indicated by the presence of anti-thyroid antibodies. Other causes include thyroidectomy, radioactive iodine treatment, neck irradiation, iodine deficiency and various medications, including amiodarone and lithium, in which case the occurrence of hypothyroidism is most likely in patients with anti-thyroid antibodies.\textsuperscript{249}

Secondary hypothyroidism may occur with tumours or infarction of the pituitary gland.

Tertiary hypothyroidism may occur with tumours or infarction of the hypothalamus; other causes include granulomatous disease and carbamazepine.

**IMMUNE-RELATED DISORDERS**

**Multiple sclerosis**

In this chapter neuropsychiatric manifestations of multiple sclerosis (MS) will mainly be considered; other aspects are detailed in Chapter 36.

Fatigue may occur and may be severe. Sexual dysfunction is very common, with decreased libido, erectile dysfunction or decreased vaginal lubrication. Uncommon symptoms and signs include aphasia and seizures, which may be either partial or grand mal in type, and various paroxysmal phenomena, such as hemifacial spasm, Lhermitte’s sign, trigeminal neuralgia, and lancinating pains in the extremities.

Dementia of variable severity, ranging from mild, almost subclinical impairment to debilitating, is eventually seen in the majority of patients. In rare cases, dementia may constitute the sole or predominant presenting feature of MS. In one case, for example, the only symptom in addition to the dementia was optic neuritis,\textsuperscript{251} and in two other cases it was unsteady gait.\textsuperscript{252} In one very rare case, a gradually progressive dementia constituted the only clinical evidence of MS.\textsuperscript{253} Although the correlation of dementia and plaque location and number has not been worked out definitively, it appears that cognitive deficits correlate both with the total burden of plaques within the cerebral white matter and with atrophy of the corpus callosum, which in turn may merely reflect overall disease activity in the hemispheric white matter.

Depression is eventually seen in perhaps one-quarter of patients.\textsuperscript{254} Depression may occur on a reactive basis in any debilitating disease, and MS is no exception. Certain facts, however, suggest strongly that depression in MS may also be a direct result of plaque formation. Patients with MS are more likely to experience depression than are normal control subjects\textsuperscript{255} or patients with comparably disabling neurological diseases that generally spare the cerebral cortex, such as amyotrophic lateral sclerosis.\textsuperscript{256,257} Furthermore, in contrast to what one might expect if the depression were reactive, there is little or no correlation between the occurrence of depression and the extent of the patient’s disability,\textsuperscript{258} and, regardless of the degree of overall disability, patients are more likely to experience depression when the plaques are in the cerebrum than when they are in the cerebellum or spinal cord.\textsuperscript{259,260} Furthermore, there is a correlation between depression and the presence of plaques in the inferior left frontal white matter,\textsuperscript{261} left arcuate fasciculus\textsuperscript{262} and right temporal white matter.\textsuperscript{263}

Euphoria may occur and is typically of the ‘bland’ or non-infectious type; it has been noted in anywhere from one-quarter\textsuperscript{254} to the vast majority of patients\textsuperscript{264} and is correlated with cerebral rather than spinal plaque formation.\textsuperscript{259} The contrast between this euphoria and the patient’s actual condition can be quite dramatic: one of Wilson’s patients, ‘bedridden and unable to stand, remarked, “you will not believe me when I say I feel thundering well”’.\textsuperscript{265} This bland euphoria is typically not accompanied by hyperactivity or pressure of speech and is often seen in concert with some degree of intellectual impairment.\textsuperscript{254} Although they are unusual, definite manic episodes may also occur in addition to this bland euphoria;\textsuperscript{266,267} indeed, out of all of the reasons for admission to psychiatric hospital for patients with MS, mania is the most common.\textsuperscript{268}
Emotional incontinence, with uncontrollable laughter or crying in the absence of a corresponding affect, is seen in about one-tenth of patients, generally only in far-advanced cases.

Psychosis may, rarely, dominate the clinical picture, in one very rare case, MS presented with a psychosis characterized by social withdrawal, ‘mystic’ visual hallucinations and various delusions.

Almost all plaques demonstrate increased signal intensity on T2-weighted or FLAIR MRI, and active plaques show enhancement with gadolinium. In some cases, severe plaques may undergo cystic change, and on T1-weighted MRI such plaques will appear as ‘black holes’ with greatly reduced signal intensity. Plaques are typically found in the centrum semiovale and in a periventricular distribution, where they tend to favour the occipital horns.

The CSF is abnormal in almost all cases. A mild lymphocytic pleocytosis, in the range of 6–30 cells/mm³, is seen in about one-third of cases, and the total protein is mildly elevated (rarely over 100 mg/dL) in about one-half. The IgG index is elevated in over two-thirds, and oligoclonal bands are present in about 90 per cent. The myelin basic protein is elevated in over three-quarters of cases, and the total protein is mildly elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent. The myelin basic protein is elevated in over three-quarters of cases. The 14-3-3 protein is present in over 90 per cent.

Systemic lupus erythematosus

SLE occurs in 0.015–0.05 per cent of the general population. It is far more common among females than males, and among black populations than white populations; in black females, the prevalence rises to 0.4 per cent.

Clinical features

Although lupus may appear at almost any age, the majority of patients fall ill between puberty and 40 years of age.

SLE is a systemic disease and in most cases cerebral lupus occurs in the setting of other symptoms, including constitutional symptoms (fatigue, fever, weight loss) and those referable to other organ systems, such as the musculoskeletal system, skin, heart, lungs or kidneys. Musculoskeletal symptomatology is very common and includes myalgia, arthralgia and a non-deforming polyarthritis. Cutaneous manifestations include photosensitivity, rashes (especially a malar rash) and alopecia. Cardiac symptomatology incorporates pericarditis and Libman–Sacks endocarditis. Pulmonary involvement may manifest with pleurisy, which may or may not be accompanied by pleural effusion. Renal involvement may manifest initially with proteinuria and cellular casts; over time, renal failure may occur. Various cytopenias, including anaemia, leucopenia and thrombocytopenia, may also occur.

Cerebral lupus may manifest with depression, mania, psychosis, delirium or dementia, seizures, chorea, or focal signs such as hemiparesis. Although these findings may occur independently, patients often have a mixture.

Depression, in some cases accompanied by hallucinations or delusions, has been found commonly by some authors but not others. Mania, although reported, appears rarely. Psychosis is relatively uncommon although typically characterized by delusions and hallucinations, it may rarely present with stuporous catatonia. Rarely, psychosis may constitute the presenting feature.

Delirium may occur and is often accompanied by hallucinations, either visual or auditory. Dementia may also be seen but is relatively uncommon.

Seizures are relatively common and may be partial (complex partial or simple partial) or grand mal in type. Chorea may occur and indeed may constitute the presentation of SLE. Focal deficits are common and may include hemiparesis, aphasia or hemianopia. Thrombotic thrombocytopenic purpura has been noted, but this is usually a terminal event.

In addition to cerebral involvement, the peripheral nervous system may also be involved, with either peripheral polyneuropathy or mononeuritis multiplex.

The anti-nuclear antibody (ANA) test is positive in approximately 95 per cent of patients, and the serum VDRL test may be falsely positive. As the ANA lacks specificity, however, a positive result here must be followed up by a more specific test, such as anti-native DNA (also known as anti-double-stranded DNA) or anti-Sm. During active disease, the ESR is often elevated and one or more complement levels (C3, C4, CH50) are generally decreased. Consideration may also be given to testing for the presence of serum anti-ribosomal P antibodies and for the anti-phospholipid syndrome, including lupus anticoagulant and anti-cardiolipin antibodies of both the IgG and immunoglobulin M (IgM) types. Anti-ribosomal P antibodies may be associated with the occurrence of psychosis, and anti-phospholipid antibodies may be associated with infarction.

MRI may be normal or may show evidence of infarction. When infarctions are present, they tend to occur in one of two patterns. Either there are multiple small infarcts in either the cerebral cortex or the subcortical white matter, or one finds relatively large territorial infarctions in the areas of distribution of large pial vessels.

The EEG may be normal or show slowing, which may be generalized or focal. In patients with seizures, interictal epileptiform discharges may or may not be present.

Course

Overall, the course is characterized by a gradual waxing and waning of symptoms; full remissions are unusual and generally not permanent. Although SLE is in general compatible with long-term survival, the appearance of cerebral or renal disease is an ominous sign.

Aetiology

Lupus is characterized by the presence of a large number of autoantibodies directed at various tissues in multiple organ systems. Although the cause is not known, it is strongly
suspected that the autoimmune response occurs secondary to some environmental trigger in genetically susceptible individuals.

Pathology of neuropsychiatric features
It appears that most cases of depression, mania, psychosis and delirium occur on the basis of cerebritis; however, these syndromes may also occur with appropriately placed infarctions (e.g. depression with frontal lobe; mania with frontal or temporal lobe, thalamus or caudate; psychosis with temporal lobe or thalamus; delirium with temporal lobe or thalamus). Dementia may occur on the basis of cerebritis but appears more commonly due to multiple infarctions. Seizures may likewise occur with cerebritis or with infarction.

Susac's syndrome
Susac's syndrome (retinocochleocerebral vasculopathy), first described by Susac in 1979, is a rare disorder, typically seen in young adult females.

Clinical features
Classically one sees the subacute onset of delirium, often accompanied by headache, in the setting of sensorineuronal hearing loss and visual disturbances.

MRI typically reveals multiple areas of increased signal intensity on FLAIR and T2-weighted images, scattered throughout the white and grey matter with a predilection for the corpus callosum. In some cases these lesions may demonstrate contrast enhancement.

Course
There is usually a more or less complete remission of symptoms after 2–4 years. Recurrences, although not common, may occur.

Pathology of neuropsychiatric features
In the setting of a widespread cerebral microangiopathy, there are multiple micro-infarcts affecting the white matter (especially the corpus callosum) and the grey matter. Retinal and cochlear infarctions also occur.

Although the aetiology of the angiopathy is not known, an autoimmune mechanism is suspected.

Limbic encephalitis
In the vast majority of cases, limbic encephalitis occurs on a paraneoplastic basis, most often in patients with small-cell lung cancer. It is rare, occurring in less than 0.1 per cent of all patients with cancer.

Clinical features
The onset of symptoms is typically subacute, spanning days or weeks. It is often the presenting symptom of cancer, and in some cases the tumour itself may remain undetected for years after the onset of the encephalitis.

The most common presentation is with delirium marked by prominent anterograde and retrograde amnesia, often accompanied by seizures and personality change or hallucinations. Other, less common presentations include depression, isolated amnesia, seizures, somnolence and catatonia (with ‘confusion, stereotypy, echolalia, stiffness, verbigeration, formal thought disorder, and negativism’). Rare symptoms include abnormal movements such as chorea, nicolectic attacks with cataplexy, rapid eye movement (REM) sleep behaviour disorder, and, especially in association with ovarian cancer, hyperventilation with respiratory failure.

In cases occurring on a paraneoplastic basis, one may also see other paraneoplastic syndromes, including cerebellar degeneration with ataxia; brainstem encephalitis with nystagmus, ataxia, oculomotor palsies and vertigo; opsoclonus-myoclonus; sensory neuropathy; Lambert–Eaton myasthenic syndrome; and the stiff-person syndrome.

Early in the course, MRI is often normal; over time, however, most cases will have increased signal intensity in the medial aspects of the temporal lobes on T2-weighted or FLAIR imaging; these abnormalities, although initially unilateral, typically become bilateral.

The EEG is abnormal in almost all cases and typically shows temporal slowing, which may initially be unilateral, only to become bilateral later.

The CSF may be normal or may display any one of a number of findings, including a mild lymphocytic pleocytosis, a mildly elevated total protein, or oligoclonal bands.

Although in the vast majority of cases of limbic encephalitis abnormalities will be found on MRI, EEG or CSF assay, exceptions do occur, especially early on. In cases in which the clinical findings are strongly suggestive of the diagnosis but these tests are negative, PET scanning should be considered; even in cases in which all other tests are negative, PET may reveal focal hypermetabolism in one or both temporal lobes.

A wide variety of anti-neuronal antibodies have been identified, including anti-Hu (or ANNA-1), anti-Ri (or ANNA-2), ANNA-3, anti-Ma1, anti-Ma2 (or anti-Ta), anti-amphiphysin, anti-CRMP-5 and anti-voltage-gated potassium channel (or anti-VGKC). In paraneoplastic cases, various tumours have been found, including cancer of the lung (most commonly of the small-cell type), breast, testicle, colon, pancreas, ovary, thymus, prostate and bladder; cases have also been associated with lymphoma.

Course
Although the overall course is one of progression, at times there may be plateaux; however, these almost always give way to further decline. True spontaneous remissions, although reported, are rare, and most patients die within months to a year or more, either of complications of the limbic encephalitis or from the underlying cancer.

Pathology and aetiology
There is a lymphocytic perivascular inflammation, with neuronal loss and gliosis within the limbic system, prima-
rily involving medial temporal structures. In the vast majority of cases, this inflammation occurs on a paraneoplastic basis, with antibodies raised against the cancer cross-reacting with normal neuronal tissue. However, there are cases of limbic encephalitis occurring in the context of anti-VGKC antibodies in which no cancer is found, and the mechanism underlying the genesis of this autoimmune response remains unknown.

Sarcoidosis

Sarcoidosis is somewhat more common in females than males. In the USA it is far more common in black people than white people, and in Europe people from northern countries are more commonly affected than people from southern countries.

Clinical features

Although onset in adolescence or the middle or later years may occur, most patients fall ill in their twenties or thirties. The onset is often gradual, and many cases are discovered serendipitously on chest radiography.

Sarcoidosis may be protean in its manifestations, but certain presentations deserve note. Perhaps 90 per cent of patients have pulmonary involvement, which may manifest with symptoms such as cough or dyspnoea or may be asymptomatic and discovered only incidentally by chest radiograph, which may reveal bilateral hilar lymphadenopathy or a diffuse reticulonodular appearance. Other symptoms include erythema nodosum, lupus pernio, lymphadenopathy, arthropathy and parotid gland enlargement. Hepatic involvement occurs in almost three-quarters of patients, although hepatic failure is rare. Hypercalcaemia occurs in a majority of patients, and some may develop nephrocalcinosis and eventual renal failure.

Involvement of the nervous system occurs in 5–25 per cent of patients, and in a very small minority of cases it may represent the only manifestation of sarcoidosis. With a basal meningitis, cranial neuropathies may occur; with obstruction of the outflow foramina of the fourth ventricle, hydrocephalus may occur; involvement of arteries may be followed by stroke. Cerebral involvement may be characterized by multiple granulomas or by relatively few large lesions, or even by a solitary lesion; in these cases there may be dementia, delirium, seizures or focal signs. Hypothalamic or pituitary granulomas may present with endocrinological syndromes. The cord may also be compressed and the peripheral nervous system is often involved.

Cranial neuropathies occur in approximately one-half of cases and, although various cranial nerves may be involved, one most commonly sees a peripheral facial palsy, which may be unilateral or bilateral. The eighth cranial nerve may also be involved, with deafness, as may the optic nerve or chiasm with blindness or hemianopia.

Hydrocephalus occurs in about 5 per cent of patients and may present with dementia and gait disturbance.

Stroke is rare and appears generally to present with a lacunar syndrome, reflecting granulomatous involvement of the penetrating arteries.

Dementia may occur and may be accompanied by a frontal lobe syndrome or by delusions and hallucinations. Cognitive deficits of variable degree may occur in close to 50 per cent of patients with neurosarcoidosis. Delirium has also been noted but appears to be rare.

Seizures occur in about 15 per cent of patients and may be grand mal or partial. Focal signs may occur and reflect the location of any cerebral granulomas.

Endocrinological changes have been noted in up to one-third of patients and may consist of diabetes insipidus, hyperprolactinaemia, hypothyroidism, hypogonadism and adrenocortical insufficiency. Hypothalamic involvement may also manifest with disturbances of appetite or with somnolence; rarely, symptomatic narcolepsy may occur.

MRI typically reveals any basal meningitis or macroscopic parenchymal granulomas.

The CSF is abnormal in only about 50 per cent of cases; abnormalities include a mild lymphocytic pleocytosis, a mildly elevated total protein and, in a minority of patients, oligoclonal bands or an elevated IgG index. In a very small minority of patients, the glucose level is mildly reduced. The level of CSF angiotensin-converting enzyme is elevated in a little over 50 per cent of patients. The serum angiotensin-converting enzyme level is likewise elevated in over 50 per cent of patients.

Definitive diagnosis requires biopsy evidence of typical sarcoid granulomas, and in most cases lung biopsy is performed.

Course

This is variable. Spontaneous remission of neurosarcoidosis occurs after many months in about one-half of cases, although relapses may occur; in the remaining cases the disease pursues a chronic, often fluctuating course.

Pathology

The cardinal lesion is a non-caseating granuloma. The pathology of neurosarcoidosis is described above.

Other disorders

Hashimoto’s encephalopathy

Although most patients with Hashimoto’s encephalopathy (steroid-responsive encephalopathy associated with autoimmune thyroiditis, SREAT) are in their forties, the age of onset varies widely, from childhood to the eighth decade. The onset is typically subacute, over days or perhaps weeks. The overwhelming majority of patients have delirium, which in most cases is accompanied by any or all of tremor, myoclonus, ataxia and seizures. Stroke-like episodes are common and are typically characterized by aphasia; hemiplegia or hemisensory loss may also occur. These stroke-like episodes are of brief duration, lasting in the order of hours
or a day or more, and typically undergo a full remission. Very rarely Hashimoto’s encephalopathy may present with psychosis\(^\text{287}\) or dementia.\(^\text{288}\)

**Sydenham’s chorea**

Sydenham’s chorea, also known as St Vitus’ dance, rheumatic chorea and chorea minor, is one of the major manifestations of rheumatic fever, occurring in about one-quarter of patients. Because of the widespread treatment of streptococcal pharyngitis with penicillin, Sydenham’s chorea is currently uncommon; it occurs more frequently in females than males, with a ratio of approximately 7:3.

Neuropsychiatric features are very common. Obsessions and compulsions occur most notably.\(^\text{289}\) one prospective study reported them in 70 per cent of patients,\(^\text{290}\) and another study in 82 per cent.\(^\text{291}\) The course of these obsessions and compulsions is of interest. Although they tend to peak in severity along with the worsening of the chorea and to remit before the chorea does, in fact they generally make their appearance before the chorea sets in.\(^\text{291}\) Importantly, it appears that in cases of rheumatic fever it is only those patients who develop Sydenham’s chorea who develop obsessions and compulsions; patients without chorea remain free of them.\(^\text{290}\)

Tics, similar to those seen in Tourette’s syndrome, may also occur during Sydenham’s chorea.\(^\text{292}\)

Delirium is seen in less than 10 per cent of patients,\(^\text{293}\) but it may be profound.\(^\text{294}\)

Mania is a rare manifestation\(^\text{295}\),\(^\text{296}\) and may present as either pure mania or mixed mania or, rarely, be coupled with a depression.\(^\text{295}\),\(^\text{297}\) Depression is even rarer than mania in Sydenham’s chorea.\(^\text{295}\)

Psychosis, with hallucinations and delusions, may occur in a small minority of patients\(^\text{298}\) and may symptomatically resemble the psychosis seen in schizophrenia.\(^\text{299}\),\(^\text{300}\)

**BRAIN TUMOURS AND HYDROCEPHALUS**

**Brain tumours**

**Clinical features**

Although brain tumours may occur at any age, most patients are middle-aged or older. The onset ranges from acute to insidious, depending in large part on the aggressiveness of the tumour involved. Certain gliomas, such as glioblastoma multiforme, may evolve rapidly over several weeks or months, whereas some meningiomas may attain a large size without ever causing symptoms and may indeed be found incidentally on imaging for other reasons or at autopsy. The overall symptomatology may be divided into the following domains: headache; non-focal symptoms; focal signs and specific syndromes, such as dementia or personality change; and seizures. In this chapter we consider primarily the neuropsychiatric manifestations.

Dementia is classically seen with tumours of the frontal lobe or corpus callosum, when it is often accompanied by apathy, dullness and somnolence, or by frontal lobe syndrome. Tumours of the thalamus and hypothalamus may also cause dementia, and with hypothalamic tumours one often sees additional symptoms such as hypopituitarism, weight gain or diabetes insipidus.

Personality change may be seen with tumours of the frontal lobe or temporal lobe and, rarely, with tumours of the thalamus or hypothalamus. Although this personality change may be non-specific, in cases of frontal lobe tumours one classically sees an accompanying frontal lobe syndrome.\(^\text{301}\)

Delirium may occur with tumours of the temporal lobe\(^\text{302}\) or the hypothalamus.\(^\text{303}\)

Amnesia, with isolated short-term memory loss, may be seen with tumours that impinge on any part of the circuit of Papez, for example the fornix (e.g. by a sub splenial tumour), the mamillary bodies (e.g. by a craniopharyngioma) and the thalamus.

Mania may uncommonly occur with tumours of the mesencephalon, hypothalamus, thalamus, cingulate gyrus or frontal lobe.

Depression may rarely constitute the presentation of a tumour, as has been noted with a tumour of the anterior portion of the corpus callosum.\(^\text{304}\)

Psychosis may occur with tumours, most commonly of the temporal lobe; other locations include the frontal lobe and the corpus callosum.

Tumours located in the hypothalamus may present with dementia, personality change, delirium, amnesia or mania. Other symptoms may also be seen, including diabetes insipidus, anorexia with profound weight loss, and hyperphagia with extreme weight gain, which may, in rare instances, be accompanied by episodic rage.\(^\text{305}\)

With growth of the tumour and enlargement of the area of peri-tumoural oedema, the clinical picture evolves, with worsening of initial symptoms and addition of new ones. In some cases, hydrocephalus may occur, with symptoms as discussed below. In other cases, there may be acute clinical exacerbations resulting from either intra-tumoural haemorrhage or infarction secondary to arterial compression.

MRI should be obtained in all cases, generally with gadolinium enhancement.

**Course**

The natural course varies widely, depending on the malignancy of the tumour itself, ranging from as little as months in the case of glioblastoma multiforme up to a decade or more with low-grade gliomas.

**Aetiology**

Brain tumours may be either primary to the CNS or, more commonly, metastatic.

Of the primary brain tumours, gliomas and meningiomas constitute the vast majority of cases. Primary CNS lym-
Adult hydrocephalus

Clinical features

Acute hydrocephalus is a form of non-communicating hydrocephalus in which there is a complete, or near-complete, obstruction of CSF flow. It is characterized clinically by a rapid onset of symptoms, over days, hours or even quicker. Patients present with headache, stupor and vomiting; without treatment, coma and death may ensue rapidly.

Chronic hydrocephalus may represent either a communicating or a non-communicating condition; when it occurs as a result of non-communicating hydrocephalus, one finds only a partial obstruction. Clinically, chronic hydrocephalus typically presents gradually, or even insidiously, and is characterized by dementia marked by forgetfulness, apathy and a generalized slowing of thought and behaviour; rarely, akinetic mutism may occur. Gait disturbance also occurs and may either precede or follow the onset of dementia. The gait may be shuffling, apractic or ‘magnetic’ in type. Urinary urgency, frequency or incontinence may also occur. There may be generalized hyperreflexia and bilaterally positive Babinski signs.

Although ventriculomegaly is evident on CT or MRI, MR scanning is preferred as it is more likely to reveal the underlying cause of any obstructive hydrocephalus. In addition, on T2-weighted or FLAIR images, one typically sees evidence of transependymal flow of CSF from the ventricles into the immediately subjacent white matter, producing a hazy rim of increased signal intensity in a periventricular distribution.

Lumbar puncture may or may not be necessary. In cases of non-communicating hydrocephalus, the opening pressure is normal; in cases of communicating hydrocephalus, except normal-pressure hydrocephalus (see below), it is generally increased.

Course

Acute hydrocephalus is a catastrophic event, with rapid evolution of symptoms. Chronic hydrocephalus, by contrast, is marked by a very slow progression of symptoms as CSF pressure very slowly increases. In most cases, however, a new ‘equilibrium’ is eventually reached between CSF production and outflow; in this situation, although the ventricles remain under increased pressure, they do not undergo any further expansion. When this development occurs, the previously ‘active’ hydrocephalus is said to have undergone ‘arrest’; such ‘arrested’ cases of hydrocephalus clinically manifest a plateau of symptoms, with a subsequently stable clinical course.

Aetiology

In non-communicating hydrocephalus the obstruction may occur at various sites and may be caused by various different lesions. Thus, the foramen of Monro may be obstructed by a tumour such as an astrocytoma, or by a colloid cyst of the third ventricle, and the third ventricle may be occluded by a tumour. The aqueduct of Sylvius may be stenotic or may suffer post-infectious scarring; it may also be compressed by adjacent tumours such as pineal tumours. The fourth ventricle may be compressed by cerebellar lesions such as tumours, haemorrhages or infarctions. The exit foramina of Magendie and Luschka may be occluded by scarring, as may occur after an episode of viral or bacterial meningitis, or in the course of an indolent basilar meningitis, as may be seen in meningovascular syphilis, tuberculosis and fungal infections; scarring and obstruction may also occur after a subarachnoid haemorrhage, either spontaneous or as may be seen with traumatic brain injury.

Communicating hydrocephalus is most commonly seen with obstruction of outflow at the arachnoid granulations. Although such obstruction most commonly occurs after subarachnoid haemorrhage, it may also occur in leptomeningeal carcinomatosis; rarely, egress of CSF through the arachnoid villi may be slowed in cases of extremely elevated total protein values, as in some cases of spinal tumour or polyneuropathy. Another rare mechanism underlying communicating hydrocephalus is CSF overproduction, as with papilloma of the choroid plexus. Normal-pressure hydrocephalus (see below) is an important cause of communicating hydrocephalus.
Normal-pressure hydrocephalus

Normal-pressure hydrocephalus is a form of chronic communicating hydrocephalus that occurs on an idiopathic basis.

Clinical features

Classically, the disorder presents with the triad of gait disturbance, dementia and urinary incontinence or urgency. The onset of symptoms is typically gradual and generally occurs in late middle age or later.

Of the classic triad of symptoms, gait disturbance typically constitutes the first evidence of this disorder. Patients may walk with short steps on a somewhat widened base, and sometimes there is a degree of shuffling, but the distinctive feature is a ‘magnetic’ gait; some may complain that it feels as if their feet are ‘glued to the floor’.

The dementia is characterized by forgetfulness, slowness of thought and action, apathy, and indifference. Rarely, the clinical picture may be dominated by personality change or depression; even more rarely, the picture is dominated by aggressiveness or mania.

Urinary incontinence may be only intermittent and patients may not complain of it. At times, rather than incontinence there may only be urinary urgency.

On examination, there may be generalized hyperreflexia, and the Babinski sign may be positive bilaterally; snout and grasp reflexes may also be present.

CT or MRI reveals lateral ventricular enlargement out of proportion to any sulcal enlargement that may be present. If lumbar puncture is performed, then the opening pressure is typically normal.

Course

In most cases there is a gradual progression of symptoms, and some patients may eventually develop akinetic mutism and an inability to stand. Often, however, the hydrocephalus may become arrested, and symptoms may ‘plateau out’.

Aetiology

Although the opening pressure on lumbar puncture is generally normal, it appears that in these patients there are indeed elevations in CSF pressure but that these elevations occur only intermittently, typically at night. In this condition, the hydrocephalus is of the communicating type and it appears that the intermittently increased pressure occurs secondary to an impaired outflow of CSF through the arachnoid villi. The mechanism underlying this impaired outflow, however, is not known.

The mechanism whereby symptoms appear probably relates to stretching of the long periventricular axonal fibres.

Organic disorders that may manifest neuropsychiatric symptomatology include the following:

- Neurodegenerative and movement disorders
- Levodopa or dopamine agonist medication used in the treatment of parkinsonism
- Vascular disorders
- Trauma
- Hypoxic disorders
- Nutritional, toxic and metabolic disorders
- Infectious and related disorders
- Prion diseases
- Endocrine disorders
- Immune-related disorders
- Brain tumours
- Hydrocephalus.

Part 4: Mental health problems and mental illness

INTRODUCTION

Schizophrenia is the most severe of all of the mental illness, although thankfully it is not as common as other conditions such as depression and anxiety disorders. Although schizophrenia clearly runs in families, the genetic basis for this condition is poorly understood. Many patients have no family history of psychosis. Other factors such as brain trauma and obstetric complications are also considered important. The prevailing view of schizophrenia is that this is a disorder (or perhaps even a collection of disorders of similar presentation) that has its origins in faulty brain development in utero. Treatment for schizophrenia needs to be comprehensive and sustained. Medications are the bedrock of treatment, but medications alone are not sufficient and patients need many supports towards their recovery. This chapter provides a current overview of our understanding of the aetiology, course and treatment of schizophrenia.

HISTORICAL AND CONCEPTUAL CONTEXT

Although it is clear that mental illness existed in ancient times, the first clinical characterization of schizophrenia is credited to the German psychiatrist Kraepelin (1855–1926). He differentiated ‘dementia praecox’ [the dementia of youth], which later evolved into the schizophrenia concept, from bipolar disorder or ‘manic depressive insanity’. Schizophrenia was characterized by Kraepelin as having a protracted, downward-spiralling clinical course. The prominence of psychotic symptoms (delusions and hallucinations) was also acknowledged. However, schizophrenia actually got its name from Eugen Bleuler (1857–1959). This Swiss psychiatrist coined the term ‘schizophrenia’ to describe the fragmentation of mental processes that occurs with the illness. The term has been misused widely, and ascribed to ideas of schizophrenia as a ‘split personality’ and a ‘Jekyll and Hyde’ person. Since the name is now stigmatizing and conjures such negative ideas, there have been attempts to rename the condition.

Bleuler was less focused on positive symptoms as the hallmark of schizophrenia. He considered other aspects of greater importance. His fundamental symptoms became known as the ‘four As’: ambivalence, loosening of associations, affective incongruity and blunting, and autism, by which he meant emotional withdrawal. Bleuler had meant to narrow the diagnostic criteria but, inadvertently, his ideas led to a nongenre, diffuse concept of schizophrenia. Another influential clinician turned philosopher, Karl Jaspers, took this notion to another extreme and proposed that schizophrenia was characterized and recognizable by the clinician’s inability to understand the patient’s world and mental processes – the so-called ‘Praxcoxe feeling’.

In contrast, Kurt Schneider took a much more strict phenomenological approach and determined that, in the absence of an organic cause, the presence of the following symptoms (so called ‘first-rank symptoms’) were diagnostic of schizophrenia. These first-rank symptoms were:

- hearing third-person voice hallucinations;
- hearing running-commentary hallucinations;
- hearing one’s own thoughts spoken aloud;
- feeling that one’s body is under the control or influence of somebody or something else;
- actions or feelings that are experienced or behaved as coming from the influence of somebody or something else;
- feeling that one’s thoughts are being broadcast to others (thought-broadcasting);
- feeling that one’s thoughts are being taken away or external thoughts are being put into one’s mind (thought withdrawal or insertion);
- delusional perception (the belief that something ‘ominous’ has changed but one cannot figure out what it is; this is the period of perplexity, just before the patient becomes frankly delusional).

These descriptions by Schneider have been highly influential, although on their own they are not really diagnostic
or pathognomonic of schizophrenia. Schneider was, in fact, quite humble about their significance, merely considering them to be particularly useful to the clinician making a judgment about the presence or absence of schizophrenia.

More recent contributions have focused on aetiology and potential types of schizophrenia. Timothy Crow, in England, ascribed aetiological relevance to the pattern of symptoms in schizophrenia, describing how positive symptoms were associated with more neurochemical changes while negative symptoms were evidence of structural brain changes. crow and his colleague Eve Johnstone were the first to show brain changes on the computed tomography (CT) scans of patients with schizophrenia, findings that they called the ‘dementia of dementia praecox’. Crow described a type 1/type II classification of schizophrenia:

- **Type I**: more florid presentation; more positive symptoms; probably due to dopamine dysregulation; shows a good response to antipsychotic therapy.
- **Type II**: more chronic; predominantly negative symptoms; associated with enlarged brain ventricles and cortical tissue loss; shows a poor response to antipsychotic therapy.

William Carpenter in the USA has asserted that people who have an illness with predominantly negative symptoms (the so-called ‘deficit syndrome’) have a distinct subtype of schizophrenia that differs on brain chemistry, structural brain changes, treatment responsiveness and course. Peter Liddle in England described three syndromes of schizophrenia: (i) a positive syndrome – ‘reality distortion’ characterized by delusions and hallucinations; (ii) a negative syndrome (broadly similar to the concept of deficit syndrome; see above); and (iii) a ‘disorganization’ syndrome characterized by positive formal thought disorder, inappropriate affect and poverty of speech content. Robin Murray in England and Daniel Weinberger in the USA have emphasized the notion that schizophrenia is a disorder of faulty brain development. Evidence from many studies over the past 30 years supports their neurodevelopmental hypothesis of schizophrenia. This evidence includes:

- postmortem brain changes of under- or maldeveloped cells and brain structures;
- brain imaging findings at the time of diagnosis;
- gene abnormalities, especially among those that code for brain development;
- obstetric complications;
- season of birth phenomenon – a curious, well-replicated, excess of births of people with schizophrenia in the first 3 months of the year;
- heightened associations of schizophrenia with prenatal (first trimester) infections, malnutrition and other prenatal insults;
- presence of minor physical anomalies that signify brain maldevelopment.

Today, this is the prevailing theory of schizophrenia, having been supported by direct evidence of abnormalities of motor and language milestones, cognition and social performance that occur in early childhood, antedating florid psychosis; it is the focus of much of the current research. Weinberger has even developed ‘prenatal-lesioned’ (rat) animal models of schizophrenia that simulate some of the neurochemical abnormalities in schizophrenia. Crow has also suggested that this faulty brain development is genetically based and that it is related to speech development and to sexual dimorphism. Nancy Andreasen in the USA has proposed that schizophrenia is a disorder of brain dysconnectivity. She has described a series of imaging studies of pattern of brain abnormalities that are associated with schizophrenia.

This brief historical overview provides a useful context for considering what we currently know about schizophrenia and how we treat the condition. The reader is also directed to several excellent reviews on schizophrenia and some authoritative books. Sadly, the reality is that schizophrenia remains an enigmatic condition. Because of this and because of its association (albeit overstated and misunderstood by the lay public) with violence, schizophrenia remains a highly stigmatizing condition. One study evaluated ‘potential discriminatory experiences’ among 732 people with schizophrenia in 27 countries: positive discrimination was rarely noted, and the majority of patients had experienced some form of negative discrimination. Over 70 per cent of patients did not wish to reveal their mental illness in public. Patients felt they were discriminated against in getting (29% of patients) and keeping (29%) a job, and most patients (64%) said they would decline to even apply for a job because of the certainty of discrimination. Stigma is a pervasive problem.

**DIAGNOSIS**

Schizophrenia is a complicated diagnosis. Current operational criteria for the disorder, such as those of the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) in the USA and the tenth revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10) in Europe emphasize a Schneiderian view of the condition being characterized by delusions (fixed, false beliefs), hallucinations (typically ‘hearing voices’ in the absence of any sensory input), disturbances of speech (illogically, non-linearity of thought and conversation), restricted affect and emotionality, and impairments of thinking (memory, attention, reasoning, awareness). It is important to distinguish this psychosis from other psychotic conditions, which it can resemble in presentation (Table 38.1). It is also important to note that many patients may not present with florid symptoms. Additionally, patients may present with depressive symptoms first as part of a prodromal state, and then there is the later emergence of delusions and hallucinations.
Given the impact of symptoms, the condition is typically associated with a decline in social or occupational performance. Indeed, this may be what parents, friends or colleagues notice first – a withdrawal, dropping out of college, or inability to cope with the stress of work. For many patients, the onset of such ‘disintegration’ is insidious. Other people experience a more florid presentation, manifest by prominent delusions, hallucinations and bizarre behaviours, leading to disruptive public behaviour and emergency contact with the police. There are also cognitive impairments (in executive functioning, attention, reasoning, comprehension, and both short- and long-term memory) that, although in many cases are more subtle and ‘overshadowed’ by the delusions and hallucinations, are still quite disabling aspects of the illness.

Patients can be ill for many months or even years before they come into treatment, and there is increasing evidence linking the duration of untreated psychosis (DUP) with poorer outcome,¹⁶ now confirmed in systematic reviews (Figure 38.1). There are a variety of reasons as to why this may be, including neurobiological concepts of kindling and the strengthening of neural circuits involved in psychopathology with time, psychological notions linking continued trauma from frightening psychotic experiencing leading to further morbidity, and social explanations of increasing loss of social capital (education, family ties, occupational and vocational opportunity) the longer a young adult remains ill. It is likely that each plays a part.

Figure 38.1 Summary correlations between duration of untreated psychosis (DUP) and outcomes by follow-up point in months. The size of the squares is roughly proportional to the amount of data available in the systematic review. Note the consistency of findings with longer DUP associated with poorer outcomes in a variety of domains.

Cl, confidence interval.

Reproduced with permission from ref. 16.
Thus, while there is a lack of strong evidence that reducing DUP will improve outcome (although evidence is accumulating, e.g. Power et al.\textsuperscript{17}), this notion of intervening early engenders great zeal and determination among many disciplines who find reasons to support it. This observation has led to considerable developments in service delivery. Early intervention services for young adults with a first episode of psychosis are now becoming common around the world. The interventions that these and other services should deliver are reviewed later in this chapter.

Taken to another stage, early intervention through an effort to identify people with prodromal symptoms (e.g. oddities of behaviour and speech, strange non-delusional ideas) or early fragments of the schizophrenia syndrome, so-called ‘at-risk mental states’ (ARMS), have begun. Some studies have suggested that giving antipsychotics (or perhaps even antidepressants, alone) to these patients might forestall a psychotic break. However, there are serious ethical considerations with this approach.\textsuperscript{18} The earlier the intervention is delivered, the lower the proportion of a group of people with ARMS will actually develop a psychotic syndrome; the positive predictive value for such a syndrome may be relatively low, although in a treatment-seeking group that, by definition, has disability of some sort, there are other morbidities that merit intervention. This complex context is compounded by costs to all those treated with antipsychotics in terms of side effects, which may be serious and even life-threatening; even follow-up and ‘watchful waiting’ may have down-sides in terms of anxiety and stigma.

Although a dramatic presentation may lead some to wonder ‘how hard can it be to diagnose this person as psychotic?’, the presentation could (and in fact is likely to) be complicated by abuse of drugs. This complicates things considerably. Also, as stated above, many people who develop schizophrenia become depressed as the illness evolves. It can be difficult to determine whether the person has major depression or is in the early stages of a psychotic illness. It is therefore best to wait to see how things play out definitively over months before making such a serious diagnosis as schizophrenia. Practically, the ICD mandates that clinicians consider this illness as ‘schizoaffective disorder’ if the duration is less than 6 months.\textsuperscript{19} This is because some patients may have only a single psychotic episode, which looks indistinguishable from schizophrenia, but they will regain normal functioning without any recurrence. Similarly, patients who abuse drugs such as cannabis can have a psychotic break that appears like schizophrenia, but they too may regain normal functioning without further episodes once they stop taking the drugs; this is known as ‘drug-induced psychosis’.\textsuperscript{6} Thus, these recent classifications build in to the diagnosis the notion of poor prognosis first emphasized by Kraepelin (who would have seen mainly people with poor prognosis in his asylum setting). This excludes schizophrenia syndromes that either are brief with a good prognosis or have a putative aetiological association with drugs. Others suggest that the schizophrenia syndrome should merely reflect the psychological phenomena rather than comment on cause or course.

Schizophrenia typically begins in adolescence or in early adulthood. This is one of the most robust findings about the disorder that shapes its huge personal and societal impact and probably betrays a great deal about its biology and the vulnerability of the postpubertal brain to generate the syndrome. This is an important developmental period involving the maturation of myelinated connections bringing cognitively important cortical areas such as the dorsolateral prefrontal cortex ‘online’, and the sculpturing of those connections at the ultra-structural, synaptic level.

Schizophrenia is often said to occur equally in men and women, although the more one defines the disorder to exclude affective disturbance, the more there is a preponderance of men. Most affected young men and women develop schizophrenia at a similar age in their later teens and twenties, but the risk period for women goes on for longer, such that their average age at onset is around 4 years later. In addition, the illness tends to be milder in women, with, on average, a better outcome. The reasons for these gender differences are not known. However, it has been suggested that overall the illness is milder in females and that this might be because of some moderating effect of sex hormones upon the dopamine system.

### Causes

Ultimately, we do not know what causes schizophrenia.\textsuperscript{6–10} However, we consider that schizophrenia runs in families and is associated with birth complications, head injury, epilepsy and drug abuse. Cannabis abuse raises one’s risk for schizophrenia by 2- to 4.5-fold. The initial evidence by Andreasson and colleagues in a longitudinal study of Swedish conscripts caused controversy, as it was one of the first pieces of evidence to support an environmental ‘cause’ of schizophrenia.\textsuperscript{20} The debate has continued with valuable findings from other cohort studies but remains controversial because of the difficulties in the distinction between the effects of acute intoxication, after which a psychotic syndrome may wear off, as in the drug-induced psychoses mentioned above, and the question as to whether cannabis use can precipitate an ongoing schizophrenia syndrome that persists even once cannabis is cleared from the body. Given that cannabis use is common in people with the disorder and that some people are reluctant to stop using cannabis, probably because of an underlying and unrecognized dependence syndrome, these two issues are difficult to tease apart. A meta-analysis of all relevant studies confirmed an association, although more modest than some authorities had been arguing (Figure 38.2).\textsuperscript{21} However, it is possible that, overall, average results such as these mask individuals at particularly strong risk who are mixed in with others at low or even no risk. Some studies suggest
that people who also have a genetic vulnerability are 16 times more likely to become psychotic when they abuse cannabis. The relationship of cannabis to the risk of schizophrenia has become an important research and even political issue for healthcare policy.

Schizophrenia is not due to a single cause. However, it is not known whether schizophrenia is a disease with many causes or whether schizophrenia is a collection of similar diseases, each with a different single (or simple) cause. An ongoing debate about the causes of schizophrenia is whether any particular event (e.g. genetic defects, birth complications) leads to this condition (like the model of multiple causes of epilepsy) or alternatively, whether each of these can cause a psychotic condition that has a different cause but is similar in presentation and fits under the general profile of schizophrenia (as in pneumonia, whether caused by a virus or by bacteria).

**Genetic component**

Whether schizophrenia is a single illness or multiple illnesses has not been teased out, but we do know that it has a strong genetic basis that puts relatives at risk.\(^{(22,23)}\) We know that the condition is overrepresented, in a complex manner, in families. Also, bipolar disorder appears to be overrepresented – albeit not to the same extent – in the families of people who have schizophrenia. In a study by Lichtenstein and colleagues, the heritability of schizophrenia and bipolar disorder was estimated at 64 per cent and 59 cent, respectively, and first-degree relatives of people with either condition had an increased risk for these disorders.\(^{(24)}\) Environmental influences were estimated at 4.5 per cent for schizophrenia and 3.4 per cent for bipolar disorder. There appears to be substantial overlap between these disorders, attributable to shared genetic effects rather than environmental influences. However, the genetics of schizophrenia are highly complex. Genetic studies have shown abnormalities on several chromosomes (e.g. chromosome 5, 8, 11, 13, 22).\(^{(24)}\) As with many aspects of schizophrenia, the findings are inconclusive and do not point to a precise gene involved. More recent genetic studies have focused on the search for abnormalities in genes or their related proteins that are involved in development (e.g. dysbindin, neuroregulin, synaptosome-associated protein of 25 000 Da (SNAP-25), brain-derived neurotrophic factor (BDNF)).\(^{(22)}\) These approaches seek candidate regions based upon prior studies and for known pathophysiological links, with many now focusing on gene regions that are involved in neurodevelopment. Additionally, new approaches also apply genome-wide single-nucleotide polymorphism arrays, exploring for rare copy number variants (CNVs). A study group found evidence for rare genetic variants in an extremely large patient sample (3391 patients with schizophrenia) compared with matched control subjects (n = 3181).\(^{(25)}\) In addition to the anticipated deletions in the region on chromosome 13 that have already been implicated in velocardiofacial syndrome (a genetic condition in which 30% of patients develop a psychosis that is indistinguishable from schizophrenia), the study found small deletions on chromosomes 1 and 15 that had not been reported previously. A separate consortium also found small deletions in the same areas on chromosome 15.\(^{(26)}\) Although these variants are rare and represent deletion of sections of DNA, they substantially increase the risk of schizophrenia. Nevertheless, they still account for only a small amount of the total number of cases of schizophrenia.

**Birth and other environmental factors**

One of the most reproducible findings in schizophrenia is that affected patients are far more likely to have been born in the first 3 months of the year – the so-called ‘season of birth effect’.\(^{(27)}\) This curious, yet robust, association points to birth or to the time in utero as relevant to the development of schizophrenia. It has been reliably estimated that about 20 per cent of people who develop schizophrenia have had some sort of birth complication. These include events such as prenatal exposure to influenza, haemolytic anaemia, severe malnutrition, pre-eclampsia, asphyxia or fetal distress. A study examined BDNF from umbilical cord and maternal blood samples collected in a large cohort of people who later developed schizophrenia. It was observed that BDNF was significantly reduced in those patients who experienced fetal hypoxia, further emphasizing the importance of obstetrical complications as an aetiological event in schizophrenia.\(^{(28)}\) The birth complication may occur because of some problem in pregnancy or labour or the fetus may be neurodevelopmentally challenged in some way. Brain development in utero might have gone wrong in some way due to genetic misprogramming or due to some external injury (e.g.
a mother with an infection during the critical first 3 months of pregnancy). Another study found that mothers who were exposed to the death of a relative during the first trimester of their pregnancy were 1.67 times more likely to have offspring who later developed schizophrenia or related psychoses. Interestingly, the study did not find any higher risk of schizophrenia if the death of the relative occurred in the 6 months before conception or even after the first trimester. There are several lines of evidence that point to the vulnerability of the fetal brain to the physiological impact of stress, especially the effects of glucocorticoids early in brain development. There is a confluence of evidence that these risk factors (in utero stress, infection, malnutrition, vitamin D) may play a role in the aetiology of schizophrenia.

People with schizophrenia frequently abuse alcohol or illicit drugs. This occurs throughout the illness. This relationship is also often seen at the time of the person’s first presentation of psychosis, raising the vexing ‘chicken and egg’ question. Indeed, it is a key question as to whether substance abuse can ‘cause’ schizophrenia, whether it is some epiphenomenon or the result of people self-medicating to cope with the symptoms of schizophrenia. The preponderance of evidence points to some likely causative role for some drugs, particularly cannabis; as argued above, part of this association may be explained by genotype–environment interaction.

Other aspects of the environment undoubtedly influence the genesis of schizophrenia. We have been through a period where received wisdom was that the incidence or first occurrence of schizophrenia was the same everywhere. The evidence for this notion came mainly from the highly influential study in ten countries by the World Health Organization that indicated similar incidence of the disorder in the different sites. However, the point of the study was, in fact, to indicate that the disorder occurred at all in different settings and cultures, not that the incidence was the same. When the syndrome was defined fairly broadly (so numbers of cases and statistical power were higher), there were significant differences, also hinted at with more narrow definitions but with far lower precision or ability to differentiate. This should have come as no surprise given that Farris and Dunham, two Chicago social scientists, had identified in the 1920s marked gradients in the first occurrence of paranoid schizophrenia, but not bipolar disorder, according to the socioeconomic characteristics of small areas of that city. The incidence over 10 years was obviously higher in the central, poorer districts than in the more affluent, peripheral districts. Although it is accepted that people with chronic illness tend to drift into less affluent areas (so-called ‘social drift’), the contribution of the social environment to the first occurrence of the illness is more challenging.

A series of studies from the UK have reinvigorated interest in the influence of the social environment, building on the evidence of the associations that Faris and Dunham identified, including their apparent distinction between non-affective psychosis (schizophrenia) and affective illness. There is considerable evidence linking social adversity at the neighbourhood level and evidence linking lower social bonds (social cohesion) in communities with an increased risk of first-episode schizophrenia. It is the areas in which people live and interact with others that are important, rather than the country level.

Another dimension of the environmental aspect of risk comes from studies of migrant populations, a paradigm combining aspects of person and place. Just like the link with cannabis, the finding that migrant groups are at increased risk has been contentious, particularly because, in the UK and in the rest of Europe, the phenomenon linked perhaps the most stigmatizing disorder, schizophrenia, with one of the most socially disadvantaged groups, the black Caribbean migrant community. Several decades of research have been necessary to ensure that the association is not due to diagnostic bias, under-enumeration of the migrant population and other biases, but it is now clear that the link does exist and that it survives adjustment for obvious alternative explanations such as poverty and cannot be explained by reasons such as different patterns of drug use in these groups. Not only has a systematic review shown uncanny consistency in the findings of studies throughout the world and including many migrant groups in many countries, but also studies in the UK now demonstrate that this is not a phenomenon confined to Afro-Caribbean people. Rather, it seems as if being a migrant, and perhaps particularly a ‘visible’ minority in a host community, leads to an increased risk of schizophrenia and other psychotic disorders; the effects are huge, with relative risks of five-fold or so. The fact that the incidence of schizophrenia appears unremarkable in the country of origin, the lack of obvious familiality or selective migration to suggest purely genetic explanations, and the apparent normal development of children from migrant groups destined to develop schizophrenia all point towards the explanation of this phenomenon being in the realm of a psychosocial trigger related to the experience of being a minority in a host community.

Thus, studies of the social environment not only show large effects but also offer insights into new mechanisms, such as ‘social defeat’, in which psychological experience can itself become toxic, particularly perhaps in an individual (brain) that is vulnerable for other reasons, whether genetic or related to the very early environment. One can see the necessity to develop realistically complex models that are not confined to either genetic or environmental models.
BRAIN ABNORMALITIES AND THE NEURODEVELOPMENTAL HYPOTHESIS

There is evidence that brain development is disturbed in schizophrenia. The evidence comes from postmortem brain studies of people with schizophrenia who died from natural causes (e.g. heart attack, although this could also influence or bias postmortem brain findings) or from suicide (which could also affect the brain). Although this type of research has its own methodological problems, these studies have shown convincing evidence of abnormal (underdeveloped) cells and of cells that are misplaced or misaligned in the brains of people with schizophrenia. More recent studies have shown deficits in the expression of neurodevelopmental genes and BDNF in several postmortem brain collections.

Imaging studies of patients show a range of brain abnormalities: smaller cortex overall, preferentially less grey matter than white matter, enlarged ventricles (especially the lateral ventricles), enlarged caudate nucleus and putamen (these latter findings are likely due to the effect of antipsychotic medications), smaller thalamus and reduced temporal lobes (especially reductions in the hippocampal regions). These subtle findings occur more often in the temporal lobes than in any other brain regions, with perhaps more left hemisphere involvement. Magnetic resonance imaging (MRI) studies have also included relatives of patients with schizophrenia as a comparison group. These reveal much milder, but similar, findings in healthy relatives (who do not have the illness but may have genes susceptible to schizophrenia). This raises the question of whether such brain abnormalities are present from birth or even before the onset of schizophrenia. Studies of patients in their first episode of psychosis show the same patterns of abnormalities on brain imaging, but in a more attenuated form. Studies of prodromal populations show even milder, barely detectable brain abnormalities. In one such study, the prodromal patients who went on to have a psychotic break had more temporal lobe abnormalities on MRI than patients who did not progress to psychosis. There are also many functional imaging studies that include the use of positron-emission tomography (PET), single-photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI) and magnetic resonance spectroscopy (MRS). These confirm a pattern of underactivity of the frontal lobes. Studies have also shown that hearing voices is associated with overactivity in the (left) temporal lobe regions. Also, both MRS studies of first-episode patients and longitudinal MRS studies reveal a decrement in N-acetyl-aspartate (NAA), a putative marker of neuronal integrity.

Collectively, these findings have led many people to consider schizophrenia as a neurodevelopmental disorder. Cortical vulnerabilities may become exposed at adolescence when the brain shows heightened plasticity. Drugs or stress during adolescence may be other critical events.

Seemingly in direct opposition to the brain-imaging evidence that supports the neurodevelopmental hypothesis in schizophrenia, other, long-term imaging studies report a progressive loss of brain tissue. For example, MRI studies in patients with first-episode schizophrenia who are then rescanned years later demonstrated that progressive brain changes occur in patients who relapse and are more symptomatic. A more recent study tested the relationship between vulnerability in the expression of BDNF polymorphism and progressive brain tissue loss on MRI. Their results showed that patients who possess the met-met allele had the most reduction in frontal lobe tissue. Interestingly, patients who received most medications had the most frontal tissue loss, an effect that proved independent of BDNF polymorphism status.

OTHER THEORIES ABOUT THE CAUSES OF SCHIZOPHRENIA

Oxidative stress has been proposed as another mechanism to understand how schizophrenia occurs and how the disease has such a broad constellation of effects. It is proposed that, through vulnerability to oxidative damage, there are free radical effects that impact on cellular processes, especially mitochondrial, prostaglandin and cell membrane functioning. This hypothesis has been studied in a variety of ways, including plasma and cerebrospinal fluid assays for breakdown products of oxidative stress, brain imaging of neurochemistry using MRS, and treatment studies using vitamin E or fish-oil products. There continue to be other, more speculative ideas about schizophrenia. Some authors have suggested that infections might cause schizophrenia, either through prenatal efforts (see earlier) or through retroviral or genetic encoding effects. Toxoplasma gondii has been studied as an example. It is also suggested that urban factors might be causative for schizophrenia, exactly what these factors are is unclear at present. One study suggested that schizophrenia might be caused by irritation of the brain that could occur from middle-ear disease. The study determined that people who had middle-ear disease were over 3.6 times more likely to have a later diagnosis of schizophrenia (or over 4 times more likely if the middle-ear disease was on the left side). It is no longer believed that parents can cause schizophrenia through their communication styles; these old hypotheses (the ‘double-blind’ hypothesis, the ‘schizophrenogenic matter’ hypothesis) were highly damaging.

BRAIN CHEMISTRY AND SCHIZOPHRENIA

Overactivity of the dopamine neurotransmitter system is the most compelling neurochemical abnormality in schizophrenia. This is also the most easily explained theory:
people become psychotic because their dopamine is overactive. There is certainly evidence for this, including functional brain-imaging studies that show excess of dopamine in the brain of patients when they are acutely psychotic. But, like all the other explanations of schizophrenia, it is not quite as simple as ‘too much dopamine’. Some researchers have suggested that there is overactivity of dopamine in one brain region (e.g. temporal lobes), concomitant with underactivity in another area (e.g. frontal lobes). Also, the fault may not be across all dopamine receptors but perhaps may be selective in some of the subclasses of dopamine receptors or even beyond the actual receptors, as a downstream deficit in cell signalling. It is clear that other neurotransmitter systems are affected in schizophrenia; the neurotransmitter systems implicated in this disease include cholinergic, glutamatergic, noradrenergic and serotonin. Deficits in these other neurotransmitter systems (e.g. glutamate receptors) may be primary or may underlie schizophrenia directly or indirectly through their interrelated effects on the dopamine system. Thus far, the dopamine system has been the most pronounced neurochemical abnormality. Additionally, dopamine dysregulation plays a role in how antipsychotic drugs work. The neuropharmacology of antipsychotics is described later.

TREATMENT: GENERAL CONSIDERATIONS

Schizophrenia is a difficult illness to treat. Antipsychotic drugs work best on positive symptoms but have generally limited impact on negative or cognitive symptoms. This is a real drawback since, in the long run, negative and cognitive symptoms tend to be more disabling. These are the features that most limit functional outcome and the patient’s capacity to work. Additionally, antipsychotic medications have a substantial side-effect burden. This includes both distressing side effects (e.g. sedation, restlessness) and life-shortening effects (e.g. myocarditis, pulmonary embolism, obesity, metabolic syndrome). It is perhaps not surprising, given the inadequate efficacy combined with adverse effects of these medications, and the inherent impairment of insight among patients, that many patients become non-adherent with their treatment. This adds further complexity to the care of people with schizophrenia. It is also important to appreciate that the medications alone are ineffective and that patients need counselling, support, family involvement, care advice and job skills training. Most services struggle to provide the breadth of personnel, skills and resources that are needed for comprehensive care. Additionally, there is considerable variability in the access to care and in the medication practices (e.g. variability between practitioners with underdosing of medications, patients staying too long on a medication, with patients receiving two or more antipsychotics simultaneously). A well-constructed comprehensive plan, delivered over time in a consistent and collaborative manner, compiled with the support of family members and a strong sense of hope and personal resilience, collectively offers the best chance for a successful long-term outcome for patients with this chronic, relapsing condition.

Treatment expectations: from relapse to recovery

Although many patients will relapse over time, especially if they stop their medication (there is a one in five risk of relapse over 1 year when patients stop their medications), it is nevertheless equally important to emphasize that patients can recover and lead a satisfying life, albeit often with diminished lifetime goals. A clinical US study by Harding and colleagues found that 68 per cent of patients met defined recovery criteria when they were contacted again some 32 years after their (lengthy) hospitalization. More recently, Harrow and colleagues, in an ongoing Chicago study, found that 41 per cent of patients had recovered when contacted after 15 years. In an effort to raise the bar in treatment in order to enhance remission and recovery, Andreasen and colleagues proposed criteria for remission. There are also operational criteria for recovery. There is also a growing consumer perspective that views ‘recovery’ less as an outcome and more as a recovery process. In this recovery model, patients are less focused on the symptoms and disability of schizophrenia and instead are focused on living a meaningful life in the community. This is a more personal and optimistic model that places greater emphasis on individual choice and collaboration in treatment, on personal resilience and self-determination, on hope and on spirituality. It is akin to how somebody copes with having multiple sclerosis, diabetes mellitus or coronary artery disease: the medicines are key, but what really matters is the patient’s own resilience, hope and personal outlook. We have a poor understanding of how all of these potentially powerful individual strengths and effects ultimately impact the course of schizophrenia. Much of our focus is on the prevailing medical model, whereby we seek to diligently quantify and compare the effects of medicines.

Treatment settings

Most people with schizophrenia receive their care as outpatients in community facilities or programmes that they attend regularly, sometimes daily or weekly. Many patients live at home and their care is in effect overseen by their families, a visiting nurse or a multidisciplinary (assertive community treatment, ACT) team. Many patients live in supported housing, group homes or personal care homes overseen by counsellors or care managers. Patients do best when they have regular contact with their treatment team, especially when they can also access their treatment team in times of stress or relapse.
Unfortunately, many people with schizophrenia need to be hospitalized when they get sick. This is best achieved on a voluntary basis. Hospital stays are generally short (on average, a week or less), and the patients are then returned to their community setting with a (revised) treatment plan and the support to avert another hospitalization. The construction and range of community services are covered in chapter 73. Hospital admission is indicated when the patient poses a risk to him- or herself or to others. Patients who have bizarre and highly disturbing behaviour often need to be hospitalized. Patients may also have to be hospitalized for worsening of their illness due to side effects of medications or due to medical co-morbidities. For some patients, simply staying out of the hospital is a laudable outcome; these patients require the most intensive community support. For a minority of patients, long-term hospital care is a sad and hard-to-come-by necessity.

When a patient refuses to come into the hospital and they truly pose a risk to self or others, then the clinician may commit the patient involuntarily to in-patient care. The circumstances and procedures for involuntary commitment are covered in chapter 79.

**Treatment team and resources**

‘It takes a village!’ Although the patient and psychiatrist might together decide on medications and other aspects of treatment, successful care requires much more than that. It requires a team of mental health professionals working collaboratively with the patient and their family. Increasingly, patients also help themselves by organizing into self-help groups (e.g. Schizophrenia Anonymous, analogous to Alcoholics Anonymous) or by helping each other as trained peer counsellors (peer-support specialists). Patients also turn to the Internet for education, support and resources. A European study showed how patients could use a Web-based self-monitoring system to detect when they were relapsing and to communicate this more effectively to their psychiatrists.

**MEDICATION CHOICES**

Antipsychotic medications, in spite of their limitations, are truly the bedrock of treatment. Unfortunately, clinicians and patients struggle greatly together to find the best fit among the choices of available medications. Medication choice remains highly variable and individualized. It is not driven by neurobiological considerations. Indeed, medication choice remains a trial-and-error process, with the patient’s risk for particular side effects associated with any given medication generally being taken into consideration. We know generally what dose of medication to prescribe, but we have little scientific understanding to guide actual dosing decisions for a particular patient. By perhaps too simply an analogy, it is important to learn in general how to drive a car, but it is crucial to know how best to drive your own car. This wide variability in medication choices and treatment decisions, underlying an inability to predict response or tolerability for the particular patient, is a major obstacle in treating schizophrenia. There is some hope that pharmacogenetics will offer greater predictability of treatment response and side-effect liability. Initial pharmacogenetic studies of clozapine have shown the promise of this strategy.

**Mechanism of action of antipsychotics**

Exactly how antipsychotics work remains a mystery. Most evidence points to effects on blocking dopamine receptors in the mesolimbic system. For first-generation antipsychotics (FGAs; see below), it has been proposed from neuroimaging (PET, SPECT) studies that the drugs need to achieve at least a 60 per cent occupancy rate of dopamine receptors in order to be clinically effective. The dilemma is that at 70 per cent occupancy rate of dopamine receptors, these drugs cause muscle side effects. Some drugs, such as haloperidol, are more potent in their binding and can saturate the dopamine receptors at relatively low doses. Other antipsychotics are low-potency agents and are generally given at higher doses. Among second-generation antipsychotics (SGAs; see below), the situation is even more complex. These drugs are highly variable in the extent and manner that they bind to dopamine receptors. Risperidone, olanzapine and ziprasidone bind to dopamine (D2) receptors at proportionately lower rates than FGAs and at relatively lower rates compared with each other (risperidone is the most potent in D2 binding among these three drugs). Clozapine generally reaches only a 40–50 per cent D2 occupancy rate, and giving more medication will not exceed this rate (‘glass-ceiling effect’). Quetiapine has an even lower rate (28% average) of D2 binding, although Kapur and colleagues have proposed the elegant ‘kiss-and-run’ theory to explain that quetiapine appears to saturate D2 receptors. In contrast, aripiprazole virtually saturates D2 receptors with a 90–95 per cent D2 occupancy rate, even at low doses, this agent, however, has a partial agonist effect – that is, it functions more as a dopamine agonist when the synapse has insufficient dopamine, and it becomes more of a dopamine antagonist when there is an excess of dopamine. The dopamine hypothesis of antipsychotic action is complicated further by the existence of multiple subtypes of dopamine receptors, and these medications have variable affinities for these receptors. Efforts to design highly selective dopamine antagonists with sensitivity to a particular subtype alone have not produced clinically robust antipsychotic agents.

Kapur has also emphasized that dopamine antagonism alone is ‘necessary but not sufficient’ for antipsychotic effects. In truth, these drugs have wide-ranging effects on other neurotransmitter systems – cholinergic, noradrenergic, serotonergic and histaminergic. This may explain some
variability in their effects on symptoms, although it is generally considered that these binding profiles are more discriminatory of the side-effect burden of each drug. More recently, research efforts have focused selectively on these neurotransmitters as a target to add specific drugs to treat specific symptoms. As an example, anticholinesterase agents have been tried as augmenting agents alongside antipsychotic medications in an effort to enhance cognition.68 An exciting new development is the advent of a completely new class of antipsychotic drugs,69 acting via glutamate and related receptors, which have shown promising results in early (phase II) clinical trials. Not only is their action through a non-dopaminergic (in the first instance) mechanism, suggesting new understanding of the disease and also freedom from the side-effect profiles of current drugs, but also they may have efficacy against the particularly disabling cognitive deficits that define poor outcome for many people. Further evidence is eagerly awaited.

Nevertheless, all of the currently available antipsychotics bind to D2 receptors at least to some extent, providing at least some unifying hypothesis as to their mechanism of action. On the other hand, clozapine, the most effective antipsychotic, binds the least of all antipsychotics to D2 receptors. Clozapine has a highly complex binding profile to multiple neurotransmitters. Meltzer has suggested that its relative antagonism at dopamine and serotonin receptors is key to clozapine’s mode of action. To that end, risperidone, ziprasidone and sertindole were developed with a predominance of dopamine-serotonin antagonism. Conversely, olanzapine most closely resembles clozapine in its complex pharmacology at multiple receptors. There is intense interest in new drugs that are in development.67 There are several selective antagonists that act at glutamate receptors, and one has already shown a favourable clinical profile.69 The neuropharmacology of many FGAs and SGAs is summarized in Table 38.1.

First- and second-generation antipsychotics

The classification of antipsychotics is awkward and confusing. Older (‘typical’, ‘conventional’) antipsychotics are now being increasingly referred to as ‘FGAs’. Clozapine and the newer drugs (‘atypicals’) that have come after it are referred to as ‘SGAs’. This classification suggests a class effect, although none really exists. It is now generally appreciated that, leaving aside clozapine, which usually is considered unique, there is no major difference in efficacy between FGAs and SGAs. Moreover, there is no overwhelming evidence of superiority of one drug over another within either the earlier FGA class of drugs or the current SGAs. These points are hotly debated. An appraisal of the current literature is helpful here. Geddes and colleagues in Oxford conducted a highly influential meta-analysis of studies comparing FGAs and SGAs.70 They suggested that the clinical benefits of SGAs were ‘overemphasized’ and that too high doses of FGAs were used in these studies, thereby ‘stacking the deck’ in favour of SGAs. Conversely, Davies and colleagues reported similarity between FGAs and SGAs in another meta-analysis.71 Leucht and colleagues examined 1-year relapse rates in studies comparing FGAs and SGAs.72 In their meta-analysis, SGAs were superior to FGAs. More recently, Leucht and colleagues reported another meta-analysis, showing no difference between antipsychotics.72 Another study suggested that source of funding was the major determinant of whether one drug fared better than another in comparative clinical trials among SGAs.73 Several large, often independently funded studies have produced comparative data to inform this key consideration of relative merits among available antipsychotics. In the USA, Lieberman and colleagues reported the results of the 1457-patient pragmatic study Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE).74 Although open to multiple interpretations, the 18-month study found that on the primary study measure (‘all cause discontinuation’), the SGAs (risperidone, quetiapine, ziprasidone) were similar to perphenazine. In contrast, olanzapine proved to be the most robust and yet also the least well-tolerated antipsychotic. In England, Jones and colleagues reported the results of the 314-patient pragmatic study Cost Utility of the Latest Antipsychotic drugs in Schizophrenia Study 1 (CUtLASS 1). This group hypothesized that randomization to prescription of an SGA compared with an FGA would result in a benefit in terms of quality of life (and a variety of secondary outcomes) at 1 year. Such a benefit was definitely excluded (Figure 38.3), leading to a clear cost-effectiveness for the FGA and possibly at least clinical equipoise between the two groups; patients showed no preference for SGA drugs.75

In a parallel study of treatment-resistant schizophrenia (CUtLASS 2), clozapine stood out as the most effective drug.76 Phase II of the CATIE study also reported clozapine’s superiority.77 The Treatment of Early Onset Schizophrenia Study (TEOSS) provides comparative data on FGAs versus SGAs for the treatment of schizophrenia.78 In this study of childhood schizophrenia, 116 children and adolescents aged 8–19 years were randomized to 8 weeks of treatment with olanzapine, risperidone or melperone. Efficacy was generally similar across all three groups, with response
rates of 50 per cent, 46 per cent and 34 per cent for patients receiving molindone, risperidone and olanzapine, respectively. Olanzapine was associated with most weight gain and risperidone with some gain; molindone, chosen originally because of historical information suggesting that it had a low liability for weight gain, was not associated with weight gain in the study. Another European study, the European First Episode Schizophrenia Trial (EUFEST), showed some advantage in 1-year efficacy for SGAs over the FGA haloperidol. Another US study showed equal efficacy between quetiapine and risperidone and olanzapine in patients with first-episode schizophrenia.

It should be appreciated that inadequate understanding of the optimum and individualized dosing for all of these drugs greatly hampers both their utility and comparisons between the agents. It is also plausible, although not supported by any research data, that these drugs perform differently in different groups of patients, despite appearing broadly similar in overall outcomes. Getting the 'right fit' of drug, and its best dose, for any patient still remains more art than science. It is also important to appreciate that very often patients do not take their medication, and this is a major barrier in the treatment of schizophrenia.

### Clozapine

Clozapine is indicated for patients who are treatment-refractory – that is, they have not responded well enough to prior medications. It is also indicated for patients with schizophrenia who are suicidal. Psychiatrists vary widely in which medicines they choose, in what doses they use them and in how long they treat the patient with any given drug; hence, there is uncertainty as to when it is time to use clozapine. Many experts feel that clozapine is underutilized. These variable medication practices, real concern about the adverse-effect profile of clozapine, and the cumbersome procedures for administering and monitoring of clozapine therapy collectively contribute to this powerful drug being either unused or relegated to the treatment of last resort. This contrasts with the evidence for clozapine's efficacy, first confirmed in the seminal clozapine/chlorpromazine study and now well replicated.

### Antipsychotic formulations

Many of the FGAs and SGAs are available in formulations other than tablets. Liquid and dissolvable-wafer formulations are useful in acutely psychotic patients who (often as in-patients) refuse to take their medicines. Likewise, acute intramuscular preparations can be given to patients who are agitated and dangerous when they are refusing to take any medications orally. These options are typically short-term, with the intent of transition to oral tablet formulations as the situation stabilizes.

Some antipsychotics are available in long-acting injectable formulations. These are typically given every 2 weeks or once a month. They offer the patient and clinician the assurance that the medication is 'on board', although if the patient does not turn up for their regular injection, then non-compliance is declared. Studies generally suggest lower relapse rates with long-acting injectable antipsychotics, especially if patients are followed for beyond 1 year. However, some patients dislike injections and find this approach stigmatizing, coercive and potentially painful. Other research confirms high tolerability and satisfaction among those patients who commit to this treatment approach. It is likely that other formulations and delivery systems (intranasal, transdermal, surgical) will be developed in the future. Because medication non-adherence is such an obstacle to effective treatment, further breakthroughs in formulations as well as newer drugs that are more efficacious or better tolerated are sorely needed.

### Combining medications

It is common for psychiatrists to give patients two antipsychotic medications simultaneously. The rationale for this is invariably either to boost the effectiveness of the first antipsychotic or to reduce its side-effect burden by adding a different drug and thus lowering the required dose of the first drug. Many clinicians like this approach. Many patients also prefer this approach and achieve clinical stability with this trial-and-error cocktail. However, scientific evidence to support the validity of this approach is remarkably lacking.

Another commonly used strategy is to combine some other psychotropic drug with the antipsychotic. This is done to augment or boost the antipsychotic effect. Augmenting agents include antidepressant medications, anticonvulsants, lithium and benzodiazepines. Antidepressants are given to augment the antipsychotic effect, but they are most commonly prescribed for co-morbid depression or anxiety. Benzodiazepines are typically used for co-morbid anxiety. Although these approaches appear reasonable and are commonplace in practice, the scientific evidence to support any of these augmentation strategies is, at best, inconclusive. Cholinergic agents and glutamatergic agents are being studied as adjunctive treatments to target cognitive features. Several large-scale studies of these agents are in progress. Most recently, the approach of giving N-acetyl-cysteine in a precursor of glutathione (a key element in the phospholipid pathway) showed some benefit in a 24-week placebo-controlled, double-blinded study in patients with schizophrenia.

### Switching medications

It is generally considered that 4–6 weeks of treatment with an antipsychotic given at adequate dose is required before determining that the drug is ineffective and moving on to another choice. The drug to choose next is a matter of considerable debate, in the relative absence of guidance from available research. It is recommended that patients are switched gradually, ideally over weeks, from one drug to
another, in some form of cross-tapering strategy. Abrupt changes in medication risk withdrawal effects combined with acute tolerance effects of the new drug. Also, if the transition is unsuccessful, the patient can relapse. Drug-free holidays and intermittent antipsychotic therapy are not recommended because of the acknowledged heightened risk of relapse with these strategies.91

**Managing medication side effects**

Patients are highly variable in their tolerance and propensity to experience the wide range of side effects with antipsychotic medications. In general, side effects are often dose-related, and so judicious prescribing is warranted to minimize exposure to these side effects. On the other hand, some side effects (e.g., agranulocytosis with clozapine therapy) are not related to dose and appear to be largely idiosyncratic in occurrence.

A point of distinction between FGAs and SGAs is the higher rate of muscular side effects observed during treatment with FGAs. Acute effects such as dystonia and akathisia are highly distressing for patients and greatly increase the risk that the patient will stop taking that medication. In long-term care, tardive dyskinesia (TD) is a major worry and was seen at an incident rate of 5 per cent per year during the first 5 years of treatment with a FGA. TD is disfiguring, is often distressing to patients and has been associated with a shortened lifespan. TD can still occur during treatment with an SGA, although available evidence suggests that the risk of TD is ten times lower with SGAs than with FGAs.92

On the other hand, SGAs are generally much worse than FGAs in causing obesity and a host of metabolic disturbances. These are now major considerations in the treatment of schizophrenia.93,94 Clozapine is the worst drug for these side effects,95 olanzapine appears to be second. The more recent drugs (ziprasidone, aripiprazole) may be less likely to induce obesity or metabolic disturbances; however, patients are certainly not immune to these effects on either drug. The occurrence of obesity and metabolic disturbances (elevated glucose, insulin intolerance, diabetes mellitus, hyperlipidaemia, hypercholesterolaemia) has greatly complicated the management of schizophrenia.96 Choice of medications is also influenced powerfully by these considerations. Patients may be switched from one drug to another in order to reduce weight gained or to reduce metabolic disturbances that have emerged in therapy.97 These individual decisions seem clinically intuitive; however, scientific evidence has not caught up with clinical practice around these matters. Similarly, patients are increasingly being prescribed statins along with their antipsychotic medications. This approach has yet to be validated scientifically.98 There are also non-pharmacological approaches to reduce the burden of these side effects;99 these approaches appear to be beneficial. However, implementing lifestyle changes is difficult.

**PSYCHOLOGICAL TREATMENTS**

Patients require tremendous support to cope with this disabling condition. Family members also require education about the illness and support.

**Individual therapies**

Patients benefit from supportive counselling and practical psychotherapy. A focus on coping strategies, education about schizophrenia, and developing awareness of risk factors and the patient’s individual pattern of relapse are helpful aspects of therapy. Cognitive-behavioural therapy (CBT) has been modified with some success in treating patients with schizophrenia.100 A large multicentre British study found only a minimal impact of CBT in maintenance treatment.101 A variant of CBT, compliance therapy (CT), has also been studied. Kemp and colleagues found a 20 per cent reduction in relapse compared with non-specific supportive therapy in an 18-month clinical trial.102 The results of subsequent studies have been less conclusive. The impact of peer support has not been scientifically validated. Psychoeducation remains a major therapy.103

**Group therapies**

Psychoanalytically oriented group therapy or individual psychoanalysis is not an appropriate approach for patients with schizophrenia. Group therapy aimed at socialization, illness psychoeducation, and developing support is appropriate and helpful. Social skills training is also effective in boosting the patient’s community engagement, developing social skills and reducing relapse.104

**Family therapies**

There is ample and compelling evidence that giving support, psychoeducation and specific instructions to family members can reduce relapse in the patient. This is one of the most evidence-based interventions in schizophrenia. A Cochrane systematic review synthesized data from randomized controlled trials involving 4124 people with schizophrenia and their families.105 They found evidence for benefit such that about eight families had to be involved in the intervention in order to prevent one relapse (number needed to treat (NNT) 8; 95% confidence interval (CI) 6 to 11), with a similar effect for reduction in hospital admission, possibly through, in part, increased adherence to medication. Family members also benefit from, and do good work in, advocacy and self-help organizations.106

**Cognitive remediation**

Initially based upon the literature on cognitive retraining for patients who have suffered head trauma, there is now a growing literature on the impact of cognitive remediation...
in healing patients with schizophrenia. The results of several studies are generally positive and hold out the promise that cognition can be enhanced through computerized training modules. However, a recurrent problem seen in these studies is that learning does not appear to sustain and generalize from the computer to everyday life.\(^{107}\)

**VOCATIONAL AND SUPPORT SERVICES**

Although most patients with schizophrenia are not in active employment, there is evidence from several health services research studies and demonstration projects that patients can work if supported adequately. Even patients who are hallucinating can sometimes hold down a job that is low in stress. On the other hand, patients with cognitive problems or negative symptoms do not do well in the work environment. Also, although patients may attain a job, staying employed and staying stable while employed is a major challenge for many people with schizophrenia. A study by McGurk and colleagues showed a better employment rate when cognitive remediation was also used for people who were returning to work.\(^{108}\)

Some patients need highly intensive monitoring in the community. This community outreach, called assertive community therapy (ACT), is delivered in the patient’s home on a daily basis by a highly specialized multidisciplinary team. It is an effective treatment for patients with severe schizophrenia.\(^{109}\)

**OTHER TREATMENT CONSIDERATIONS**

Electroconvulsive therapy (ECT) is an uncommon treatment for people with schizophrenia, given adjunctively with antipsychotic medications. Patients with catatonia and patients who are recurrently suicidal are the best candidates for ECT.\(^{109}\) Transcranial magnetic stimulation (TMS) has been shown in research to reduce auditory hallucinations in patients with schizophrenia.\(^{103}\) Psychosurgery and deep brain stimulation are not acceptable treatments for schizophrenia.

**KEY POINTS**

- Schizophrenia is extraordinarily complex.
- Genetic causative influences predominate but by no means tell the complete story.
- Current thinking on schizophrenia sees it as a neurodevelopmental disorder.
- Dopamine dysregulation is important but by no means the complete picture neurochemically.

**REFERENCES**

Mood disorders are characterized by a significant and pervasive change in mood to either depression or elation that goes beyond the normal experience of happiness during auspicious times and unhappiness during inauspicious times. Typically, mood disorders are recurrent and onset of episodes is often associated with stressful events or situations. Symptoms of depression and less frequently elation are commonly associated with physical illnesses and other psychiatric disorders.

The two main classification systems for mental disorders are the World Health Organization (WHO) International Classification of Diseases, version 10 (ICD-10) and the American Psychiatric Association’s Diagnostic and Statistical Manual, version 4, text revision (DSM-IV-TR). In their classification of affective disorders, these systems are broadly similar but have some significant differences. They both have separate categories for single and recurrent episodes of mood disorders. The persistent but mild mood disturbances of cyclothymia (repeated depressed and elated mood) and dysthymia (sustained depressed mood) are also recognized in both.

The most notable difference between DSM-IV and ICD-10 is that ICD-10 recognizes only one type of bipolar affective disorder (BAD) whereas DSM-IV separates this condition into bipolar I disorder, bipolar II disorder and cyclothymia. Another difference is DSM-IV’s inclusion of mood disorders secondary to medical conditions in a subcategory of mood disorders, whereas ICD-10 separates ‘organic mental disorders’ into a separate category. The DSM-IV classification refers to ‘major depressive episodes’, whereas ICD-10 names them ‘depressive episodes’. Additionally, DSM-IV has subcategories for ‘partial remission’ and ‘full remission of a major depressive episode’, whereas ICD-10 specifies only ‘full remission’.

Both classification systems distinguish mania and hypomania according to severity of symptoms. DSM-IV allows a diagnosis of BAD with the presence of just a single episode of mania or hypomania, whereas ICD-10 requires at least two episodes of mood disturbance, one of which must be hypomanic, manic or mixed. In DSM-IV, bipolar I is diagnosed following the occurrence of at least one manic episode or mixed episode, with or without depressive episodes. Bipolar II requires depressive episodes and at least one hypomanic episode but the absence of any manic episodes. DSM-IV categorizes cyclothymia as a type of BAD, whereas both dysthymia and cyclothymia are included under persistent mood disorders in ICD-10. DSM-IV includes rapid cycling as a specifier for bipolar disorders, but it is not mentioned in ICD-10.

The aetiology of affective disorders is multifactorial, even in individual patients, and there are many ways to group the different factors. For example, the biopsychosocial model takes account of biological, psychological and social factors that influence a person over their lifespan. These factors can also be grouped into predisposing factors, precipitating factors and perpetuating factors. Another way to view the aetiology of affective disorders is to separate the components into genetic and environmental factors. In this chapter we have used the biopsychosocial model.

Biological factors

The biological factors contributing to affective disorders have been investigated from a number of different perspectives: genetic factors, neurochemical changes, neuroendocrine abnormalities, cellular factors and cerebral pathophysiology.

Genetics

Family studies show the risk of mood disorders to be increased in first-degree relatives of patients with depression, and that the earlier the age of onset, the higher the risk. Relatives of patients with bipolar disorder have a higher risk of both bipolar disorder and unipolar depres-
sion, whereas relatives of patients with unipolar depression have a higher risk only of unipolar depression.

Although family studies show heritability, they do not show whether this is due to genetic factors or behavioural and environmental factors within certain families. It is from the work of twin studies that evidence has emerged of genetic factors contributing to the heritability of affective disorders. Twin studies have looked at the discrepancy in the concordance of the rate of affective disorders between monozygotic and dizygotic twins. These studies show concordance rates of 40–50 per cent in monozygotic twins and 20–25 per cent in dizygotic twins for depression. In bipolar disorder, the results have been even more marked. The approximate lifetime risk of bipolar disorder in relatives of a bipolar proband has been shown to be: monozygotic cotwin, 40–70 per cent; first degree relative, 5–10 per cent; unrelated person, 0.5–1.5 per cent.

One of the most influential twin studies looking at the heritability of depression and attempting to separate environmental and genetic factors in the causation of depression was published by Kendler and colleagues at the University College of Virginia. They interviewed a large number of female twins and found considerable heritability of depression, with the extent of heritability proportional to the severity of depression. They also found that members of adult twin pairs do not share most environmental experiences of causative importance for depression. From this, they concluded that shared genetic factors are considerably more important than shared environmental factors in the tendency for depression to aggregate in families.

It is likely that genetic susceptibility to depression is polygenic. For example, twin studies have shown both a correlation between depression in women and neuroticism and also a correlation between depression in women and heritability of neurotic traits.

Adoption studies support a combined genetic and environmental aetiology of affective disorders. The rate of bipolar disorder in biological parents of probands with bipolar disorder has been shown to be higher than for non-related adoptive parents in some studies.

To date, molecular genetics has contributed only modestly to the understanding of the genetic component of affective disorders. It is assumed that the genetic component of affective disorders is related to alleles, variations of normal genes. The presence of different forms of the same gene, causing different phenotypes within a population, is known as genetic polymorphism. Linkage studies search for linkage of a disorder to a known gene. An early linkage study suggested linkage of bipolar disorder to markers on chromosome 11 in an Old Order Amish population; however, this result has not been confirmed in subsequent studies on the same population. More recent, larger studies have consistently suggested a linkage of bipolar disorder to loci on chromosomes 4, 12 and 18 and 21. These studies also support the theory that the inheritance of susceptibility to affective disorders is polygenic.

Allelic association studies compare the genotypes of patients and controls, with the aim of identifying an excess of certain alleles in patient populations. These studies have focused particularly on genes that code for monoamine transporters, but to date results have been inconclusive. Although some studies have shown an association between different alleles of the serotonin transporter gene (SERT) in both unipolar depression and bipolar disorder, the association is weak and not confirmed in some subsequent studies. Another finding has been that patients with rapid cycling bipolar disorder may be more likely to express a low activity allele of the catecholamine-0-methyl transferase gene. It has been suggested that this might contribute to rapid changes in mood.

**Neurochemistry**

The monoamine theory of affective disorders arose from observations that certain drugs, such as reserpine, that depleted monoamine neurotransmitters could induce depression, while chemicals, such as amphetamine and ecstasy, that cause release, reducing reuptake or reducing breakdown. Monoamines include serotonin (5-hydroxytryptamine, 5-HT), noradrenaline, dopamine and acetylcholine.

Much research has focused on the role of serotonin in depression. Studies have shown that levels of tryptophan, a substrate of serotonin synthesis, are reduced in patients with untreated depression. It is not clear whether this is related to the cause of depression or is an effect of depression. Tryptophan depletion has been shown to induce depression in females and also to cause a return of severe depressive symptoms in patients recovering from and in remission after a depressive episode. Other studies have shown a serotonin metabolite to be reduced in the cerebrospinal fluid (CSF) of depressed patients. Further studies showed that this is only the case for some depressed patients and that these patients have a higher risk of suicide attempts, suggesting that the association is more with impulsivity. Perhaps the best evidence of the role of serotonin in depression is the efficacy of selective serotonin reuptake inhibitors (SSRIs) in treating depression.

Although there is no consistent evidence that levels of noradrenaline are altered in patients with depression, some antidepressants inhibit noradrenaline uptake while having little effect on 5-HT uptake, suggesting that noradrenaline does play an important aetiological role.

The dopamine system has also been associated with depression. The psychostimulants amphetamine and cocaine stimulate dopamine release and cause euphoria in normal volunteers. Parkinson’s disease, which is due primarily to dopamine depletion, is associated with an increased risk of depression, and the dopamine agonist bromocriptine has been shown to have antidepressant properties. Furthermore, the antidepressant effects of bupropion are attributed primarily to its effects on the dopamine system,
The dopamine system appears to be particularly important in bipolar disorder. Prodopaminergic stimulants can trigger mania and anti-manic medications tend to block the effects of dopamine. Patients with bipolar depression have been found to have reduced CSF levels of the dopamine metabolite homovanillic acid (HVA); conversely, some manic patients have been found to have increased levels of CSF HVA.16

The idea that affective disorders can be attributed to levels of neurotransmitters alone is clearly an oversimplification. Antidepressants cause rapid changes in neurotransmitter levels, but therapeutic effects take considerably longer to emerge. There are likely to be a number of interconnected neurotransmitter abnormalities present in affective disorders. Activity of one monoamine system influences the activity of the other monoamine systems via positive and negative feedback loops. These observations have led to the development of the neurotransmitter receptor hypothesis, which theorizes that depression is related to abnormalities in the receptors of monoamine neurotransmitters, with depletion of one or more neurotransmitters causing compensatory up-regulation of postsynaptic neurotransmitters.

Neuroendocrinology

The hypothalamic–pituitary–adrenal (HPA) axis is intrinsically involved in the physiological response to stress. Simplistically, the HPA axis involves corticotropin-releasing factor (CRF) from the hypothalamus, promoting the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary. ACTH in turn stimulates glucocorticoid release from the adrenal cortex. Negative feedback loops provide regulatory control. One of these negative feedback loops involves cortisol, which binds to glucocorticoid receptors in various areas of the HPA axis and the hippocampus, reducing further HPA activity. The involvement of the hippocampus in regulation of the HPA axis has led some researchers to refer to it as the ‘HHPA axis’.

A large amount of research has focused on the role of the HPA axis in depression. Some 50 per cent of patients with depression show hyperactivity of the HPA axis,17 and studies have shown evidence of increased CRF, impaired pituitary response to CRH administration, increased levels of ACTH, adrenal gland enlargement, raised serum cortisol, and dexamethasone suppression test non-suppression in patients with depression. It is not understood whether the effect on the brain of raised cortisol levels is depressant or antidepressant. Excessive cortisol secretion in Cushing’s syndrome is associated with an increased risk of depression. However, studies have shown that large doses of cortisol administered to patients with depression can be mood-enhancing. Additionally, hypercortisolaemia is also associated with psychotic illness and, in particular, mania.

The primary actions of glucocorticoids are intracellular. It has been suggested that transport across the cell membrane may be disturbed in depression, leading to low intracellular levels of intracellular cortisol. Furthermore, it has been proposed that antidepressants may influence this mechanism to increase intracellular levels of cortisol.18

Hyperactivity of the HPA axis in depression has a number of implications. It may have effects on cellular resilience, neuronal atrophy and, in turn, cognitive function. Elevated plasma cortisol may both suppress some aspects of cellular immunity and increase the levels of pro-inflammatory cytokines, which in turn are associated with raised levels of C-reactive protein (CRP). Raised CRP is an important risk factor for ischaemic heart disease, and perhaps this is part of the link between depression and heart disease. Antidepressant therapy has been shown to reduce the levels of these pro-inflammatory cytokines and CRP.

It has long been recognized that patients with hypothyroidism frequently exhibit cognitive impairment and depression, and patients with depression have higher than normal rates of hypothyroidism. A quarter of patients with major depression have a blunted thyroid stimulating hormone (TSH) response to thyrotropin-releasing hormone (TRH).19 Studies have shown that patients with uncorrected hypothyroidism have a poor response to antidepressants, and there have been reports of tri-iodothyronine (T3) accelerating the rate of onset of antidepressant response. It is on the basis of this that thyroxine (T4) and T3 have been proposed as agents to augment antidepressant therapy, although this is specifically not recommended in the National Institute for Health and Clinical Excellence (NICE) 2004 guidance for depression20 that applies to National Health Service (NHS) provision in England and Wales.

The hypothalamic–growth hormone axis is also likely to be involved. Patients with depression have been shown to have a reduced growth-hormone response to stimulation with α2-adrenergic agonists such as clonidine.21 This may persist after recovery, suggesting that it may be a marker for depression vulnerability.

Cellular factors

Neurotransmitters in the brain such as the catecholamines are located in the extracellular space. The cellular response is determined by intracellular signalling pathways. When neurotransmitters bind to receptors on the outer membrane of cells, their message is carried either by ion channel effects or by influencing the levels of small molecules, originally called ‘second messengers’, such as cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA). There is some evidence that antidepressants may modify intracellular signalling pathways by influencing intracellular messengers such as cAMP. There is also evidence of cell-signalling abnormalities in bipolar disorder. For example, concentrations of the PKA regulatory subunits in the cytoplasm are significantly lower in cells of various parts of the brain in bipolar disorder. Studies have also shown a higher concentration of cAMP-stimulated phosphorylation of
Rap1, a protein found in the platelets of patients with bipolar disorder. Lithium treatment has been associated with changes to the phosphatidylinositol system and also to other components of the intracellular messaging system, although the exact relationship between lithium’s intracellular effects and its therapeutic effect is not yet clear.

The molecular and cellular theory of depression suggests that a decrease in survival promoting neurotrophic factors may occur in depression. Changes to growth factors and neurotrophins such as brain-derived neurotrophic factor (BDNF) have been considered to influence cellular resilience and result in neuronal atrophy in patients with depression. Clinical imaging studies have supported this by demonstrating a decreased volume of certain brain structures in the brains of patients with depression. This in turn may affect cognitive function. The molecular and cellular theory also suggests that, via secondary messenger signalling systems, antidepressants increase the concentration of neurotrophic factors, which are essential for neuronal survival.

It may be through mechanisms such as these that the observed phenomenon of ‘kindling’ occurs in depression. Kindling refers to a process in which repeated stimulation causes an escalating response. Although it is classically applied to epilepsy, it can also be applied to depression. After a single depressive episode, 85 per cent of patients will experience a recurrence; and although the first episode is often provoked by a negative life event, subsequent episodes are often unprompted. Recurrent depressive episodes also typically increase in frequency and duration.

**Cerebral pathophysiology**

Based on limited postmortem studies of patients with mood disorders, there is some evidence of changes in cortical and subcortical structures.

Structural brain imaging studies have shown that patients with unipolar depression have a tendency to smaller basal ganglia, hippocampi, cerebella and possibly frontal lobes. In bipolar disorder, imaging studies have shown a tendency to reduction in prefrontal cortex volume and enlargement of cerebral ventricles.

Functional neuroimaging studies of patients with depression have shown hypoperfusion in frontal, temporal and parietal areas. Other studies have shown reduced global cerebral activity in patients with depression. Patients with bipolar depression have been shown to have reduced amygdala activity. Few conclusions have been able to be made from this work regarding cause and effect at this stage.

**Physical illness**

Various medical illnesses increase the risk of depression. For some of these, it is likely to be due to the effect of having a significant life event (see Social factors, below), but some conditions have a particular association with affective disorders.

Depression is common following a stroke. Some 30–40 per cent of patients who survive intracerebral haemorrhage develop depression, and depression probably impairs rehabilitation.

Up to 33 per cent of patients develop depression after a myocardial infarction, and prognosis in heart disease is worse for patients with depression. The relationship between cause and effect is not clear and probably goes both ways.

Multiple sclerosis, temporal lobe epilepsy and early traumatic brain injury are associated with increased risk of bipolar disorder.

Although it is not a physical illness, there are a lot of physiological changes at the time of childbirth, and during the months following this there is a significantly raised risk of bipolar disorder.

**Psychological factors**

Psychological factors are clearly important in the aetiology of depression. Most of the literature comes from the ideas of psychoanalysis and cognitive-behavioural theory.

**Psychoanalytical theory**

Psychoanalytical theories of depression focus on loss, overdependence on external approval and internalization of anger.

Karl Abraham is credited with beginning psychoanalytical theory with the publication of a paper in 1911, but it was the work of Freud and in particular the publication of *Mourning and Melancholia* in 1917 that established the psychoanalytical theory of depression, which primarily interprets depression as a reaction to loss. Freud noted the similarities between grief and depression and suggested that, just as mourning results from loss by death, so melancholia (depression) results from loss of other kinds. Klein contributed to the theory in the 1930s by developing the idea of the ‘depressive position’ (developmental stage), whereby during the period around age 4–12 months the infant recognizes the mother as a ‘whole object’ and that she will return, even following episodes when the infant has been angry. Klein suggested that depression was more likely in people who failed to pass through the depressive position.

Bibring and Jacobson wrote about the importance of self-esteem in depression and how problems with self-esteem are related to both experiences at the oral stage and failures at later stages of development.

Further developments by Bibring in the 1950s and Blatt in the 1970s hold that the depressed person reacts intensely to a loss in later life due to it bringing back the fears of a loss during childhood of parental affection, either through actual loss of the parent or inappropriate parenting. The loss in later life causes the person to regress to the helpless and dependent state of childhood that they were at when the original loss occurred. The display of helplessness and appeal for affection and security is a cry for love.
Psychodynamic theory explains mania as a defence against depression.

Although psychoanalytical theories provide reasonable explanations for some of the behaviours exhibited by patients with mood disorders, there is little objective evidence to support or refute them.

Cognitive-behavioural theory

Cognitive-behavioural theories attribute depression to pessimistic views about oneself and the world.

The beginning of the cognitive model for depression originated from work by Seligman in the 1960s involving giving electric shocks to dogs following a warning, in a situation where they could not escape. The dogs learned to whimper and accept the shocks, and they continued with this behaviour later even when they had the opportunity to escape. This was described as ‘learned helplessness’. According to the helplessness model of depression described by Peterson and Seligman, vulnerability to depression derives from a habitual pattern of explaining the causes of life events, which they called ‘attributorial style’.

Beck grouped the negative thoughts of depressed patients into the three categories (‘cognitive triad’): about the self, about present experiences, and about the future. Beck proposed that the negative self-beliefs including worthlessness are formed during childhood as a result of negative experiences, such as loss of a parent or rejection by peers, and these become ‘core beliefs’: Beck also developed the idea that people with depression misperceive reality through the following cognitive distortions, and this contributes to their negative beliefs about themselves:

- Overgeneralization
- Magnification of bad events and minimizing good events
- Personalization to assume responsibility for bad events that were in reality outside the person’s control
- Selective abstraction – focusing on the bad things and ignoring the good
- Arbitrary interference – drawing conclusions when there is little evidence to support them.

Abramson and others proposed that people have consistent ‘attributorial styles’. People with negative attributional styles have been shown to be more likely to have depressed reactions to difficult events. Negative cognitive styles have also been shown to precede and predict depressive episodes. More behaviourally oriented approaches theorize that a person becomes depressed when he or she ceases producing behaviour that elicits positive reinforcement.

Social factors

Social factors in the aetiology of depression come into play at a very early stage. Longitudinal studies have shown an association between impaired fetal growth and low birth weight with depression. Neurodevelopmental problems may be associated with an increased risk of depression, possibly exemplified in the 1946 British birth cohort study, which showed that children with low educational test scores were at increased risk for childhood and adult affective disorder.

Childhood disadvantage has been linked with increased risk of depression, with some of the strongest evidence for this coming from Brown and Harris’ surveys of inner-city populations.

Mental illness is linked strongly to several aspects of social inequality. Unemployment is associated with increased risk of depression. Being married has been shown to be protective, particularly for men.

Life events, particularly losses, are often the precipitating factor for a depressive episode. Situations of ‘entrapment’ and ‘humiliation’ appear to be particularly important. In the 6-month period following a life event, risk for depression and deliberate self-harm is increased six-fold. There are, however, methodological difficulties in assessing life events. Studies show that people suffering from a variety of physical illnesses report relatively high levels of adverse events in the years preceding onset of the illness. It may be that illness leads people to exaggerate their life difficulties, or that healthy people downplay their problems. Or it may be that life events are associated with the decision to seek help rather than the actual illness itself. Both Brown and Harris’ studies of inner-city women in London and Kendler’s twin studies showed that the association between stressful life events and depressive episodes declines as the number of previous depressive episodes increases.

Stressful life events can also precipitate manic episodes in bipolar disorder, with such events more common in the 6 months before first presentation. There is less association between milder episodes of hypomania and life events.

Social risk factors for bipolar disorder include single marital status, unemployment and possibly low income. Studies show social class to be stable over time for people with a diagnosis of bipolar disorder; however, unrecognized subsyndromal illness effects may confound assessment of presumed premorbid socioeconomic status.

Dysfunctional relationships within families have been associated with increasing the risk of bipolar disorder, but it is unclear whether this is cause or effect of illness in subjects and possibly also other family members.

DEPRESSION

Introduction

The concept of depression has evolved over time. Current classification systems owe a lot to the German psychiatrist Emil Kraepelin, known as the father of descriptive psychiatry, who coined the term ‘depressive states’ in the 1920s. The concept of cognitive and intrapsychic factors in
depressive disorders was introduced by Freud in 1917 with the publication of *Mourning and Melancholia*, which shifted the focus from objective behavioural signs to subjective symptoms. The introduction of antidepressants in the 1950s reinforced biological models of depression. George Engel is credited with introducing the concept of illnesses having biological, psychological and social components, and the biopsychosocial model is generally accepted as the current model for depression.

**Clinical features**

The core symptoms of depression include sustained depressed mood, loss of interest and enjoyment, and reduced energy and activity. Symptoms are often divided into groups according to their nature.

**Emotional symptoms** include the following:

- Depressed mood, which should be present most days and throughout the day
- Anhedonia – loss of ability to experience pleasure
- Loss of interest in activities
- Irritability
- Diminished emotional reactivity
- Anxiety
- Tearfulness.

**Biological symptoms** of depression include the following:

- Diurnal variation in mood, with mood commonly improving as the day progresses
- Sleep disturbance, most commonly insomnia, classically involving early-morning wakening. Patients with atypical depression have hypersomnia
- Reduced energy, fatigue and decreased activity
- Change of appetite, which is usually decreased and may result in loss of weight. In atypical depression appetite is increased
- Reduced libido
- Constipation.

**Cognitive symptoms** include the following:

- Reduced concentration and attention, often with indecisiveness
- Impaired memory
- Slowness of thought processes.

**Behavioural features** include the following:

- Social withdrawal
- Reduced eye contact
- Psychomotor retardation or agitation
- Reduced facial expression
- Self-neglect.

**Depressive cognitions** include the following:

- Pessimism involving negative ideation about the future, with feelings of hopelessness and helplessness, and often thoughts of suicide and self-harm

- Feelings of guilt, with inappropriate self-blame
- Feelings of worthlessness and being a failure, resulting in loss of confidence and low self-esteem.

In severe depressive episodes, patients often experience psychotic symptoms, which are usually mood-congruent, including the following:

- Hallucinations, which are usually auditory and typically in the form of second-person auditory hallucination. Other modalities of hallucinations can also be present
- Delusions, which are usually mood-congruent, and the content typically including thoughts of guilt, poverty, persecution and illness. Cotard’s syndrome describes patients who experience extreme nihilistic delusions of death and disintegration.

**Epidemiology**

The epidemiology of depressive disorders is complicated by difficulties in defining the boundaries of depression, dysphoria and euthymia due to diagnostic criteria imposing discrete diagnoses on a symptom continuum of varying severity and duration.

Studies show considerable variability in the lifetime rates of depression, ranging from under 5 per cent to 30 per cent, but it is generally accepted that the lifetime prevalence is between 10 per cent and 20 per cent. The 6-month prevalence rate is considered to be between 2 per cent and 5 per cent based on surveys in several countries. A cross-sectional WHO world health survey carried out in 60 countries covering all regions of the world showed a 1-year prevalence of depressive episode (ICD-10 criteria) of 3.2 per cent, with a 95 per cent confidence interval of 3.0 per cent to 3.5 per cent. The prevalence of depression is higher in patients with medical conditions, with 10–14 per cent of patients under general hospital care affected. Women are twice as likely as men to suffer from depression. There is increasing evidence that the prevalence of depression is increasing and that the age of onset is decreasing.

**Risk factors**

Risk factors for depression include the following:

- Past history of a depressive episode – depression tends to be a recurrent illness
- Family history – studies show that genetics are a major factor in the aetiology of depression, with heritability of depression estimated to be between 40 per cent and 70 per cent
- Personality traits of neuroticism, obsessionality and impulsivity
- Being from a lower social class
- Living in an urban area
- Unemployment
- Being divorced, although the association is less clear for women than for men
Lack of a confidant

Adverse life events, in particular events of loss in vulnerable individuals

Other psychiatric disorders – co-morbidity with depressive episodes is particularly common with anxiety disorders, substance misuse and personality disorders

Physical illness – certain neurological illnesses, particularly cerebrovascular disease, Parkinson’s disease, multiple sclerosis and epilepsy, may increase the rate of depression through shared neurotransmitter abnormalities. Endocrinological disorders, notably Cushing’s syndrome, Addison’s disease and disorders of thyroid function, have a particular association with increased rates of depression. Having any severe or prolonged medical condition can increase the risk of depression.

Brown and Harris’ often quoted paper ‘Social origins of depression: a study of psychiatric disorders in women’ identified having three or more children under the age of 11 years, lack of paid employment and lack of a confiding relationship as risk factors for depression, although subsequent studies have not consistently supported the first two of these factors.

Impact
Depression is one of the major causes of disability globally. The WHO has estimated that depression is currently the fourth leading cause of disease burden in the world, after perinatal conditions, lower-respiratory tract infections and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), and predicts that by 2020 it will be second, after ischaemic heart disease.

Patients with depression have elevated standardized mortality ratios compared with the general population. Suicide is the main reason for this, but also contributing are increased rates of cardiovascular disorders, some other medical conditions, and substance misuse and dependence. The presence of depression in patients with coronary artery disease is associated with a doubling of the risk of cardiac death, and in the 2 years following a myocardial infarction the presence of depression is associated with a more than two-fold increase in incidence of cardiac and all-cause mortality. Although the relationship of cause and effect is not clear, suggested mechanisms include that heart disease may increase the likelihood of depression; depression may make heart disease more likely through unhealthy behaviours such as physical inactivity, smoking and poor adherence to medical advice. Other possibilities are that both disorders may share a biological basis, such as alterations in autonomic or hypothalamic–pituitary–adrenal axis function, abnormal platelet function or systemic inflammation.

Onset
Depression can start at any time in life. The age of onset is usually later than for bipolar disorder. Genetic factors play a more important role in early-onset depression. Late-onset depression is less likely to be associated with a family history and tends to be milder but more likely to become chronic than early-onset depression. A significant number of patients suffer prodromal depressive symptoms before diagnosis. The first manifestations of depressive symptoms are often mild and brief and are recognized only retrospectively.

Early detection of symptoms and appropriate treatment can prevent the development of more severe episodes.

Outcome
The average length of a single depressive episode is about 6 months. Longer episodes are less likely to end with full remission. Chronicity (defined as a non-remitting episode of major depression of at least 2 years’ duration) occurs in 10–25 per cent of patients with depression. The rate of recovery from an index episode of depression declines over time. The course of depressive disorder for the majority of patients is recurrent. Approximately 25 per cent of patients have a recurrence of a depressive episode within 1 year of an index episode, and the proportion increases to around 75 per cent at 10 or more years. The first interval between episodes is longer than subsequent intervals, and a later age of onset of depression correlates with shorter first and subsequent intervals. The length and severity of episodes tend to increase with subsequent episodes.

Studies in primary care show that a considerable proportion of patients diagnosed with depression have a poor prognosis, with only about 25 per cent fully recovered after 12 months. About 50 per cent have intermittent symptoms and another 25 per cent have persistent symptoms over the same period. In the longer term, over 50 per cent of patients are still unwell 11 years later, with nearly 40 per cent having a relapsing or chronic course over this time.

Some 45 per cent of severely depressed patients recognized by their general practitioner (GP) remained depressed after 12 months, and of these nearly 30 per cent remained severely depressed.

There are several factors increasing the risk of recurrence of depressive episodes, including early age of onset, substance misuse, personality disorder, diagnosis of dysthymia, history of previous depressive episodes, and lack of social support.

The incidence of recurrence is much less in patients on prophylactic treatment.

Patients admitted to hospital with depression with psychotic features have different short- and long-term outcomes than patients admitted with ‘neurotic depression’. In the short term, patients with depression with psychotic features tend to improve more quickly, responding to biological and short-term pragmatic therapies. However, in the long term, patients admitted with depression with psychotic features have a considerably worse prognosis, with much higher rates of re-admission and long-term social dysfunction.
About 10 per cent of patients with an initial diagnosis of unipolar depression will have a subsequent manic or hypomanic episode and be re-diagnosed with bipolar disorder.

**Suicide**

The rate of suicide is significantly increased in patients suffering from depression compared with the general population. It is also higher than in other mood disorders.

Risk of suicide is generally higher in patients who require hospitalization compared with those treated in the community. The risk of suicide in depressive disorder may be at its highest early in the course of the illness. The standardized mortality rate (SMR) for suicide in major depression has been estimated at 20 compared with suicide in the general population (SMR = 1.0). It is generally accepted that 15 per cent of patients hospitalized with depression subsequently die from suicide.

**Diagnosis of depression**

**Classification systems**

The two widely used classification systems for making the diagnosis of depression are ICD-10 and DSM-IV.

**ICD-10**

ICD-10 depression diagnoses are as follows:

- Depressive episode (F32)
  - Mild depressive episode (F32.0)
  - Moderate depressive episode (F32.1)
  - Severe depressive episode without psychotic symptoms (F32.2)
  - Severe depressive episode with psychotic symptoms (F32.3)
  - Other depressive episodes (including atypical depression) (F32.8)

- Recurrent depressive disorder (F33)
  - Recurrent depressive disorder, current episode mild (F33.0)
  - Recurrent depressive disorder, current episode moderate (F33.1)
  - Recurrent depressive disorder, current episode severe without psychotic symptoms (F33.2)
  - Recurrent depressive disorder, current episode severe with psychotic symptoms (F33.3)
  - Recurrent depressive disorder, currently in remission (F33.4).

The diagnosis of depression in ICD-10 is based on the presence of particular symptoms and the impact of those symptoms on the individual. ICD-10 lists ten symptoms that an individual with a depressive episode typically has. The ten symptoms are divided into a group of three symptoms that an individual with depression will usually have, and seven other symptoms:

- Core symptoms:
  - Depressed mood
  - Loss of interest and enjoyment
  - Reduced energy and decreased activity.

- Other common symptoms:
  - Reduced concentration and poor attention
  - Reduced self-esteem and confidence
  - Ideas of guilt and unworthiness
  - Pessimistic thoughts
  - Ideas or acts of self-harm or suicide
  - Disturbed sleep
  - Diminished appetite.

The severity of the episode is based primarily on the number of symptoms present, the level of distress caused by the symptoms and the impact of the symptoms on social function.

For the diagnosis of mild depressive episode, at least two core symptoms and at least two of the other symptoms should be present. The patient is usually distressed by the symptoms and has some difficulty in continuing with ordinary work and social activities.

Moderate depressive episode requires at least two core symptoms and at least three other symptoms. There will usually be considerable difficulty in continuing with social, work or domestic activities.

Severe depressive episode requires all three of the main symptoms and at least four of the other symptoms. The patient will usually show considerable distress or agitation, unless retardation is a marked feature.

Symptoms should be present for at least 2 weeks for a diagnosis of mild or moderate depressive episode. A diagnosis of severe depressive episode may be made following a shorter duration of symptoms if they are particularly severe or if psychotic symptoms are present.

For the diagnosis of recurrent depressive disorder, presence of at least two episodes lasting a minimum of 2 weeks is required. There should be several months without significant mood disturbance between them.

**DSM-IV**

DSM-IV sets out criteria for the diagnosis of major depressive episode or major depressive disorder, recurrent, and then uses *specifiers* to further categorize the severity:

- Major depressive disorder, single episode
  - Mild
  - Moderate
  - Severe (with or without psychotic symptoms)

- Major depressive disorder, recurrent
  - Severe (with or without psychotic symptoms)

If a patient with recurrent major depressive disorder currently meets the full criteria for a major depressive episode, its current severity should be specified.

DSM-IV also includes specifiers that can be used to clarify the features of the episode, such as ‘with catatonic features’, ‘with melancholic features’ and ‘with post partum onset’. Additionally, if the full criteria are not currently met for a major depressive episode, the following specifiers are available to describe the current clinical status: ‘in partial remission’, ‘in full remission’ and ‘chronic’. The longitudinal
course specifiers ‘with/without full interepisode recovery’ can be used, as can ‘with seasonal pattern’.

DSM-IV sets out the following criteria for a major depressive episode:

- Five or more of the following nine (compared with ten in ICD-10) symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either depressed mood or loss of interest or pleasure:
  - Depressed mood most of the day, nearly every day
  - Markedly diminished interest or pleasure, in all or almost all activities most of the day, nearly every day
  - Significant weight loss when not dieting, or weight gain, or decrease or increase in appetite nearly every day
  - Insomnia or hypersomnia nearly every day
  - Psychomotor agitation or retardation nearly every day
  - Fatigue or loss of energy nearly every day
  - Feelings of worthlessness or excessive or inappropriate guilt nearly every day
  - Diminished ability to think or concentrate, or indecisiveness, nearly every day
  - Recurrent thoughts of death or recurrent suicidal ideation.

- The symptoms do not meet criteria for a mixed (affective) episode.

- The symptoms cause clinically significant distress or impairment in social, occupational or other important functioning.

- The symptoms are not due to the direct physiological effects of a substance or medical condition.

- The symptoms are not better accounted for by bereavement.

The severity specifier to be used depends on the number of criteria symptoms present, the severity of the symptoms and the degree of functional disability or distress:

- Mild major depressive episode is characterized by the presence of five symptoms and minor social and either mild disability or capacity for normal function but with substantial and unusual effort.

- Moderate major depressive episode has a severity that is in between mild and severe.

- Severe major depressive episode without psychotic features is characterized by the presence of most of the criteria symptoms and clear-cut observable disability.

### Age, culture and diagnosis

There are significant differences in the way people of different ages and cultural backgrounds tend to present when they have depression. Elderly people sometimes present with agitation, confusion and functional decline and may mistakenly be considered to have dementia. Children often present with irritability, social withdrawal and deterioration in performance at school.

Since the 1970s many ethnographic studies have shown that the presentation, attribution, classification, prevalence and prognosis of mental disorders vary greatly between cultures. This can create significant difficulties if Western classifications are used without taking into consideration these cultural differences. Definitions of depression in classification systems such as ICD-10 and DSM-IV are descriptive syndromes that are highly heterogeneous and socially shaped. In view of this, some commentators disagree with the way organizations such as the WHO denote depression as a universally valid mental disorder that is amenable to a standard mental health toolkit.

Symptoms of depression show some differences across cultures. People from the Indian subcontinent are more likely to report somatic symptoms while suffering from a depressive episode. Patients from China are more likely to report weakness or tiredness, while Middle Eastern cultures often associate depression with heart problems. A number of studies have shown ubiquity of somatic presentations worldwide, whereas ‘psychologization’ may be more culturally specific to Western cultures.

Somatization is an important mechanism for many patients with depression and may involve both patient and doctor factors. Both anxiety and depression tend to amplify pain. There are a number of reasons why somatic symptoms may continue even in the absence of dysphoria. Somatic symptoms may secure advantages from partners, family and employers. Somatization may be inadvertently encouraged by doctors. Goldberg and Bridges have suggested three functions that somatization performs. First, it allows people who are unsympathetic to psychological illness or who live in cultures where mental illness is stigmatized to occupy the sick-role while psychologically unwell. Second, it enables the people to avoid blame by casting the individual as the suffering victim. Third, by reducing blame, it may save patients from being as depressed as they might otherwise have been.

Thought content in depression is also influenced by cultural background. It is not unusual for patients from some African countries suffering from severe depression to have delusions about evil spirits and other themes that are not commonly seen in European cultures. Patients from cultures where mental illness is associated with considerable stigma will perceive their depressive symptoms in a very different way and may not spontaneously present them.

### Differential diagnosis

Before making a diagnosis of depressive episode, it is important to consider:

- the onset of the disorder, concentrating on any potential precipitating factors such as recent life events (the highest risk being associated with loss or entrapment);
- the course and severity of the symptoms;
previous episodes of mental illness (especially previous hypomanic or manic symptoms to identify patients who have bipolar disorder);
• any associated medical problems (low mood secondary to a general medical condition);
• substance misuse;
• recent bereavement (normal bereavement is not a mental disorder);
• use of pharmacological agents that can cause mood disturbance.

Differential diagnoses for a depressive episode include the following:

• Other mental disorders: depressive symptoms are common in almost all psychiatric disorders, but in particular it is important to consider the following:
  • Other mood disorders, including bipolar disorder, cyclothymia and dysthymia
  • Anxiety disorders, including generalized anxiety disorder, mixed anxiety and depressive disorder, obsessive-compulsive disorder, panic disorder and phobias
  • Schizophrenia and schizoaffective disorder (especially with negative symptoms and post-schizophrenic depression)
  • Eating disorders (anorexia nervosa, bulimia nervosa)
  • Stress-related disorders, including adjustment disorders, bereavement and post-traumatic stress disorder
  • Personality disorders, especially borderline personality disorder
  • Substance-induced depressive disorder.

• Neurological disorders:
  • Cerebrovascular disease
  • Parkinson’s disease
  • Epilepsy
  • Multiple sclerosis
  • Huntington’s disease
  • Tumours
  • Head injury.

• Endocrine disorders:
  • Thyroid disorders (hyper- and hypothyroidism)
  • Parathyroid disorders (hyperparathyroidism causes ‘moans, bones and abdominal groans’, referring to depression, bone pain and constipation)
  • Adrenal (Cushing’s syndrome, Addison’s disease, hyperaldosteronism)
  • Menstrual, menopausal and postpartum-related symptoms.

• Infectious and inflammatory disorders:
  • HIV/AIDS
  • Syphilis
  • Infectious mononucleosis
  • Tuberculosis
  • Systemic lupus erythematosus (SLE)
  • Rheumatoid arthritis.

• Other physical conditions:
  • Malignancy
  • Cardiopulmonary disease
  • Porphyria
  • Uraemia
  • Vitamin deficiency
  • Anaemia
  • Sleep apnoea.

Medication-related:

• Steroids
• Antihypertensives (beta-blockers, methyldopa, reserpine, calcium channel blockers)
• H1 blockers (ranitidine, cimetidine)
• Sedatives and hypnotics.

• Substance misuse:
  • Opiates, benzodiazepines, cannabis, alcohol
  • Stimulants, including amphetamine and methylenedioxymethamphetamine (MDMA, ecstasy).

Investigations

There are no specific tests that can be used to diagnose depression. Investigations are used mainly to exclude other independent problems or to identify treatable causes of depression. It is appropriate to check full blood count, urea, creatinine, electrolytes, serum calcium, liver function tests, thyroid function tests, glucose, erythrocyte sedimentation rate (ESR), plasma viscosity and, especially in older patients, vitamin B12/folate levels. More specific tests should be considered if indicated by history of symptoms or physical examination.

Management

General principles

The aim of managing depressive disorder is to treat the acute symptoms to ease distress, re-establish the patient’s normal level of psychosocial functioning and reduce the likelihood of future relapse. The majority of patients with depression are treated in primary care. Patients referred to specialist psychiatric services usually have more severe depression, are treatment-resistant or have depression complicated by other factors such as co-morbidity. The most severely affected patients are usually managed in in-patient settings, sometimes on a compulsory basis. Reasons for hospital admission include significant suicide risk, risk to others, serious self-neglect, severe distress perhaps due to psychotic symptoms, lack of social support, and for initiation of ECT.

Patients with treatment-resistant depression can benefit from an in-patient assessment and close monitoring while new treatments are initiated. Depressive disorder complicated by a serious medical condition is often best treated in a hospital with close liaison with medical teams.

It is often possible to manage even severely depressed patients in the community with intensive support by specialist teams, often including home-based assessment and treatment. Patients with mild and moderate depression are
usually managed in primary care settings, ideally by a multidisciplinary team.

The establishment of a collaborative relationship is an important foundation for effective care of patients with depression. Management needs to include regular monitoring of mental state and risk, review of concordance with treatment, and checking for side effects and efficacy of medication. Core to any management of mental disorders is psychoeducation, as this allows better understanding of the specific nature of their illness. There is evidence that active case management can improve outcomes in depression. Active case management includes:

- proactively following up patients;
- assessing patient adherence to psychological and pharmacological treatments;
- monitoring the patient’s progress;
- taking action when treatment is unsuccessful;
- delivering psychological support.

**Assessment**

Assessment of a patient with a depressive episode is performed according to the general principles of any psychiatric assessment; however, there are several specific areas that should be addressed. It is essential to enquire about possible psychosocial precipitants of the current episode as well as predisposing and potential perpetuating factors. Understanding these factors is crucial for the development of an appropriate management plan that targets the specific needs of the individual patient. Assessment should always include a full risk assessment, including history of previous deliberate self-harm and suicide attempts. Enquiry should be made regarding physical illness and medication. While assessing a patient with symptoms of depression, it is very important to ask specifically about past history of manic or hypomanic symptoms in order to exclude the possibility of bipolar disorder.

**Treatment**

It is useful to divide the treatment of depression into two phases. Acute treatment is aimed at symptom control and achieving remission. The long-term treatment focuses on maintenance and prevention of relapse. Treatment should include biological and psychosocial approaches.

**Pharmacological treatment – acute phase**

The risk/benefit ratio for use of antidepressant drugs in mild depression is poor. These drugs are therefore not currently recommended as a first-line treatment in mild depression. There is much stronger evidence for their efficacy in moderate and severe depressive episodes.

The efficacy of different antidepressants is similar; however, the side-effect profile varies. Current UK guidelines recommend SSRIs as first-line treatment of depression, although choice of medication should also take into account previous responses to medication. The UK Committee on Safety of Medicines advises using the lowest possible dose of an SSRI and monitoring closely for potential side effects in the early stages of treatment (especially restlessness, agitation and presence of suicidal thoughts). If for any reason antidepressants need to be stopped, the doses should be reduced gradually in order to reduce the likelihood of discontinuation reaction symptoms.

The first-choice antidepressant should be continued at an initial dose for at least 4–6 weeks before any decision about its efficacy is made. If there is no improvement after that time, and there are no concerns about compliance or side effects, it may be appropriate to gradually increase the dose. If there is still no effect, then changing to another antidepressant should be considered. The drugs that should be prescribed as a second choice include another SSRI, a serotonin and noradrenaline reuptake inhibitor (SNRI), mirtazapine, moclobemide, reboxetine or a tricyclic antidepressant. Whenever possible, it is important to take into consideration the patient’s choice following discussion about benefits and potential problems that may be encountered for the individual patient.

When changing from one antidepressant medication to another, it is important to take into account the possibility of discontinuation reactions and interactions between the two antidepressants. Most antidepressants have the potential for causing symptoms when they are discontinued if they have been taken regularly for more than a short period of time. Because of this, antidepressants should be phased out gradually unless a serious adverse event has occurred. Simultaneous administration of some antidepressants may lead to problems caused by pharmacodynamic interactions, such as serotonin syndrome, hypotension or drowsiness, or pharmacokinetic interactions, such as increased plasma levels due to enzyme inhibition.

There are three ways of changing from one antidepressant to another, with the rapidity of change depending on the risk of interactions between the medications. The first is a direct switch from one drug to another. Generally this is tolerated when changing from one SSRI to another because their effects are so similar that the administration of the new drug is likely to prevent significant discontinuation symptoms. The second way of changing antidepressants is by cross-tapering, whereby the dose of the antidepressant being discontinued is reduced slowly while the new antidepressant dose is introduced slowly. The third way is to phase out the first antidepressant completely before introducing the new drug, often having a washout period in between finishing one drug and starting the next to ensure complete elimination of the first medication. A washout period is particularly important when changing to a monoamine oxidase inhibitor (MAOI) from any other class of antidepressant, and vice versa.

Treatment of severe depression with psychotic symptoms requires antidepressant therapy to be augmented with an antipsychotic. Care needs to be taken because of the
increased potential for side effects due to interactions between antidepressants and antipsychotics. The most common problems are anticholinergic effects and sedation. Atypical antipsychotics are less likely to cause these problems. Careful dose titration is important.

Routine use of benzodiazepines in the treatment of depression is not recommended. For patients presenting with severe anxiety symptoms, a short course at the lowest possible dose may be considered.

To reduce the risk of relapse, treatment with antidepressants should be continued for at least 6 months after achieving remission. It is important to maintain the dose of antidepressant that was originally effective. Six months following remission, the need for continuing medication should be reviewed carefully. Important factors to consider include the number of previous episodes, residual symptoms and ongoing psychosocial stressors. Patients who have a history of two or more depressive episodes should be treated for at least 2 years. Continuation of treatment for more than 2 years should be considered for patients with a more complicated history and higher chances of relapse.

**Treatment-resistant depression**

Treatment resistance is defined as a failure to respond to two different antidepressants given for a sufficient period of time and at an adequate dose. Patients meeting these criteria for treatment resistance should be reassessed carefully and the diagnosis reviewed. Attention should be paid to previous treatment history, perpetuating factors, adherence to current treatment, co-morbidities and suicide risk. Treatment should be continued within the multidisciplinary team if appropriate.

Very complex cases may require referral to specialist mental health services with expertise in the treatment of mood disorders.

Drug treatment options for treatment-resistant depression include the following:

- Augmentation with lithium should be considered.
- Venlafaxine may be more effective than some other antidepressants in treatment-resistant cases.
- Augmenting antidepressant treatment with another antidepressant is often effective, but the risk of side effects is increased. The most widely used combination is adding mirtazapine to an SSRI.
- Phenelzine may be used if patients are willing to comply with the dietary restrictions. Phenelzine may not be appropriate for individuals with a high risk of suicide due to its significant toxicity in overdose.

**Electroconvulsive therapy**

The efficacy of ECT in severe depression is well established from long-term trials. It is usually used only when there are psychotic or severe endogenous features present, and usually after a failed trial of pharmacological treatment. ECT is also indicated when depression has become life-threatening as a result of refusal of food and fluids.

A systematic review and meta-analysis in 2003 by the UK ECT Review Group concluded that ECT was significantly more effective than simulated ECT and pharmacotherapy. They also found that bilateral ECT was more effective than unipolar ECT, and that high-dose ECT was more effective than low-dose ECT.

NICE published a technology appraisal Guidance on the Use of ECT in May 2003 for England and Wales. It recommends that ECT is used to achieve rapid and short-term improvement of severe symptoms after an adequate trial of other treatment options has failed and when the condition is considered to be life-threatening. ECT is not recommended as a maintenance therapy in depressive illness because the long-term risks and benefits of ECT have not been established. There are several risks that should be considered before using ECT for treatment of depression, including those associated with anaesthesia and of cognitive impairment following ECT.

**Neurosurgery**

Surgical treatment of depression started in 1935, and some 12 000 procedures were carried out in the UK between 1936 and 1961. Initially the procedure was fairly crude (prefrontal leucotomy), but over time more evidence-based procedures were performed, targeting very specific parts of the brain. Adverse effects from this surgery were considerable, including severe amotivation and personality change, and some 15 per cent of patients developed epilepsy.

Psychosurgery declined rapidly in the 1960s with the advent of antidepressants and a changing social climate. There are now very few psychosurgical operations carried out in the UK. It is illegal in some countries. It is used only in exceptional cases where all other treatments have repeatedly failed and the patient remains ill but retains capacity to consent to the procedure. Stereotactic subcaudate tractotomy (SST) is the treatment of choice for severe mood disorders. New techniques are associated with fewer adverse effects than the earlier procedures, and good outcomes with respect to the depressive illness being treated have been reported as ranging from 34 per cent to 68 per cent, although of course there were no control subjects in these studies.

**Treatment of post-stroke depression**

Depression is commonly seen in patients following cerebrovascular accident. Treatment with antidepressants is effective and leads to faster rehabilitation. There is particularly good evidence for the efficacy of fluoxetine, citalopram and nortriptyline. As with all patients, it is important to consider the possible interaction of antidepressants with other prescribed medication, such as warfarin.

**Treatment of depression in diabetes mellitus**

There is a 24 per cent lifetime prevalence of co-morbid depression in individuals with diabetes mellitus.
approximately three times higher than the prevalence of depression in the general population. The presence of depression is associated with poorer metabolic control, and there is evidence that treatment of depression may improve glycaemic control. Therefore, early detection and appropriate treatment is important. The NICE guideline for depression recommends screening for depression in high-risk groups such as patients with diabetes mellitus in primary care. This was taken further in 2006, with the introduction to the Quality and Outcomes Framework (QOF), a performance-related pay scheme for GPs in the UK. The QOF requires screening individuals on GPs’ registers of patients with diabetes for depression. SSRIs are recommended for first-line treatment. Due to their effects on glucose control and weight, tricyclic antidepressants and MAOIs should not be prescribed routinely. It is important to monitor blood glucose closely while starting, changing the dose or discontinuing antidepressant treatment.

Psychological treatment of depression
Patients with mild depression should be offered psychological therapy before considering antidepressant medication (see NICE guidance, below). It can be offered as the only treatment for patients with mild depressive disorder and in combination with medication for moderate and severe episodes. A number of different types of treatment are available, and the choice should be based on availability, patient preference and past experience. The appropriate treatment should be delivered by a trained healthcare professional.

Cognitive-behavioural therapy (CBT) should be considered for patients who prefer this type of intervention to medication and to those who, despite an adequate treatment with antidepressants, still experience some depressive symptoms. In more severe cases, it is appropriate to offer CBT in combination with medication, as this appears to be more effective than either treatment alone. A course of CBT is usually given over 10–12 weeks, although for patients with more severe depression the course is often longer. Sometimes follow-up sessions are considered, usually two to four sessions over a year after the initial course of treatment.

CBT for depression is typically directive and short-term. It focuses upon changing the depressed patient’s negative thoughts regarding his or her self, world and future. With depression tending to be a relapsing condition, relapse prevention is an important part of CBT treatment. Relapse prevention includes identifying high-risk situations, learning and practising coping skills and creating lifestyle balance.

CBT has been shown to be more effective than pill-placebo and equivalent to antidepressant medication. It is effective across a wide range of patient severity and can prevent relapse as effectively as continuous antidepressant medication. CBT combined with antidepressant medication has been shown to be more effective at reducing depressive symptoms in chronically depressed patients than either treatment alone.

Interpersonal therapy (IPT) aims to achieve symptomatic relief for patients with depression by addressing current interpersonal problems associated with the onset of the disorder. Treatment is usually of a similar duration to that for CBT. There is less evidence of efficacy for IPT than there is for CBT, but studies have shown IPT to be superior to placebo and equivalent to CBT and antidepressant therapy for mild depression and superior to placebo but less effective than antidepressants in severe depression. IPT has also been shown to increase the length of time between episodes of depression in patients not receiving antidepressants. As

**Figure 39.1** National Institute for Health and Clinical Excellence (NICE) stepped care model

CBT, cognitive-behavioural therapy; ECT, electroconvulsive therapy.
with CBT, there is evidence that combined IPT and antidepressant therapy is superior to either treatment alone.\textsuperscript{75}

It may be appropriate to consider psychodynamic psychotherapy for patients with mild to moderate depressive illness in more complex cases where there is co-morbidity with personality disorders.\textsuperscript{76} It should not be offered to patients suffering from severe depressive disorder, especially if psychotic symptoms are present. Treatment is lengthy but some benefits are seen while in therapy, including a reduction in treatment-seeking and need for medication. Due to the nature of psychodynamic psychotherapy, there is a paucity of trials with adequate methodology and statistical power to show efficacy or otherwise of this treatment in depression.

**NICE guidance**

NICE, an organization that produces guidance on public health, health technologies and clinical practice for England and Wales, released the guideline *Depression: Management of Depression in Primary and Secondary Care* in December 2004.\textsuperscript{20} The guideline’s recommendations are presented via a stepped care model (Figure 39.1).

Stepped care is a model of healthcare delivery that has been applied to a range of disorders, particularly those of a chronic nature. There are two main features of a stepped care system. First is that the recommended treatment offered for the condition should be the least intensive of those currently available but still likely to provide significant health gain. More intensive treatments are reserved for patients who do not benefit from simpler first-line treatments. Second, stepped care is self-correcting, in that the results of treatments and decisions about treatment provision are monitored systematically, and changes are made (‘stepping up’) if current treatments are not achieving significant clinical improvement.

In the NICE depression guideline, there are five steps with each step up, representing increased complexity of intervention. With higher steps, it is assumed that interventions in previous steps have been considered or implemented before the higher step is used.

The key priorities for implementation recommended in the NICE guideline are as follows:

- Screening for depression in primary care and general hospital settings in high risk groups: NICE recommends use of the following two questions for screening in these settings. The test is negative if both are negative, but if either is positive, further assessment is recommended:
  - During the past month, have you often been bothered by feeling down, depressed or hopeless?
  - During the past month, have you often been bothered by having little interest or pleasure in doing things?
  - Watchful waiting as opposed to intervention is recommended as the initial step for patients with mild depression.

- Antidepressants are not recommended for the initial treatment of mild depression, because the risk/benefit ratio is poor.
- Guided self-help based on cognitive-behavioural therapy is recommended for patients with mild depression.
- Short-term psychological treatment is recommended for patients with mild and moderate depression.
- An SSRI is recommended as the first-line antidepressant if one is to be prescribed, because SSRIs are as effective as tricyclic antidepressants but less likely to be discontinued due to side effects.
- Patients should be informed about discontinuation symptoms if antidepressants are prescribed.
- A combination of antidepressants and individual CBT should be considered for patients at initial presentation with severe depression.
- Maintenance treatment with antidepressants for 2 years is advised for patients who have had two or more depressive episodes in the recent past and who have experienced significant functional impairment during the episodes.
- A combination of antidepressant medication and CBT should be considered for patients with treatment-resistant depression.
- CBT should be considered for patients with recurrent depression who have relapsed despite antidepressant treatment.

NICE makes a number of specific recommendations for treatment-resistant depression. Venlafaxine may be considered for patients who have failed two adequate trials of alternative antidepressants. When prescribing venlafaxine, be aware of the increased likelihood of patients stopping treatment because of side effects, its higher cost, its high propensity for discontinuation symptoms if stopped abruptly, and its toxicity in overdose. NICE recommends that an electrocardiogram (ECG) is carried out and blood pressure checked before starting venlafaxine. NICE recommends that a trial of lithium augmentation should be considered for patients who have failed to respond to several antidepressants. Augmentation of one antidepressant with another, such as addition of mirtazapine or mianserin to SSRIs, should be considered, but patients on these combinations should be monitored carefully, particularly for serotonin syndrome. NICE recommends phenelzine for patients who have failed to respond to alternative antidepressants and are prepared to tolerate the side effects and dietary restrictions, and the risk of toxicity in overdose has been considered.

NICE specifically recommends against augmentation of antidepressants with carbamazepine, lamotrigine, buspirone, pindolol, valproate or thyroid hormone due to insufficient evidence of efficacy and, particularly in relation to carbamazepine, significant risk of adverse effects due primarily to effects on the metabolism of other
medications. Dosulepin is also not recommended due to increased cardiac risk and toxicity in overdose.

BIPOLAR AFFECTIVE DISORDER

Introduction

The Greek physician Aretaeus of Cappadocia (c. AD 81–138) is credited with the first description of what is now known as bipolar affective disorder. The German psychiatrist Emil Kraepelin's distinction between manic–depressive psychosis and dementia praecox (schizophrenia) in the late 1800s was an enormous breakthrough in the understanding of bipolar disorder. Kraepelin did not distinguish between patients with psychotic unipolar depression and patients with both mania and depression. The understanding of unipolar depression and bipolar affective disorder as separate disease entities came in the 1960s from the work of Leonard and Angst.

Clinical features of mania

Typical features of mania include:

- elevated mood (excitement usually not in keeping with the current situation), but also commonly irritability and aggression, especially if confronted;
- increased self-esteem, which may manifest as grandiosity, inappropriate optimism, overfamiliarity and reduced social inhibition;
- increased energy manifesting as decreased need for sleep, overactivity, racing thoughts and pressured speech;
- distractibility and reduced attention span;
- inappropriate behaviour, particularly engagement in activities that are high risk for detrimental consequences, such as reckless spending, inappropriate sexual encounters and dangerous driving;
- significant disruption to occupational functioning and in family and social life.

Patients with mania may also experience dysphoria and some depressive symptoms. Sometimes they become suspicious. Psychotic symptoms can occur in more severe manic episodes. Patients can present with delusions, which are nearly always mood-congruent, and hallucinations. Some grandiose ideas can be delusional, such as of having a special role or power, and frequently have a religious content. Persecutory delusions can develop from extreme suspiciousness.

Due to the severity of disruption in functioning and the potential serious consequences, mania usually requires an admission to hospital, sometimes with compulsory detention.

Hypomania

Hypomania occurs when symptoms are less severe and do not meet criteria for mania, although mood during a hypomanic episode is still clearly different from the individual’s usual mood. Patients with hypomania do not require hospitalization (DSM-IV criteria) and there are no psychotic symptoms present. The disturbance in a hypomanic episode is not severe enough to cause marked impairment in social and occupational functioning. There is often increased productivity or creativity, although distractibility and poor concentration may lead to impaired social or occupational functioning.

Clinical features of depression in bipolar disorder

In bipolar disorder, depressive episodes usually present with low mood, loss of interest and enjoyment, reduced energy, poor concentration, disturbed sleep and loss of appetite. Confidence and self-esteem are usually low, and hopelessness and ideas of guilt may be present. Psychotic symptoms may occur in severe episodes, and these are usually mood-congruent.

In comparison with unipolar depression, bipolar depression may be more likely to present with melancholic symptoms such as worthlessness, psychomotor retardation and mood-congruent psychotic symptoms. Atypical features such as hypersomnia are more often present.

Course

Depressive episodes in bipolar disorder are typically shorter than in unipolar depression, but they are usually less responsive to treatment.

Clinical features of a mixed affective episode

Manic or hypomanic symptoms occur along with depressive symptoms within the same episode of illness. Depressive symptoms and symptoms of mania or hypomania may alternate from day to day or even from hour to hour. A typical episode may consist of depressive mood being accompanied by increased activity and pressured speech. Manic symptoms can be accompanied by loss of energy and libido.

Course

Mixed affective episodes can develop in isolation or may evolve from a manic or depressive episode. Mixed affective
episodes last from weeks to several months. They may resolve back to euthymia or may evolve into a depressive episode or, much less commonly, into a manic episode.

**Clinical features of rapid-cycling bipolar disorder**

The term ‘rapid cycling’ is applied to bipolar disorder when four or more separate mood episodes occur within a 12-month period. Apart from their frequency, the mood episodes are no different from mood episodes that occur in non-rapid-cycling bipolar disorder. Of patients with bipolar disorder seen in mood clinics, it is estimated that 10–20 per cent will have rapid cycling. A rapid-cycling pattern is seen predominantly in women. This pattern can occur at any time during the course of bipolar disorder and is associated with a poorer long-term prognosis. In some individuals it can be associated with antidepressant use.

**Course of bipolar disorder**

Bipolar disorder is a recurrent condition, with 90 per cent of individuals who have a manic episode having a future manic episode. Manic episodes frequently precede or follow depressive episodes, and in many patients a clear pattern is evident. Studies suggest that, without long-term treatment, patients with bipolar I disorder would average four episodes over a 10-year period. The interval between episodes for both bipolar I and bipolar II disorder tends to decrease as the age of the individual increases, and in both conditions 5–15 per cent of individuals have four or more mood episodes within a given year (rapid cycling). Individuals who have psychotic symptoms during manic episodes are more likely to have psychotic symptoms in subsequent manic episodes.

Although most individuals with bipolar disorder have resolution of symptoms between episodes, 20–30 per cent of patients with bipolar I disorder and 15 per cent of patient with bipolar II disorder continue to suffer mood symptoms. Up to 60 per cent of patients with bipolar I disorder have ongoing social impairment between episodes.

**Epidemiology**

The epidemiology of bipolar disorder is complicated by issues related to defining cases. As with other mental disorders, defining cases depends on imposing discrete diagnoses on a symptom continuum of varying severity and duration. With case definition being fundamental to epidemiology, variation in defining cases has influence on prevalence rates and understanding of risk factors. Diagnosis in individual patients may change over time due to changing presentation of symptoms. As bipolar disorder can be diagnosed only after a manic, hypomanic or mixed episode, a significant number of patients who present initially with depressive episodes are subsequently diagnosed with bipolar disorder following a manic pole episode. Additionally, although many patients have classic presentations, many do not. A patient may initially be considered to have bipolar disorder but over time the pattern of illness may become more clearly that of schizoaffective disorder and the diagnosis changed accordingly. In an adult cohort of patients experiencing a first psychotic episode, only 75 per cent kept their diagnosis of bipolar disorder after 6 months. Therefore, the true incidence of bipolar disorder can only be estimated retrospectively.

Diagnosis also depends on interpretation of symptoms. The boundaries of bipolar disorder are not clear. Bipolar disorder with marked psychotic features overlaps with schizoaffective disorder. Patients with recurrent depressive episodes and mild or brief episodes of hypomania may or may not be diagnosed with bipolar disorder. Bipolar II disorder is receiving increasing recognition and as a result is being diagnosed more frequently. There are moves to lower the threshold for diagnosis of hypomania, which would result in increasing the prevalence of bipolar II disorder and reducing the prevalence of recurrent depressive disorder. There is an overlap of bipolar disorder with some personality disorders such as borderline personality disorder.

Prevalence rates for bipolar disorder across different studies are considerably more consistent than for depression. Large population studies such as the US National Institutes of Mental Health (NIMH) Epidemiologic Catchment (ECA) Study and the National Comorbidity Survey (NCS) (carried out in the USA) have shown a lifetime prevalence of bipolar disorder of 0.3–1.5 per cent. The lifetime prevalence of bipolar I disorder (0.8%) is perhaps slightly higher than that of bipolar II disorder (0.5%), although increasing awareness of bipolar II disorder may increase the rate of this diagnosis. Poor recognition of and uncertainty about diagnosis of hypomania may currently result in underdiagnosis of this condition.

Studies show the 6-month prevalence of bipolar disorder to be only slightly lower than the lifetime prevalence reflecting a high degree of chronicity and recurrence. The male to female ratio is approximately equal. The median age of onset is in late adolescence and early twenties, but a significant proportion of later-onset cases brings the mean age of onset up to late twenties. There is speculation that many patients actually exhibit symptoms in childhood but are not diagnosed. Ninety per cent of patients have their first episode before the age of 50 years. In patients who present later in life, organic factors are more likely to be involved.

A significant number of patients having their first manic, hypomanic or mixed affective episode have experienced a previous depressive episode. The risk of patients with depression having a subsequent manic pole episode and conversion to a diagnosis of bipolar disorder appears to increase in proportion to the severity of the depression. Of patients presenting with depression requiring hospitalization, the estimated risk of a subsequent manic episode is
5 per cent. Factors in patients with depression that are associated with an increased likelihood of subsequent conversion to a diagnosis of bipolar disorder include early age of onset, postpartum onset and depression with psychomotor retardation.

There is some divergence between Europe and North America in the diagnosis of children and adolescents with bipolar disorder. Rates of diagnosis of bipolar disorder in children and adolescents in North America are considerably higher than in Europe.

**Risk factors**

Genetic factors are probably the predominant factor in relation to lifetime vulnerability to bipolar disorder, but other factors are more important as risk factors for determining when episodes of illness will occur. Genetic factors are discussed in the earlier section Aetiology of affective disorders.

There appears to be a seasonal pattern to bipolar disorder, with studies showing an increase in the number of manic episodes in the late spring and early summer. Disruption to biological rhythms such as from international travel or shift work is associated with increased risk of manic or depressive episodes. The postpartum period is a time of increased risk of illness for patients with bipolar disorder. Adverse life events are a risk factor for both depressive and manic episodes. Organic disease of the central nervous system may be a risk factor, particularly for late onset bipolar disorder.

Family studies have suggested that many patients who go on to be diagnosed with bipolar disorder exhibit subsyndromal symptoms for some time before they develop diagnostic illness. Therefore, there are patients who exhibit mood swings and cyclothymia who are probably at higher risk of subsequent bipolar disorder.

**Co-morbidity**

Co-morbid psychiatric conditions are common in patients with bipolar disorder. Studies have shown considerably increased rates of alcohol and substance misuse and dependence. Panic disorder and, to a lesser extent, anxiety disorder are also more common in patients with bipolar disorder.

**Impact**

The economic cost to society of bipolar disorder is huge. The ECA study concluded that, over a 6-month period, about 10 per cent of patients with bipolar disorder received in-patient treatment. The NCS study showed that 45 per cent of patients with bipolar disorder had received psychiatric treatment within the past 12 months.

**Suicide**

Individuals with bipolar disorder are at substantially increased risk of completed suicide than the general population. A meta-analysis of studies containing a total of 2257 cases of suicide by Harris and Barraclough gave an SMR for suicide in bipolar disorder of 15 compared with the general population (SMR = 1.0). Nearly a third of patients with bipolar disorder admit to at least one previous suicide attempt. It is estimated that 10–15 per cent of patients with bipolar I disorder die from suicide. Nearly 80 per cent of patients with bipolar disorder who commit suicide have experienced a depressive episode immediately before death. Mixed affective states are associated with a particularly high risk of suicide.

**Diagnosis**

**Classification systems**

The two widely used classification systems for making the diagnosis of bipolar disorder are ICD-10 and DSM-IV.

**ICD-10**

The ICD-10 diagnoses for manic and mixed episodes and bipolar affective disorder are as follows:

- Manic episode (F30)
  - Hypomania (F30.0)
  - Mania without psychotic symptoms (F30.1)
  - Mania with psychotic symptoms (F30.2)
  - Other manic episodes (F30.9)
- Manic episode, unspecified
- Other mood disorders (F38)
  - Mixed affective episode (F38.00)
  - Bipolar affective disorder (F31)
    - Bipolar affective disorder, current episode hypomanic (F31.0)
    - Bipolar affective disorder, current episode manic with/without psychotic symptoms (F31.1/F31.2)
    - Bipolar affective disorder, current episode mild/mod depression (F31.3)
    - Bipolar affective disorder, current episode severe depression with or without psychotic symptoms (F31.4/F31.5)
    - Bipolar affective disorder, current episode mixed (F31.6)
    - Other bipolar affective disorders (F31.8)
    - Bipolar affective disorder, unspecified (F31.9).

ICD-10 requires a manic episode of any of the three severities as requiring elevated mood and an increase in the quantity and speed of physical and mental activity. The diagnosis of manic episode should be used only for a single episode. If there are previous or subsequent affective episodes, then the diagnosis should be bipolar affective disorder.

Hypomania is described as a lesser degree of mania but too persistent and marked for the diagnosis of cyclothymia. It requires persistent mild elevation of mood, increased levels of energy with increased activity, and usually strong feelings of wellbeing in physical and mental efficiency. Other features include talkativeness, overfamiliarity, increased sociability and sexual drive, and reduced need for sleep. Sometimes irritability and antisocial behaviour replace euphoric sociability. Concentration and attention
are usually reduced. ICD-10 states that symptoms are severe enough to cause interference in social function but not to severely disrupt work or cause social rejection.

A diagnosis of mania requires elevated mood out of keeping with the individual’s circumstances, with increased energy, overactivity, pressure of speech and reduced need for sleep. There is also social disinhibition, reduced attention span, distractibility, and grandiosity or overoptimism. There may be perceptual disorders such as subjective hyperacusis or increased appreciation of colour or texture. Symptoms must be present for at least 1 week and severe enough to cause almost complete disruption of ordinary work and social function.

Mania with psychotic symptoms is used when a patient fulfilling the criteria for a manic episode also has delusions or hallucinations. In these circumstances the manic symptoms tend to be severe. The delusions should be specified as congruent or incongruent with the mood.

A mixed affective episode requires at least 2 weeks of a mixture, sometimes with rapid alternation (usually within a few hours), of hypomanic, manic and depressive symptoms.

Bipolar affective disorder requires at least two episodes of affective disorder, one of which must be manic, hypomanic or mixed.

**DSM-IV**

DSM-IV sets out criteria for the diagnosis of mood episodes and bipolar disorders and uses specifiers to further categorize the severity of the current clinical state:

- Mood episodes
  - Major depressive episode
  - Manic episode
  - Mixed episode
  - Hypomanic episode
- Bipolar disorders
  - Bipolar I disorder
  - Bipolar II disorder
  - Cyclothymic disorder
  - Bipolar disorder not otherwise specified.

The following specifiers are used to describe the clinical status of the current or most recent mood episode:

- Mild, moderate, severe with/without psychotic features
- In partial remission
- In full remission.

The following specifiers are used to indicate the pattern of episodes in bipolar disorders:

- With/without full interepisode recovery
- With rapid cycling.

Manic episode criteria in DSM-IV are as follows:

- A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).
- During the period of mood disturbance, at least three of the following symptoms have persisted (four if mood is only irritable) to a significant degree:
  - Inflated self-esteem and grandiosity
  - Decreased need for sleep
  - More talkative than usual or pressure to keep talking
  - Flight of ideas or subjective experience that thoughts are racing
  - Distractibility
  - Increase in goal-directed activity
  - Excessive involvement in pleasurable activities that have a high potential for painful consequences.

The symptoms do not meet criteria for mixed episode.

The mixed disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

The symptoms are not due to the direct physiological effects of a substance.

Mixed episode criteria in DSM-IV are as follows:

- The criteria are met for both a manic episode and for a major depressive episode nearly every day during at least a 1-week period.
- The mood disturbance is sufficiently severe to cause marked impairment in occupational function or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
- The symptoms are not due to the direct physiological effects of a substance.

Hypomanic episode criteria in DSM-IV are as follows:

- A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 4 days, that is clearly different from the usual non-depressed mood.
- During the period of mood disturbance, at least three of the following symptoms have persisted (four if mood is only irritable) to a significant degree:
  - Inflated self-esteem and grandiosity
  - Decreased need for sleep
  - More talkative than usual or pressure to keep talking
  - Flight of ideas or subjective experience that thoughts are racing
  - Distractibility
  - Increase in goal-directed activity
  - Excessive involvement in pleasurable activities that have a high potential for painful consequences.

The episode is associated with an unequivocal change in function that is uncharacteristic of the person when not symptomatic.

The disturbance in mood and the change in functioning are observable by others.

The episode is not severe enough to cause marked impairment in social or occupational functioning, or to
necessitate hospitalization, and there are no psychotic features.

- The symptoms are not due to the direct physiological effects of a substance.

Bipolar I disorder requires the occurrence of one or more manic or mixed episode with or without a history of major depressive episodes.

Bipolar II disorder requires the occurrence of one or more major depressive episodes with at least one hypomanic episode.

The rapid-cycling specifier can be applied to bipolar I and bipolar II diagnoses. The criteria for this are that there have been at least four episodes of a mood disturbance in the previous 12 months that meet the criteria for a major depressive, manic, mixed or hypomanic episode. Episodes must be separated by partial or full remission for at least 2 months or a switch to an episode of opposite polarity.

Screening tools and rating scales

A number of instruments have been developed for use as diagnostic tools or severity rating scales. There is little evidence about use of screening tools for early detection of bipolar disorder. The gold standard against which to compare diagnostic tools is clinical assessment by experts, although even this is not perfectly consistent. Table 39.1 shows the diagnostic scales for bipolar disorder.87

Medication-induced mania/hypomania

A range of medications may induce symptoms of mania, including the following:

- Antidepressants: all antidepressants may trigger a manic episode, although the risk, many clinicians believe, is less with SSRIs and bupropion. Currently DSM-IV excludes mania induced by antidepressants as being diagnostic for bipolar disorder, but it is possible that patients who develop mania as the result of antidepressants do actually have bipolar disorder
- Other psychotropic medication: mania has been observed to result from treatment with some antipsychotics, mood stabilizers, anti-epileptic medications and stimulants (methylphenidate)
- Antiparkinsonian medications, including amantadine, bromocriptine, levodopa and Procyclidine
- Corticosteroids and anabolic steroids
- Respiratory medications, including salbutamol, aminophylline and ephedrine
- Analgesics, including opioids, nefopam and indometacin
- Antimicrobial agents, including some tuberculosis medications, zidovudine, dapsone, chloroquine and clarithromycin
- Others, including cimetidine, metoclopramide, baclofen, cyclizine and interferon.

Investigations

There are no specific tests that can be used to diagnose mania. Investigations are used mainly to exclude other independent problems or to identify causes of the manic symptoms.

Physical checks usually performed for a patient with mania include the following:

- A thorough physical examination
- Blood tests, including full blood count, urea, creatinine, electrolytes, serum calcium, liver function tests, thyroid function tests, glucose, ESR and plasma viscosity. More specific tests may be indicated by features of the history, findings on clinical examination or results of the initial tests
- Drug screen.
In specific circumstances, such as when there is a high index of suspicion of intracranial pathology, late onset or fluctuation course, it is appropriate to also arrange the following:

- Computed tomography (CT) or magnetic resonance imaging (MRI) scan of the brain
- Electroencephalogram (EEG).

**Management**

**General principles**

Treatment of bipolar affective disorder is aimed at treating acute episodes, reducing the severity and frequency of future episodes, and improving psychosocial functioning between episodes. A number of different treatment strategies can be used to substantially decrease morbidity and mortality. Management consists of pharmacological treatments, psychological therapies, and education for the individual, family, and carers. It is important that the management plan not only covers treatment of the acute episode but also includes long-term strategies to maintain optimum mental health and social function between episodes.

The establishment and maintenance of collaborative relationships with patients with bipolar disorder and their families and carers is fundamental to achieving the above goals of treatment. When appropriate, patients should be encouraged to involve their families and carers in their treatment. They should be given full and clear information about the illness and treatment at each step, and this may include the use of self-help resources and support groups. Patients and carers should be advised about self-monitoring for early warning signs of relapse, given education about lifestyle that may help to reduce relapse such as sleep hygiene and work patterns, and given information about coping strategies. Patients and carers must be aware of a clear route of contact to services for times of relapse and crisis.

Patients and their carers often have useful knowledge gained from their experience of previous episodes that can be taken into account when planning future management. Patients should be given the opportunity to make informed decisions about their care and treatment. Respect for patients’ preferences is likely to improve concordance. Patients should be encouraged to develop advance directives, particularly if they have had severe episodes or detention under mental health legislation. An advance directive should contain details of early warning signs from the patient’s perspective that may indicate a possible relapse and the patient’s preferred course of action in the event of a relapse, including who to contact and wishes around medication. To be useful, advance directives need to be reviewed regularly, recorded in the patient’s care plan, and copied to the patient, care coordinator and GP.

It is particularly important to maintain a collaborative relationship with patients and carers and to provide education about the illness and support during the maintenance phase. Patients frequently discontinue treatment when they feel well, but relapses are common. Patients are also frequently unwilling to accept anti-manic medication at times when they have higher levels of activity, especially if their performance is not impaired by distractibility.

Clinicians caring for patients with bipolar disorder should take account of the needs of patients’ family members and carers. Regular assessment should be made of the impact of the disorder on relationships, the welfare of dependent children, and the physical, social, and mental health needs of carers. Families and carers may benefit from contact with support groups.

The place of treatment for a patient with bipolar disorder having an acute episode will depend on the nature of the episode, severity of symptoms, risk to the patient or others, and availability of support in the community. It is often possible to treat hypomanic and severe depressive episodes in the home environment, with the support of crisis intervention teams. Hospitalization may be required to protect the patient from physical harm to self or others, to protect against the consequences of injudicious behaviour, or to avoid overstimulation. It must be remembered that mania can be a life-threatening condition, not only from suicide but also from the complications of exhaustion, dehydration and hyperthermia. Hospitalization may have to be against the patient’s wish, using mental health legislation.

**Treatment of acute manic and hypomanic episodes**

Manic patients frequently have marked behavioural disturbance, and initially treatment may need to focus on this. Very disturbed patients should be managed in a supportive environment with minimal stimulation balanced against provision of facilities for using up excess energy. Using distraction techniques and avoiding confrontation are important. The patient’s physical health needs to be reviewed regularly, particularly checking for adequate hydration. Benzodiazepines such as lorazepam and antipsychotics, either alone or in combination, may be required to control severe behaviour disturbance. Restraint and rapid tranquilization using intramuscular medication may be required.

Treatment of mania and hypomania is predominantly based on pharmacotherapy. Both antipsychotics and mood stabilizers are effective. Patients with bipolar disorder may be quite sensitive to antipsychotics, so it is appropriate to start with a low dose. Benzodiazepines are useful in the short term for ameliorating behavioural disturbance and agitation, and their addition allows antipsychotic medications to be initiated at a low dose rather than at tranquilizing doses, which are associated with significant side effects and increased risk of sudden death due to their effects on myocardial transmission. Medications initiated in the acute phase are often continued as anti-manic prophylaxis, and this should be taken into account when treatment is initiated.

Carbamazepine has been used for long-term treatment of bipolar disorder, but recent trials have shown it to be
substantially less beneficial than lithium at preventing relapse. Enzyme induction can be another complicating factor with carbamazepine. It is no longer generally recommended for routine use in acute mania.

If a patient is taking antidepressant medication at the onset of an acute manic episode, the antidepressant should be stopped. The rate of withdrawal of antidepressant medication depends on balancing the severity of manic episode with the likelihood of discontinuation symptoms.

If the patient is not already taking anti-manic prophylaxis, the following considerations should be taken into account when selecting anti-manic medication:

- Previous responses to anti-manic medication.
- Antipsychotic medications may be more effective when there are severe symptoms or behavioural disturbance. The side effects of weight gain and metabolic disturbance should be taken into account, especially in individuals at risk of diabetes.
- Valproate should generally be avoided in women of childbearing potential.
- Lithium has a slower onset of action, usually taking a week to achieve a response, so generally it should be avoided if symptoms are severe.
- Lithium has a narrow therapeutic window and requires monitoring of blood levels, and so it should be avoided in patients who are unlikely to be able to cooperate with this.

When patients develop a manic episode while being prescribed anti-manic medication, the following steps should be taken:

- Check concordance with medication.
- If on antipsychotic prophylaxis, consider increasing the dose. If there is no response to this, consider adding lithium or valproate.
- If on lithium, check serum levels and increase the dose if needed in order to achieve serum levels of 0.8–1.0 mmol/L. If there is inadequate response to optimum lithium levels, consider augmentation with an antipsychotic.
- If on valproate, increase the dose until there is clinical improvement or side effects limit further dose increase. Patients on doses higher than 45 mg/kg should be monitored carefully for liver toxicity. If there is inadequate response to maximum tolerated doses of valproate, consider augmentation with an antipsychotic.
- If the patient is prescribed carbamazepine for manic prophylaxis, the dose should not be increased routinely, but addition of an antipsychotic should be considered.

**Treatment of acute depressive episodes in bipolar disorder**

The drug treatment of depressive episodes in bipolar disorder is complicated by limited information from well-conducted randomized controlled trials. The main risk when treating depressed patients who have bipolar disorder is of causing a ‘switch’ to mania. Current guidance in the UK recommends prescribing anti-manic medication concurrently if antidepressants are to be prescribed.

In patients who are on anti-manic medication at the time of developing a depressive episode, concordance should be checked and the dose increased if necessary.

If the depressive episode is mild, it is often appropriate to delay medication changes, particularly if previous episodes of mild depression have not developed into more severe depression, because the episode may be self-limiting or may respond to supportive psychosocial measures. If symptoms persist, or if there is perceived to be significant risk of deterioration at the initial assessment, the patient should be treated in the same way as patients with moderate or severe depressive episodes.

Treatment for moderate or severe depressive episodes in patients with bipolar disorder generally involves initiation of an antidepressant. SSRI antidepressants are considered to be less likely than tricyclic antidepressants to cause switching to mania and so are generally recommended as first-line drugs. Antidepressant treatment should be initiated at a low dose and titrated up gradually. If an antidepressant is being initiated and the patient is not already taking anti-manic medication, this should also be initiated, with the choice of anti-manic medication being based on the same considerations as when starting it for a manic episode.

Because of the risk of causing a switch to mania in bipolar disorder, consideration should be given to discontinuing antidepressant therapy soon after the patient achieves remission from depressive symptoms and sometimes even symptoms have been less severe for a few weeks. The antidepressant should be withdrawn slowly over a number of weeks. Anti-manic therapy should be continued.

Antidepressant therapy should generally be avoided in patients with rapid-cycling bipolar disorder or a recent hypomanic episode because these patients are at particularly high risk of having a manic switch.

An alternative to starting an antidepressant may be the addition of quetiapine as monotherapy or in addition to existing antimanic medication if it is not an antipsychotic. Two randomized controlled trials showed quetiapine to be effective monotherapy for depression in both bipolar I disorder and bipolar II disorder. Quetiapine is not associated with switching to mania.68

Lamotrigine has been shown to be effective in treating bipolar depression and is commonly prescribed for this in North America. Studies have shown that lamotrigine may be effective prophylaxis against future episodes and does not cause switching or rapid cycling. Lamotrigine is increasingly prescribed for patients with a history of rapid-cycling bipolar disorder. Evidence supports its use in bipolar II disorder, but current UK guidelines recommend against its use in bipolar I disorder.

When depression is resistant to treatment, consider the following:

- Check concordance with medication.
- Check for evidence of substance misuse, ongoing psychosocial stressors, and co-morbid disorders such as anxiety or severe obsessional symptoms.
- Review physical health.
- Consider individual psychological therapy focused on depressive symptoms.
- Increase antidepressant therapy up to maximal recommended dose.
- Change antidepressant therapy. Mirtazapine and venlafaxine are recommended in UK guidance. There is some evidence that venlafaxine may be more likely than some other antidepressants to cause a switch to mania from studies comparing it with sertraline and bupropion.
- Consider addition of quetiapine or olanzapine if the patient is not already taking one of these.
- Consider addition of lithium.
- Consider using ECT.

Treatment of mixed episodes

Patients with a mixed affective episode should be treated in the same way that a manic episode is treated. Antidepressants should be avoided, as they may exacerbate symptoms.

Rapid-cycling bipolar disorder and acute treatment

Although the general principles of care are the same as with patients with non-rapid-cycling bipolar disorder, there are particular considerations that should be taken into account. The main risk is inducing a switch from one pole to the other. This is particularly likely when treating depressive episodes. Antidepressants should generally be avoided, as they are particularly likely to cause a switch to mania in these patients. It is recommended to focus on long-term treatment, putting less emphasis on the treatment of individual episodes. Trials of medication should be longer than usual – usually for a minimum of 6 months.

Electroconvulsive therapy in bipolar disorder

ECT can be useful in some patients in order to achieve rapid improvement in severe symptoms of depression or mania. It is generally indicated only when an adequate trial of other treatment options has been ineffective or when the episode is severe enough to be potentially life-threatening. When considering ECT, the risks of anaesthetic and coexisting medical conditions must be taken into account, along with the risk of cognitive impairment and causing a switch to the other affective pole. Lithium therapy in combination with ECT has been associated with increased risk of memory impairment and acute confusion, and so some authorities recommended a reduction in dose or withdrawal of lithium therapy before giving ECT, or starting ECT with a lower electrical stimulus.88 Anticonvulsants and benzodiazepines raise the seizure threshold and therefore oppose the desired effect of the ECT, and so it is important to monitor the length of fits carefully if these medications are being prescribed.

Long-term management of bipolar disorder

Long-term management of bipolar disorder is aimed at preventing or reducing the frequency of acute episodes, minimizing symptoms between episodes and optimizing social functioning. It should include pharmacological and psychological treatment, education about the illness, and social interventions.

There is disagreement about the appropriate label for long-term medication in bipolar disorder. ‘Anti-manic’ treatment or prophylaxis and ‘mood stabilizer’ are terms that are also used to describe long-term treatment.

Long-term medication is recommended in the following situations:

- After a manic episode that was associated with significant risk and adverse consequences
- When a patient with bipolar I disorder has had two or more acute episodes
- When a patient with bipolar II disorder has significant functional impairment, is at significant risk of suicide, or has frequent episodes.

Long-term medication generally should be continued for a period of at least 2 years after an acute episode. Long-term treatment may be appropriate if the patient has a history of frequent relapses or very severe episodes, or there are ongoing risk factors for relapse such as psychosocial stressors or substance misuse.

It is important that patients are involved in decisions about long-term medication, because there are considerable risks of adverse effects from most of the medications used. Patients should be educated about bipolar disorder and the risks of future episodes and be made aware of the possible harms from long-term medication. Patient participation in decision-making is likely to improve concordance.

A number of medications are now used for long-term treatment of bipolar disorder. Lithium was the first psychotropic agent shown to prevent recurrent episodes, but valproate, antipsychotics, carbamazepine and lamotrigine are also used. Current guidance for England and Wales recommends lithium, olanzapine or valproate for first-line therapy. If there are frequent relapses or there are ongoing symptoms causing functional impairment, alternative monotherapy or combination therapy from within this group should be considered.

The following factors must be taken into account when choosing medication for long-term bipolar treatment:

- Patient choice
- Previous response to treatment
- Clinical history, including affective pole and frequency of episodes
- Physical health, including renal function, obesity and risk of diabetes
- Whether the patient is of childbearing potential
- Likelihood of being able to cooperate with drug monitoring

Long-term medication generally should be continued for a period of at least 2 years after an acute episode. Long-term treatment may be appropriate if the patient has a history of frequent relapses or very severe episodes, or there are ongoing risk factors for relapse such as psychosocial stressors or substance misuse.

It is important that patients are involved in decisions about long-term medication, because there are considerable risks of adverse effects from most of the medications used. Patients should be educated about bipolar disorder and the risks of future episodes and be made aware of the possible harms from long-term medication. Patient participation in decision-making is likely to improve concordance.

A number of medications are now used for long-term treatment of bipolar disorder. Lithium was the first psychotropic agent shown to prevent recurrent episodes, but valproate, antipsychotics, carbamazepine and lamotrigine are also used. Current guidance for England and Wales recommends lithium, olanzapine or valproate for first-line therapy. If there are frequent relapses or there are ongoing symptoms causing functional impairment, alternative monotherapy or combination therapy from within this group should be considered.

The following factors must be taken into account when choosing medication for long-term bipolar treatment:

- Patient choice
- Previous response to treatment
- Clinical history, including affective pole and frequency of episodes
- Physical health, including renal function, obesity and risk of diabetes
- Whether the patient is of childbearing potential
- Likelihood of being able to cooperate with drug monitoring
• Cognitive state
• Risk of overdose
• Treatment advantages and side-effect profiles of the different medications.

Chronic and recurrent depressive symptoms may require long-term antidepressant therapy. This should generally be considered only for patients who have not had a recent manic or hypomanic episode, and it should usually be in combination with prophylactic medication. SSRI antidepressants at the minimum therapeutic dose are probably safest. Lamotrigine may be appropriate for patients with bipolar II disorder who have recurrent depression.

Lithium therapy
Lithium was discovered to be useful in treating mania by the Australian psychiatrist John Cade in 1949, and it has been used to treat bipolar disorder ever since. There has been considerably more research into the effects of lithium treatment than other medications used in bipolar disorder. Lithium is effective at preventing manic and depressive episodes, although it is more effective at preventing mania than depression. A review in 2001 showed that patients on lithium have a 1-year relapse rate of 40 per cent compared with 61 per cent for placebo. A systematic review and meta-analysis in 2004 calculated that the number need to treat (NNT) with lithium in order to prevent relapse into mania or depression is 10 and 14, respectively. Rebound mania following rapid discontinuation of lithium occurs in 50 per cent of patients, and intermittent lithium therapy may worsen the natural course in bipolar disorder, so it is generally appropriate to start lithium only if there is intention to continue with it long-term and concordance is likely. The current recommendation for duration of therapy is at least 3 years. Lithium should be discontinued over at least a month to reduce the chances of rebound mania.

Long-term treatment with lithium has been shown to be associated with a reduced rate of suicide, although it is unclear whether this is due to the effects of lithium or the closer monitoring that patients taking lithium require.

Lithium has a narrow therapeutically index, requiring monitoring of serum levels on a regular basis. Common side effects include mild thirst, polyuria and a fine tremor. Longer-term adverse effects that occur not uncommonly are lithium-induced hypothyroidism and nephrotoxicity, both of which require regular blood test monitoring.

Lithium interacts with a number of other medications, co-administration of which can rapidly induce toxic levels of lithium or be associated with adverse reactions. Commonly encountered interacting medications include diuretics, angiotensin converting enzyme (ACE) inhibitors, non-steroidal anti-inflammatory drugs (NSAIDs), haloperidol, carbamazepine and SSRI antidepressants.

Valproate
Valproate has been shown to be effective in the treatment of acute mania, although there is less good-quality evidence of efficacy for long-term prevention of relapse in bipolar disorder. Side effects include significant weight gain and possibly a rare risk of hepatic failure and of causing polycystic ovaries. Valproate is teratogenic and should routinely be avoided in women of childbearing potential.

Antipsychotics
There is increasing evidence of the efficacy of antipsychotics in long-term treatment of bipolar disorder. Olanzapine, risperidone and quetiapine have the most evidence of efficacy and are the only antipsychotics currently licensed for use in bipolar disorder in the UK. Antipsychotics are associated with weight gain and metabolic effects, including dyslipidaemia, impaired glucose tolerance and hypertension. Patients taking these medications should have regular assessment for these effects.

Lamotrigine
There is evidence that long-term treatment with lamotrigine can reduce the risk of depressive episodes in bipolar disorder, but there is less effect against manic episodes. A particular indication for lamotrigine is patients with bipolar II disorders who predominantly have depressive episodes. The rare but serious side effects of bone marrow failure and Stevens–Johnson syndrome need to be considered. Stevens–Johnson syndrome is more likely with rapid dose escalation, high dose and concomitant use of valproate. Lamotrigine is not licensed for use in bipolar disorder in the UK.

Carbamazepine
Carbamazepine was the first medication after lithium to be used routinely for long-term treatment of bipolar disorder. Recent studies have shown it to be substantially less effective than lithium in preventing relapse. Because of this, it is now generally considered a third-line agent.

Psychological therapy in bipolar disorder
There is evidence of efficacy for psychological interventions in the treatment of depression in bipolar disorder, but there is little evidence for psychological treatment in mania, hypomania or mixed affective states.

Structured psychological interventions such as CBT should be considered for patients with bipolar disorder once they are past the acute phase of a relapse, with the aim of reducing the likelihood of future relapses. CBT focuses on conscious cognitive biases that may lead patients to make negative interpretations of events or situations and routines such as sleep–wake cycles, which may impact on mood fluctuations. The interventions aim to enhance patients’ engagement with the environment via a combination of psychoeducation about the disorder and medication, mood monitoring for episode cues and triggers, strategies to help prevent progression when mild symptoms appear, and behavioural activation and cognitive restructuring to improve general coping ability. Compared with mood
Also recommends an annual physical health review, although this is not covered in the 2005 Scottish Intercollegiate Guidelines Network guideline for bipolar disorder. Table 39.2 shows the recommended annual review checks for patients with bipolar disorder.

It is important that the results of the annual review are shared with appropriate healthcare professionals and that clear responsibility is established for treating any problems that are detected.

### National guidance

In July 2006, NICE published the guideline *Bipolar Disorder: The Management of Bipolar Disorder in Adults, Children and Adolescents, in Primary and Secondary Care.* This was the first time NICE had reviewed this topic, although it had previously released the technology appraisal *Olanzapine and Valproate Semisodium in the Treatment of Acute Mania Associated with Bipolar I Disorder.* NICE’s bipolar disorder guideline is based on the guideline development group’s (GDG) analysis of the best available evidence and takes into account cost-effectiveness information where possible. The GDG acknowledged that there had been an increase in the research of bipolar disorder in the past decade, but it also emphasized the paucity of data in a number of areas and the lack of long-term studies in naturalistic settings.

The NICE guideline sets out a number of general principles relating to working with patients and their families, and considerations relating to specific groups of patients with bipolar disorder. Emphasis is put on the importance of establishing and maintaining collaborative relationships with patients, families and carers, and being accessible at times of crisis. Educating patients to help them manage and live with their condition is mentioned, as is the importance of having an advance directive. Patients with learning disabilities and personality disorders should have the same care as other patients. Psychosocial interventions targeted at drug and alcohol use should be considered for patients with these conditions. The guideline recommends having a robust protocol for transferring patients to services for people older than 65 years, but referral should be based primarily on patient need rather than just chronological age.

Key priorities for implementation set out in the guideline are as follows:

- Valproate should not be prescribed routinely for women of childbearing potential and, if it is chosen, precautions should be taken.
- Lithium, olanzapine and valproate should be considered for long-term treatment, with the choice depending on previous response, risk of relapse, physical health, patient preference, gender and cognitive state.
- If frequent relapses occur or there are ongoing symptoms impairing function, consider switching to alternative monotherapy or adding a second prophylactic agent.

Mood disorders/affective psychoses

- If combination prophylactic therapy is ineffective, consider referral to an expert in bipolar disorder, or a trial of lamotrigine (especially if bipolar II disorder) or carbamazepine.

- If a patient is taking an antidepressant at the onset of acute mania, the antidepressant should be stopped.

- Antidepressant therapy should not routinely be continued long term following a depressive episode because of the risk of switching to mania.

- People with bipolar disorder should have an annual physical health review, normally in primary care. This should include lipid levels in patients over age 40 years, glucose, weight, smoking, alcohol use and blood pressure.

- When diagnosing bipolar I disorder in adolescents, the adult criteria should be used, except that mania must be present, euphoria must be present most of the time on most of 7 days, and irritability may be helpful in making the diagnosis.

DYSTHYMIA

The core clinical feature of dysthymia is a chronically depressed mood that lasts for most of the day and is present most of the time for at least 2 years. Other clinical features that may be found include the same symptoms typically present in depression; however, symptoms are not severe enough to meet the criteria for a diagnosis of recurrent depressive disorder. Patients with dysthymia are usually able to maintain a basic level of social and occupational functioning.

Dysthymia usually begins in early adulthood and lasts for at least several years. It is more common in women.

The ICD-10 classification system places dysthymia within a category of mood disorders called ‘persistent mood disorders’, which also includes cyclothymia. DSM-IV-TR classifies dysthymia as a separate category within mood disorders.

Antidepressant drugs are effective in some patients, and CBT may be beneficial.

CYCLOTHYMIA

The essential feature of cyclothymia is a persistent instability of mood involving periods of hypomanic symptoms and periods of depressive symptoms. The severity and duration of the hypomanic and depressive symptoms are below the threshold for diagnosis of bipolar affective disorder. Mood swings are usually unrelated to life events.

Similar to dysthymia, cyclothymia is included in ‘persistent mood disorders’ in ICD-10 and as the separate category of ‘cyclothymic disorder’ in DSM-IV.

Cyclothymia usually develops early in adult life and has a chronic course. It is more common in individuals who have a family history of bipolar disorder. During the course of the illness there may be superimposed depressive, manic or hypomanic episodes, and in some cases the criteria for a diagnosis of bipolar disorder are met later in life.

Management of cyclothymia includes pharmacological treatment, usually with mood stabilizers. There is no evidence that any particular mood stabilizer is superior. Individuals with cyclothymia may benefit from psychoeducation and insight-oriented psychotherapy to help them understand and live with their condition.

ATYPICAL DEPRESSION

The term ‘atypical depression’ is generally applied to patients with a depressive episode who also have a predominance of the following symptoms:

- Preserved mood reactivity generally enabling the individual to still enjoy certain things but to a lesser extent
- Hyperphagia and weight gain
- Hypersomnia
- Extreme fatigue (‘leaden paralysis’), described as a heavy feeling in the arms and legs
- Tendency to an exaggerated reaction to real or perceived rejection (‘rejection sensitivity’) that must be long-standing and not limited to episodes of mood disturbance and significant enough to cause functional impairment.

Atypical depression is included in ICD-10 in ‘other depressive episodes’, a subgroup of F32, depressive episode. DSM-IV delineates atypical features as an episode specifier, which can be applied to major depressive disorder, bipolar I or II disorder and dysthymic disorder.

There is evidence that the MAOI antidepressant phenelzine may be more effective than other antidepressants for women with atypical depression.

SEASONAL AFFECTIVE DISORDER

Seasonal affective disorder (SAD) was initially proposed and described by Rosenthal in 1984. He proposed that the essential clinical feature is a clear seasonal pattern to recurrent depressive episode with onset in winter in most cases and remission usually in spring. Rosenthal described a clinical picture where symptoms tended to be mild to moderate and included fatigue, hypersomnia, overeating with a craving for carbohydrates, and weight gain. Low self-esteem and decreased functioning are also typical. This clinical pattern was said to be five times more common in females than males.

Neither ICD-10 nor DSM-IV has a separate category for SAD. DSM-IV includes seasonal pattern as one of the spec-
ifers that can be applied to the course of recurrent major depressive disorder and major depressive episodes in both bipolar I disorder and bipolar II disorder. There is a require-
ment that, in order for this specifier to be used, the seasonal pattern must have occurred during the previous 2 years without any non-seasonal episodes within the same time. It is also important to exclude episodes clearly precipitated by psychosocial stressors. A seasonal pattern appears to be more likely in bipolar II disorder.

ICD-10 includes seasonal depressive disorder within recurrent depressive disorder, which is the diagnosis that should be made if a seasonal pattern of depression is observed.

There is ongoing debate over whether SAD is a type of a depressive disorder or whether it should be considered as a description of a specific form of an atypical depressive episode.

Some authors have suggested that light therapy, also known as phototherapy, is beneficial in SAD. This involves exposure to bright artificial light and is thought to be most effective when given early in the morning. The claim is that improvement is usually seen within the first few days; however, in order to prevent relapse, it needs to be continued until the time of the year when natural remission would have occurred. It is inevitably difficult to design a random-
ized controlled trial that can test this using a double-blind methodology. There is limited evidence that antidepressants are effective in the treatment or prevention of SAD.

**SCHIZOAFFECTIVE DISORDER**

Schizoaffective disorder is characterized by equally promi-
nent affective and schizophrenic symptoms that are simulta-
nously present during an episode of illness. The symptoms must meet the criteria for both schizophrenia and either a manic or a depressive episode. The diagnosis should not be used when patients have schizophrenic symptoms and affective symptoms in different episodes of illness. Schizoaffective disorder also needs to be distin-
guished from post-schizophrenic depression, whereby depressive symptoms occur following a psychotic episode. Episodes may be recurrent and can be manic, depressive or mixed. If patients have occasional schizoaffective episodes interspersed between recurrent typical episodes of mania or depression, then the diagnosis of bipolar affective disorder or recurrent depressive disorder rather than schizoaffective disorder should be used.

First-degree relatives of patients with schizoaffective dis-
order have an increased risk of schizophrenia. Some evi-
dence suggests they also have an increased risk of mood disorders.

In schizoaffective disorder, psychotic symptoms are treated in the same way as are patients with schizophrenia. Manic or depressive symptoms are treated in the same way as they are in bipolar disorder.

The prognosis for schizoaffective disorder is generally worse than that for mood disorders but better than that for schizophrenia. Patients typically make a full recovery between episodes, with this being more likely with manic than with depressive schizoaffective episodes. Despite this, schizoaffective disorder is often associated with occupa-
tional and social dysfunction.

**POSTNATAL DEPRESSION**

The majority of women experience some degree of tearful-
ness and emotional lability in the week following child-
birth, and this is commonly known as ‘baby blues’. It is a self-limiting condition and usually lasts for a couple of days.

Postnatal depression is a depressive episode that occurs in women in the postnatal period. ICD-10 allows this diag-
nosis if symptoms begin within 6 weeks of delivery. Although the clinical features are similar to other depres-
sive episodes, there is a particular preponderance for the mother to have worries about her ability to cope with her baby or concerns about her baby’s health. It is now recog-
nized that there is a significant anxiety component to post-
natal depression.

Postnatal depression occurs in 10 per cent of women. Follow-through studies have shown a slight increase in point prevalence at 3–6 months postpartum compared with preg-
nancy, but overall there is little difference in the prev-
ance following childbirth and that in non-pregnant women.

Precipitating factors for postnatal depression tend to include psychological adjustment to the changes following childbirth, sleep deprivation, and the hard work and stresses of parenthood.

Risk factors for postnatal depression are generally the same as those for depression at any other age and include having a family history of depression, previous depressive episodes, adverse social conditions including social isolation, and relationship problems. Other risk factors include older age, being a single mother, unwanted pregnancy, severe baby blues and previous postpartum psychosis.

Early detection is crucial in the management of postnatal depression. Education about postnatal depression is an important part of antenatal care. Women with risk factors should be monitored closely. The Edinburgh Postnatal Depression Scale has high sensitivity and is now used rou-
tinely in primary care in the UK. Risk assessment is essential and must include risks to both the mother and the baby.

Treatment should generally start with organizing an appropriate support network. Psychological therapy, usually in the form of CBT, should be considered before starting pharmacological treatment. If antidepressant therapy is indicated, the same principles apply as when treating any other depressive episode. However, if the mother wishes to
continue breastfeeding, an appropriate medication should be prescribed according to current evidence of safety for the baby. If there is significant risk of harm to either the mother or the baby, hospitalization may be required. ECT is used in severe cases.

Postnatal depression may have considerable negative effects on the relationship between mother and baby. Reduced quality and quantity of interaction between mother and baby can have a negative impact on the emotional development of the baby.

**KEY POINTS**

- Typically mood disorders are recurrent and onset of episodes is often associated with stressful events or situations.
- The aetiology of affective disorders is multifactorial.
- Various medical illnesses increase the risk of depression.
- The core symptoms of depression include sustained depressed mood, loss of interest and enjoyment, and reduced energy and activity.
- The lifetime prevalence of depression is between 10% and 20%.
- The World Health Organisation (WHO) has estimated that depression is currently the fourth leading cause of disease burden in the world.
- The rate of suicide is significantly increased in patients suffering from depression.
- Biological, psychological and social interventions should all be considered for inclusion in the treatment plan for patients with depression.
- Bipolar disorder usually causes severe disruption to patients’ lives with manic episodes usually requiring inpatient treatment.
- Following a manic episode, long term antimanic therapy is required to reduce the likelihood of subsequent episodes.
- Patients with bipolar disorder are at considerably increased risk of morbidity and mortality due to physical health conditions.

**REFERENCES**

References

CONCEPT OF NEUROSIS

The term ‘neurosis’ was first used by William Cullen (1710–90) in 1784 for disorders of the nervous system for which there appeared no physical cause. The term replaced Robert Whytt’s 1768 ‘illness of the nerves’, which itself superseded the term ‘vapours’.

Mental illness, which implies previous health, has been divided into psychoses and neuroses. In psychoses, there is loss of contact with reality, and the symptoms, such as delusions or hallucinations, are not understandable and cannot be empathized with. Psychoses are regarded as severe mental illnesses and in lay terms are referred to as ‘madness’.

Neuroses or psychoneuroses, on the other hand, have symptoms that are both understandable (reality-based) and can be empathized with. Insight is usually maintained. They are regarded as milder and, in lay terms, are referred to as ‘nerves’. They are quantitatively but not qualitatively different from ‘normal’, involving for instance, inappropriate or excessive anxiety. Neuroses are most usually (but not invariably) short-lived, but they can be chronic, impairing and accompanied by a change, characteristically in symptoms and often, secondarily, in behaviour.

Neuroses can be defined as abnormal psychogenic (psychologically caused) reactions. An anxiety neurosis would have predominantly anxiety symptoms; in phobic disorder or neurosis there would be predominantly phobic symptoms. Neuroses typically have two components:
- a vulnerable personality;
- stress factors triggering the reaction.

Neuroses can thus be seen as exaggerated forms of normal reactions to stressful events – that is, they are inappropriate to the situation or the stress, or the reaction occurs at a greater frequency or severity than normal. Classically, neurosis should have no demonstrable organic basis and there should be no loss of contact with external reality, such as occurs in psychosis. Neurotic symptoms are thus maladaptive reactions to stress and reflect excessive and inappropriate use of psychological defence mechanisms.

Neurotic symptoms are unpleasant and lead to the individual seeking relief. They are often accompanied by a decrease in social functioning. Individuals with a neurosis have an increased mortality rate, including suicide and fatal head injuries.

A distinction should be made between people with neuroses, which are a group of mental illnesses, and people who are sometimes referred to, particularly by the lay population, as ‘neurotic’ individuals, who most often have lifelong personality difficulties such as overanxiousness or overemotionality.

OVERVIEW OF NEUROTIC AND STRESS-RELATED DISORDERS

Epidemiology

Individual neurotic symptoms are common in the community, as well as in primary and secondary care, and thus can be regarded as normal. These symptoms include:
- inappropriate fears;
- anxiety and panic;
- brief bouts of depressive feelings;
- tension headaches;
- irritability;
- sleeplessness.

Neurotic symptoms are often seen in general practice, resulting in significant societal burden; they may be the predominant symptoms in one-sixth of individuals seen there and relevant in up to one-third. Patients with neurosis often present with physical symptoms. Individuals with neurosis are more frequently seen in a psychiatric outpatient clinic than as in-patients in a psychiatric hospital. Neurotic disorders are the most common psychiatric condition, at any one time affecting up to 10 per cent of all individuals and affecting over 15 per cent in a lifetime.

With the high incidence of neurotic symptoms in the general population, questions arise in individual cases as to whether such symptoms should be regarded as abnormal or
such individuals as mentally ill. Should these symptoms be viewed merely as the individual’s way of dealing with the problems of everyday life, or do they represent a formal mental illness? Mild neuroses, in fact, often remit spontaneously or with mild reassurance. However, individuals with neurosis are more likely to seek medical consultation, often owing to fear of physical illness, and accurate diagnosis avoids inappropriate medical investigations.

Co-morbidity, especially with depression, substance misuse or personality disorder, is common. Neurotic disorders often precede the development of depression.

In the differential diagnosis of neurosis, one should ask why this particular patient is presenting at this particular time with this particular symptom. If an individual presents with neurotic symptoms for the first time after the age of 35–40 years, it is probable that the symptoms may be due to a depressive disorder or, alternatively, to underlying organic disease.

Aetiology

Predisposing factors leading to the development of neurosis are often similar to those important in the development of personality disorder. In fact, neuroses often arise in people with abnormal personalities, leading such individuals into social and emotional difficulties to which they overreact emotionally.

Environmental factors such as family and early background are important, but there is increasing evidence for a genetic inherited predisposition to neurosis.3

The vulnerability of people in the general population to developing a neurosis under stress follows a normal distribution, as for height or weight (Figure 40.1). The incidence of neurosis rises with increasing environmental stress (Figure 40.2). Even people with normal stable personalities will develop neurosis under severe environmental stress, as can be seen in individuals involved in natural disasters and in wartime. The incidence of neurosis approached 100 per cent in individuals in the First World War trenches for prolonged periods, and in bomber crews in the Second World War after more than 30 missions. Although one person’s stress may be another’s pleasure, due to the individual’s background and personality, certain situations such as combat are experienced as stressful by over 95 per cent of individuals. Lower percentages of people experience stress in examinations or public speaking, and up to 50 per cent of the population find job interviews stressful. Although not associated with external stresses, sensory deprivation (either experimentally or as experienced by hostages kept in solitary confinement) and, to a lesser extent, boredom can also result in extreme stress and anxiety.

A number of theories have been developed to explain neuroses. In Freudian psychoanalytical theory, neurotic symptoms are seen as the expression of intrapsychic anxiety due to unresolved emotional conflicts dating from childhood. Freud initially proposed that anxiety represented repressed libido (mental energy or drive). Later, he considered that anxiety reflected the birth experience, but he eventually replaced this theory with that of anxiety being a response of the ego to instinctual emotional tension. Freud differentiated the term ‘anxiety neurosis’, which he thought had a biological causation, from ‘psychoneurosis’, which included anxiety hysteria (phobic or situational anxiety), obsessive–compulsive neurosis and hysteria, all of which he saw as arising from unconscious conflicts. Learning theory has conceptualized the neuroses as learned maladaptive responses associated with a temporary reduction in anxiety. There is also evidence to suggest some genetic predisposition for the development of individual types of neuroses, although this may be predominantly through genetic influence on the development of personality.

As stated above, stress factors can be precipitating factors for neuroses in vulnerable individuals, and environmental factors, including family and marital factors, and social conditions, such as poor housing and unemployment, may be perpetuating factors for such disorders. Box 40.1 summarizes the factors associated with the development of neurotic and stress-related disorders.

Treatment

Evidence-based guidelines, such as from the National Institute for Health and Clinical Excellence (NICE) in the UK, are available. Cognitive-behavioural therapy (CBT) and
Neurotic and stress-related disorders are often effective treatments. SSRI antidepressants should be continued for 1 year after response. However, CBT may be more effective in preventing relapse.

Prognosis
The overall prognosis in these conditions is generally regarded as good, with up to 50 per cent of individuals recovering without treatment within 2 years and up to 70 per cent with treatment. However, up to half of individuals seen by a general practitioner (GP) will remain symptomatic 1 year later, and for patients seen by a psychiatrist about half will still be disabled after 4 years. Good prognostic indicators include a stable premorbid personality and the development of acute symptoms in response to transitory stresses. Poor prognostic factors include chronic or severe symptoms at presentation, persisting social problems and inadequate social support. There is an excess of mortality among people with neurotic disorders, largely due to increased rates of completed suicide.

CLASSIFICATION
The tenth revision of the International Classification of Diseases (ICD-10) has not retained the concept of a neurosis as a major organizing principle in classification, although it groups together three types of disorder because of their historical association with the concept of neurosis and also their association with psychological causation. These are the neurotic and stress-related disorders (which are considered in this chapter) and the somatoform and dissociative disorders, which are described in Chapter 41. Table 40.1 summarizes the neurotic and stress-related disorders on the basis of ICD-10. Mixed neurotic states are more common than the discrete syndromes. Panic disorder with or without agoraphobia and generalized anxiety disorder are the most disabling. Table 40.2 shows the frequency of neurotic conditions. The fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) uses the term ‘anxiety disorders’ rather than ‘neurotic disorders’ and, indeed, neurosis was absent from DSM-III. Table 40.3 compares DSM-IV with ICD-10 in relation to neurotic and stress-related disorders.

The basis for the current categorical classification for non-psychotic disorders has been criticized for lack of evidence, and a dimensional classification, for example with dimensions for anxiety and depression, has been proposed.4

Box 40.1 Factors associated with development of neurotic and stress-related disorders
- Lower social class
- Unemployment
- Divorced, separated or widowed
- Renting rather than owning own home
- No educational qualifications
- Urban rather than rural.
Homeless people and prisoners have twice the risk of the general population.

ANXIETY DISORDERS
Normal anxiety
Anxiety is a mood, usually unpleasant in nature, accompanied by bodily (somatic) sensations and occurring with a subjective feeling of uncertainty and threat about the future. The term ‘fear’ is used to describe a normal and...
appropriate mood when the danger can be perceived and defined. Most of the bodily changes seen in anxiety are caused by increased sympathetic adrenergic nervous system discharges – Cannon’s fight or flight reaction – which results in the release of adrenaline and other catecholamines. In our ancestral past such a reaction would prepare us to deal with a real physical threat, but today we may merely experience such reactions when under stress in everyday life, for instance in a traffic jam.

We all attempt to adjust our lives to maintain anxiety at an optimal level for us as individuals. However, like pain, anxiety is a useful warning and should not be suppressed

with drugs or alcohol. It is the central nervous system’s alarm system to protect us from threat and is activated by environmental cues. There is an inverted U-shaped relationship between anxiety and performance developed by Hebb in 1955\(^6\) known as the Yerkes–Dodson law\(^7\) (Figure 40.4). This was based on an experiment on white mice being encouraged by low-, medium- and high-intensity electric shocks to learn to locate a compartment in a box. Medium-intensity shocks produced the fastest learning. Performance is reduced at low and very high levels of anxiety: thus, poor examination results are obtained by people with low anxiety levels who do not care whether they pass or fail and by people who become so highly anxious that they cannot concentrate. The Yerkes–Dodson law predicts that anxiolytic drugs reduce performance in a person with a low anxiety level, but when a deterioration in performance is caused by high anxiety the reduction of symptoms by anxiolytic drugs should improve performance, for example in examination phobia. In assessing an individual’s true level of anxiety, one should bear in mind that the complaint of symptoms of anxiety may lie anywhere along the Yerkes–Dodson curve. The individual may also be very anxious during a formal interview, but not so for long periods during the day, or vice versa. It is useful to distinguish between *trait anxiety*, which is a lifelong personality characteristic, and *state anxiety*, which is a temporal disorder with a discernible time of onset.

GENERALIZED ANXIETY DISORDER

This is also known as anxiety neurosis, anxiety state or anxiety reaction, and is characterized by unrealistic or excessive anxiety and worry that is generalized and persistent and not restricted to particular environmental circumstances – that is, it is ‘free-floating’.

Epidemiology

Community surveys suggest about 1.6 per cent of the adult population has generalized anxiety disorder at any one time, with a 1-year prevalence range of 3–8 per cent and a lifetime prevalence of 21 per cent. The female/male ratio is 2 : 1.8 Around 15 per cent of patients attending GP surgeries and 25 per cent attending medical settings in general are ‘anxious’. Generalized anxiety disorder often begins in early adult life, between the ages of 15 and 25 years, but rates continue to increase after the age of 35 years. Being older than 24 years, separated, widowed, divorced, unemployed or a home-maker correlates with general anxiety disorder. Pure generalized anxiety disorder is, however, rare compared with the much more common mixed picture of anxiety and depression. Co-morbidity is common, perhaps up to 90 per cent, for example with panic disorder and social phobia.

Clinical features

These are summarized in Figure 40.5 and Table 40.4. Individuals will not have all the psychic (affective) and

</table>
somatic symptoms but will tend to have the same symptoms during each exacerbation, for example palpitations or trembling.

Males and individuals from lower social classes and some cultures are more likely to complain of somatic rather than psychic symptoms. It is important to understand that these are real and not merely ‘all in the mind’, and it is reassuring to the patient to be told this. In keeping with Cannon’s fight or flight reaction, in which there is stimulation of adrenergic neurons leading to the release of adrenaline and other catecholamines, autonomic hyperactivity results in increased heart rate and palpitations and an increased rate of breathing, which results in a sensation of breathlessness. In turn, hyperventilation (sometimes referred to as the ‘hyperventilation syndrome’) results in the individual excessively blowing off carbon dioxide, leading to hypocapnia, which induces peripheral vasoconstriction and a ‘pins and needles’ sensation (paraesthesia). This can be countered by breathing into and out of a paper bag.

It is thus easy to understand how a patient, unaware of the normal physiology of anxiety, can get into a vicious cycle of anxiety and worry about somatic symptoms. The patient may forget the original stress that precipitated the episode and become preoccupied about dying from a heart attack (sometimes referred to as ‘cardiac neurosis’ or the ‘effort syndrome’). Such a fear is increased if chest pain is also experienced owing to anxiety-induced increased muscle tension. Muscle tension is caused by increased blood flow to the muscles and increased tone, and contributes to the complaint of fatigue. The term ‘neurasthenia’ (fatigue syndrome) has been used in the past to refer to a neurosis where fatigue is the predominant symptom.

Depersonalization and derealization are sometimes associated with anxiety neurosis and are disorders of self-awareness. In depersonalization, the individual has an altered or lost sense of personal reality or identity. In derealization, the individual’s surroundings feel unreal. Individuals find these symptoms unpleasant and difficult to describe and are relieved when they are acknowledged by professionals. Such feelings can occur in normal individuals, especially those suffering loss of sleep, as well as in a primary depersonalization–derealization syndrome. They are also seen in individuals with depression, schizophrenia, alcohol and drug intoxication and withdrawal, and epilepsy. The feelings may also be induced by prescribed medication. Although unpleasant, they are bearable compared with panic attacks, which are associated with higher levels of anxiety (Figure 40.6).

History-taking should explore the use of alcohol, caffeine and illicit drugs as possible explanations for anxiety symptoms, as well as any association of symptoms with precipitating events. The individual may have a tense and worried facial expression and posture, and may be tremulous, pale or sweaty. There may be overbreathing and evidence of agitation (purposeless activity due to anxiety), with pacing of the floor and fidgeting. Physical examination should exclude organic causes such as thyrotoxicosis. Although investigations for thyrotoxicosis might be justified, other physical causes of anxiety, such as phaeochromocytoma, are sufficiently rare for routine investigation not to be cost-effective unless clinically indicated.

**Differential diagnosis**

Many disorders and nearly all psychiatric conditions may present primarily with symptoms of anxiety (Box 40.2). Generalized anxiety disorder very rarely begins after age 35 years; individuals presenting for the first time after this age are more likely to have depressive or other psychiatric disorders, but the distinction between general anxiety disorder and depression can be difficult. Rotational vertigo is not a symptom of anxiety.

**Aetiology**

**Predisposing factors**

There is some evidence of a genetic inherited influence on anxiety proneness associated with a vulnerability to depression, with environmental factors influencing presentation. Environmental factors, such as through social learning, are also important in themselves (e.g. anxious insecure mothers raise anxious insecure children). Individuals with a premorbid anxious (avoidant) personality disorder are more prone to develop a chronic generalized anxiety disorder. There is also an association with early childhood separation experiences, especially separation from either parent. Bowlby’s attachment theory suggests that such separations result in feelings of insecurity, which are reactivated in later life. Freudian psychoanalytical theory suggests that intrapsychic anxiety due to emotional conflict may be expressed directly as a generalized anxiety disorder.

Biological models of general anxiety disorder have been hypothesized, and involve the following:
Noradrenergic pathways (locus coeruleus–noradrenergic sympathetic autonomic nervous system), which are associated with fear and arousal

- Septo-hippocampal system and Papez circuit, which mediate anxiety and are where anxiolytic drugs act. Benzodiazepines act on γ-aminobutyric acid (GABA) type A receptor complexes.

The galvanic skin response of sweat glands to sympathetic stimulation is associated with a reduction in habituation in anxiety, but not thyrotoxicosis.

Precipitating and perpetuating factors
These include current stresses and life events, especially those associated with fear of loss. However, cognitive theories are now increasingly cited to explain the onset of generalized anxiety disorder.

Management
Most patients with generalized anxiety disorders are treated in the primary care setting. Counselling alone may be very effective, for example explanation of and reassurance about somatic symptoms of anxiety, such as palpitations, which the patient may believe are indicative of an imminent heart attack, or, more generally, reassurance that the individual is not going to lose control, ‘go mad’ or end up in a psychiatric hospital for life. Self-help materials, such as books and relaxation tapes and leaflets, reinforce counselling and can be a treatment in their own right.

Psychological treatments
There is good evidence that cognitive therapy and anxiety management techniques are effective, and these should be the first choices in treatment. Cognitive therapy is based on the idea that thoughts and feelings are related and that anxious thinking provokes or maintains the problem. The individual is taught to recognize and re-examine their anxious thoughts in order to find alternative and more helpful ways of thinking, which are then tested out in practice. Cognitive therapy also aims to identify and modify dysfunctional assumptions or beliefs that underlie anxious thinking. The aim is to replace automatic morbid anticipatory thoughts with realistic cognitions.

A cognitive-behavioural approach additionally includes exposure relaxation\(^{11}\) and is superior to other forms of psychological treatment.\(^{12}\)

Anxiety management training is based on the rationale that anxiety can be managed by breaking into the vicious cycles that keep the problem going. Education is via the explanation of anxiety and its causes and consequences. Relaxation exercises and, if indicated, breathing exercises are encouraged, and new ways of coping, such as distraction and cognitive techniques, are taught.

In both cognitive therapy and anxiety management, homework assignments for the patient may be required, and the patient should be warned that temporary setbacks may occur. Both cognitive therapy and anxiety management training may also be conducted effectively in a group setting.

Relaxation techniques are based on the assumption that mental relaxation follows physical relaxation. This may involve the use of progressive muscular relaxation, with or without the use of relaxation tapes. However, it is less effective than CBT.

The term ‘autogenic training’ (e.g. by biofeedback techniques) means learning to self-monitor anxiety levels and then apply relaxation techniques to daily activities. Yoga and transcendental meditation work as relaxation techniques and can be useful in generalized anxiety disorder.

In addition to non-directive and directive counselling and supportive psychotherapy, insight-oriented dynamic psychotherapy has been used for individuals with chronic generalized anxiety disorder who are unresponsive to other approaches. The technique aims to uncover and resolve unconscious emotional conflicts that result in intrapsychic anxiety, which is expressed as symptoms of generalized anxiety disorders.

---

Box 40.2 Disorders that can present primarily with symptoms of anxiety

- Generalized anxiety disorder
- Panic disorder
- Phobic disorders
- Obsessive–compulsive disorder
- Depressive disorder
- Schizophrenia and other paranoid psychoses
- Drug and alcohol withdrawal syndromes, e.g. delirium tremens
- Early dementia, e.g. catastrophic reactions upon psychometric testing
- Ictal anxiety due to epilepsy, especially temporal lobe epilepsy
- Thyrotoxicosis
- Phaeochromocytoma
- Unexpressed complaints of physical illness, e.g. lump in breast
- Drug and alcohol abuse, dependency and withdrawal symptoms, e.g. delirium tremens, caffeine.
anxiety disorder. In particular, brief focal psychotherapy, which focuses on a specific problem and sets an agenda and time limits of therapy, has been found to be useful. In this technique, the individual is encouraged to talk freely, but the therapist interprets the content of the talk to reveal a deeper meaning, which can be understood and accepted by the patient.

Where interpersonal conflicts and stresses underlie the generalized anxiety disorder, marital or family therapy may be required. Similarly, environmental causes, such as poor housing, may have to be tackled.

**Drug treatment**

In the past, most patients presenting with generalized anxiety disorder were treated with tranquilizers, mainly benzodiazepines such as diazepam (Valium®). However, it is now recognized that such drugs can cause dependence, and their role is limited to brief periods of use to overcome symptoms so severe that they obstruct the initiation of more appropriate psychological treatments. Acutely disabled patients may require benzodiazepine drug therapy for up to 4 weeks, but even in these circumstances additional counselling, self-help and support are also required. Chronic use of minor tranquilizers should generally be avoided, although evidence is emerging that antidepressants, and possibly buspirone, may have a role in the longer-term management of severe persistent forms of anxiety.

**Benzodiazepines** are still the first choice when a rapid anxiolytic effect (as opposed to first-line treatment in general) is required. They should be used in the lowest dose possible and only as required, rather than routinely. In the absence of anxiety, they may merely result in sedation and increase the risk of dependency. Benzodiazepines should not be prescribed as hypnotics for more than 10 nights, or as anxiolytics for more than 2–4 weeks. Diazepam and chlordiazepoxide are used as anxiolytics, whereas temazepam and nitrazepam are used as hypnotics. Diazepam is the most prescribed drug ever in the history of prescribing. Flurazepam has been used by astronauts in space. Longer-acting compounds, such as diazepam, are preferred to those with a shorter half-life, such as lorazepam, which have a greater risk of withdrawal symptoms. Benzodiazepines may impair the effectiveness of psychological therapies and also the performance of skilled tasks and driving; patients should therefore be warned of these effects. Patients should also be warned about the potentially dangerous interactions of benzodiazepines with drugs and alcohol. Benzodiazepines have a definite abuse potential, with a risk of dependence and withdrawal symptoms on discontinuing long-term use. Prescribing benzodiazepines for a period of as little as 2 weeks can be associated, on cessation, not only with the re-emergence of the original symptoms, which the patient may then blame on the drug, but also with rebound anxiety and insomnia. Thus, patients on such a short course of a benzodiazepine might experience a withdrawal syndrome upon stopping their medication. Numerous symptoms have been identified as characteristic of a benzodiazepine withdrawal syndrome. These include:

- neurotic symptoms, such as panic, agoraphobia, anxiety and insomnia;
- neurological symptoms, such as ataxia, paraesthesia, hyperacusis and micropsia;
- other major symptoms, such as hallucinations, psychosis and, in 1 per cent of patients, epilepsy.

The emergence of three new symptoms on discontinuation of benzodiazepine medication, or any symptom not part of the psychiatric disorder for which it was prescribed, such as epilepsy, is indicative of dependency. It should be noted, however, that before the benzodiazepines became available, barbiturates were widely used as anxiolytics and were associated with a much greater degree of dependency, as well as being more dangerous in overdose. Benzodiazepines are rarely fatal in overdose in normal individuals, unless combined with alcohol abuse or other drugs.

Ideally, the second choice of (but first-line drug) treatment of generalized anxiety disorder, if anxiety management training and cognitive treatment fail, is to use **SSRI antidepressants** or **selective noradrenergic reuptake inhibitor (SNRI) antidepressants**, which are often better tolerated than tricyclic or monoamine oxidase inhibitor (MAOI) antidepressants, which are also effective. It is unclear whether the combination of SSRI antidepressants and CBT is superior to either alone.

**Buspirone** is a serotonin 5-HT1A receptor agonist and is suitable for the short-term management of severe anxiety when a rapid onset of effect is not essential, and for the treatment of anxious patients with a history of dependence on alcohol or sedatives/hypnotics. It has a progressive onset of action. It has diminished efficacy in previous benzodiazepine users and produces the side effects of dizziness, headache and nausea. It results in minimal sedation and psychological impairment and has no interactions with alcohol or other psychotropic drugs. It has a low or absent risk of dependence or abuse.

**Beta-adrenergic antagonists** (beta-blockers) are effective in patients with somatic anxiety symptoms caused by autonomic hyperactivity, such as palpitations, tremor and blushing. Patients may have found that blushing is also countered by cigarette-smoking. Beta-blockers do not affect symptoms caused by increased motor tension, such as headache; nor do they affect sweating, dry mouth, nausea, diarrhoea or frequency of micturition. They have side effects of tiredness, occasional nightmares and possibly depression, and they are contraindicated in cases of asthma and heart block. They are non-sedative and do not result in psychological impairment, abuse or dependence.

Low-dose antipsychotic medications, such as trifluoperazine and flupentixol, have also been used to some extent.
Antipsychotic medication can augment a limited response to SSRIs. Although there is probably no risk of true dependence, they can produce extrapyramidal side effects and have a slight risk of tardive dyskinesia.

*Pregablin*, which has been used in neuropathic pain, has been found to be of use more recently.

**Course and prognosis**

The more chronic the generalized anxiety disorder, the worse the prognosis. A stable premorbid personality is a good prognostic sign. Generalized anxiety disorder can be complicated by the development of agoraphobia, secondary depression and abuse of alcohol and anxiolytics. Overall the course is variable and fluctuating, but chronic.

Anxiety is present usually where there is some possibility of choice of action. This may explain why some individuals facing execution, where there is no hope, do not appear anxious. Other factors such as depersonalization and denial may also be relevant, as may a paranoid attitude to circumstances in that the individual believes that others will ‘get’ them anyway, sooner or later.

**PANIC DISORDER (EPISODIC PAROXYSMAL ANXIETY)**

Panic disorder is characterized by acute and unprovoked (spontaneous) discrete periods of intense fear or discomfort (panic attacks) due to intense acute psychic and somatic anxiety symptoms, which are unexpected and not triggered by situations. During an attack, patients experience a sudden crescendo of fear and autonomic symptoms, resulting in a usually hurried exit from wherever they are: they are unable to sit out such attacks. They may also experience feelings of impending doom or death (*ango animus*) and somatic symptoms such as shortness of breath, palpitations, chest pain, tremor, faintness, dizziness, choking or smothering sensations. Fears of dying, ‘going mad’ or losing control are cardinal features. The attacks usually last for less than 30 min, with a peak of intensity around 10 min. Nocturnal panic attacks during sleep and non-fearful panic attacks rarely occur.

If panic attacks occur in a specific situation (situational), such as on a bus or in a crowd, the patient may subsequently avoid and develop a phobia (inappropriate fear) of that situation, and even generalized agoraphobia. A panic attack is often followed by a persistent fear of having another attack and of being alone. Between attacks there is comparative freedom from anxiety symptoms, although anticipatory anxiety is common and may itself precipitate an attack. Table 40.1 (page 653) summarizes the ICD-10 diagnostic criteria for panic disorder. DSM-IV allows for both spontaneous and situational panic disorder – that is, with or without agoraphobia.

The frequency of panic attacks is not an accurate measure of the severity of panic disorder or the likely treatment response.

Panic disorder is maintained because the individual fears the somatic sensations associated with panic attacks. However, the only danger is subjective, due to the individual’s interpretations of panic or its meaning or consequences (e.g. as threatening or dangerous). Catastrophic interpretations lead to anxious apprehension of future episodes and an increased vigilance regarding bodily sensations. Increasing autonomic nervous system arousal results and is then noted and responded to with fear, which in turn results in a further panic attack. Thus, a conditioned fear of fear pattern develops, with anxiety itself becoming a phobic (feared) stimulus. Individuals may stop undertaking physical exercise because this results in a raised heart rate, which sets the pattern into operation again and results in further panic attacks. The fear response may also increase muscle tension and lead to hyperventilation, exacerbating the overall experience and further aggravating the vicious cycle.

Panic disorder may also be the cause of unexplained medical symptoms.

Panic originates from the Greek god Pan, who frightened humans and animals out of the blue.

**Epidemiology**

Although the lifetime prevalence for isolated panic attacks without agoraphobia has been found to be up to 27.7 per cent, panic disorder occurs in only 1–2 per cent of the general population. It is more common (by two to three times) in females than males and may be worse premenstrually. The lifetime prevalence is around 4 per cent, compared with 8 per cent for panic attacks alone. The age of onset is bimodal, an inverted U, with the highest peak around age 15–25 years and a second peak around age 45–54 years.

**Co-morbidity**

Agoraphobia occurs in 30–50 per cent of cases, with higher rates in patients seen in psychiatric settings. The risk of attempted suicide is raised where there is co-morbid depression (two-thirds of patients), alcohol misuse (up to one-third of patients) or substance misuse. Co-morbidity with medical conditions and bipolar disorder is also seen.

**Differential diagnosis**

Panic attacks can occur in established phobic disorders (situational anxiety with avoidance) in relation to the corresponding phobic situation, and also secondarily to depressive disorders, particularly in males. Some studies suggest a co-morbidity with depression or dysthymia of 45 per cent. Panic attacks may also result from intoxication with caffeine or amphetamines or withdrawal from substances such as barbiturates.

Physical disorders such as hypoglycaemia, phaeochromocytoma and hyperthyroidism must also be considered.
Aetiology

There is evidence of a genetic inherited predisposition, with increased concordance rates for monozygotic compared with dizygotic twins. Ninety-five per cent of patients with panic disorder have been found to have a genomic duplication (DUP25) on chromosome 15, compared with 7 per cent of the general population. Such a predisposition may result from a biological vulnerability to this disorder related to ease of autonomic arousal, a lower threshold for initial panic attacks, and ease of anxious apprehension elicited by stress. There is an increased family history of agoraphobia, depression and suicide. An association has also been found between panic disorder and childhood parental death or separation from the mother. Premorbid overanxious personalities or otherwise high levels of anxiety predispose an individual to panic disorder. Panic disorder and agoraphobia also follow in about 16.7 per cent of cases after the implantation of a cardioverter/defibrillator, increasing in rate to one in five if it has been discharged.

An association with benign joint laxity has been described, with an apparent 15 times increase in incidence. Panic attacks may also be provoked by excessive caffeine intake, injections of sodium lactate, sympathomimetic drugs and carbon dioxide inhalation. The suffocation alarm theory of panic disorder postulates a central carbon dioxide hypersensitivity.

Other theories include increased postsynaptic response to serotonin, increased adrenergic activity, and decreased inhibitory reactive sensitivity due to GABA, Pentagastrin and lactate both induce panic. It is also postulated that the amygdala, hypothalamus and brainstem areas that mediate fear may also have a role.

Management

Advances in treatment have led to success rates of 80–100 per cent with CBT. A success rate of 50–60 per cent has been achieved with pharmacological treatments alone such as antidepressants and benzodiazepines.

Psychological treatments

There is good evidence for the efficacy of both behavioural methods (exposure to counter phobic avoidance, relaxation and control of hyperventilation) and cognitive methods (education about anxiety and panic and thinking errors). The CBT approach is the first-line treatment and involves an initial education in the nature of panic attacks and the undertakings to enable the individual to identify particular catastrophic interpretations and to substitute more adaptive cognitions in their place. This is often achieved by a question-and-answer technique to detect flaws in logic, for example asking the individual to look at the actual frequency of fainting, which is usually zero, compared with the number of panic attacks experienced.

As thoughts are difficult to change without corrective experiences, interoceptive exposure techniques are used to achieve a controlled exposure of the individual to somatic sensations of anxiety and panic, with the goal of habituating to such symptoms, so they can be experienced without fear. Carbon dioxide inhalation and physical exercise have been used to this end. For instance, running on the spot produces a rapid heart rate and heavy legs. Dizziness and disorientation can be produced by the individual spinning or turning the head quickly, and hyperventilation will generate blurred vision, feelings of light-headedness, tingling, numbness and hot flushes. Depersonalization can be produced by staring at a fixed object or mirror for a prolonged period. Such exercises can be practised for 1–2 min, during which the patient’s catastrophic thoughts are also elicited to demonstrate that catastrophic experiences do not follow. This process is called ‘hypothesis testing’.

Cognitive restructuring and interoceptive exposure can be undertaken individually or in groups, and often involve homework practice with more diverse, prolonged and natural interoceptive exposure exercises.

Secondary agoraphobic avoidance due to panic disorder is treated by situational exposure, and anxiety management techniques and skills are taught where appropriate. For example, the patient can be instructed in muscle relaxation techniques and breathing retraining (i.e. to teach diaphragmatic and slow breathing skills to patients who hyperventilate).

This approach to panic disorder can be completed successfully within about 12–15 sessions, and its effect is maintained over time, as such skills can leave the individual with a sense of mastery of the condition, compared with the feelings of loss of self-control that often accompany the use of drugs. Individuals can also have occasional group CBT booster sessions from time to time.

Brief panic-focused psychodynamic psychotherapy to counter fears of being trapped and abandoned has also been used.

Drug treatments

Pharmacological treatments have proven efficacy but present discontinuation difficulties in up to 50 per cent of cases due to the re-emergence of symptoms upon stopping treatment. Antidepressants, especially the SSRIs (the first-line drug treatment in the NICE guidelines), and also clomipramine, a tricyclic with a similar action on serotonin, are effective. Indeed, SSRI antidepressants should be regarded as the second-line treatment if CBT fails. Antidepressants may affect autonomic reactivity. They have a slower onset of action than the benzodiazepines, which tend to be effective only in the short term, although tolerance to anti-panic effects is said not to develop (as it does with sedation), and they can cause dependency with long-term use. NICE states that benzodiazepines should not be used in panic disorder. Pharmacological treatments are currently more commonly prescribed than cognitive-behavioural approaches, which require a skilled therapist. CBT, also recommended by NICE, may be used as an
adjunct to or replacement for pharmacological treatment if this alone has been unsuccessful after 2–3 months. Drug treatment can improve the efficacy of CBT.24

Prognosis

With treatment, the prognosis is good (50–60% of patients remit with medication; 80–100% of patients remit with CBT). However, follow-up over 20 years shows less than 50 per cent of patients remain entirely panic-free. Untreated panic disorder frequently develops into other psychiatric conditions, such as depressive disorder.

MIXED ANXIETY AND DEPRESSIVE DISORDER (OR ANXIETY DEPRESSION)

In this disorder, symptoms of anxiety and depression are both present but neither is clearly predominant. Mixed pictures of neurotic disorders are much more common than discrete entities, such as generalized anxiety disorder. Mixed anxiety and depressive disorder is seen frequently, with up to half of patients with anxiety disorder meeting diagnostic criteria for depression. It is the most common psychiatric disorder in primary care. There are many more individuals in the population with this condition but who never come to medical or psychiatric attention. Anxiety is a mood about the future, while depression is a mood about the past. Table 40.5 demonstrates the theoretical differential diagnosis between pure anxiety and pure depressive disorders.

Management

Treatment of mild mixed anxiety and depressive disorder may be best undertaken by counselling, cognitive therapy or psychotherapy, especially interpersonal therapy, but it is also frequently treated in general practice by medication. Treating the depression usually relieves anxiety symptoms. Antidepressant medication is more effective than anxiolytic medication. The SSRI antidepressants are often tolerated better than standard tricyclics. It may, however, be necessary to treat both the depression and the anxiety.15 In clinical practice, a common error is to misdiagnose depressive disorder or mixed anxiety and depressive disorder as merely a generalized anxiety disorder, and to prescribe minor tranquillizers such as benzodiazepines, often for long periods, with the associated increased risk of dependency. Such misdiagnosis often occurs because anxiety is present in nearly all cases of depression and may appear to be the predominant symptom.

PHOBIC DISORDERS

Fear is a normal prudent situational anxiety, for instance if one is under threat of attack. A phobia is an inappropriate...
situational anxiety with avoidance. The degree of avoidance is a useful measure of the severity of the disorder. The three main groups of phobic disorders and the lifetime prevalence rates are as follows:

- Specific (isolated) phobias: 11.3%
- Agoraphobia: 6.7%
- Social phobias: 13.3%

Table 40.1 outlines the ICD-10 diagnostic criteria for these three groups.

**Specific (isolated) phobias or simple or monosymptomatic phobias**

In specific phobias there is a persistent inappropriate fear of a circumscribed external object or situation, which leads to avoidance. Animal phobias occur equally in children of both sexes but are more common in women in adulthood. An individual with a phobia of cats will develop an immediate anxiety response in their presence and will avoid them, for instance by crossing to the other side of the road. Such specific phobias often start and are statistically normal in children. They often clear in early adulthood but are still common in a mild form in adults (e.g. fears of heights, the dark and spiders). For instance, half of adults are fearful of snakes. About 10 per cent of the general population have clinically significant specific phobias, most having developed in childhood, but only a small proportion seek professional help. The resultant incapacity depends on the frequency with which the phobic situation is encountered in daily life. For instance, an individual with a flying phobia may rarely have to confront this situation, unless air journeys are important to their work or social life, and treatment may not be necessary, at least for most of the year. However, avoidance of more common specific phobic objects, such as dogs and cats, may greatly interfere with an individual’s daily activities, although specific phobias are less incapacitating than other types of phobia. Also incapacitating is space phobia, which is a fear of falling when there is no nearby support.

Phobias of blood and bodily injury lead to bradycardia and hypotension upon exposure, in contrast to the tachycardia and increased blood pressure seen with other phobias. Such physiological changes on seeing blood could have conferred evolutionary advantage. This type of specific phobia is associated with a strong family history, often going back generations, and may be associated with a strong vasovagal reflex.

**Agoraphobia**

The term ‘agoraphobia’ originates from the Greek for ‘fear of the marketplace’, but it now has a wider meaning than fear only of open or public spaces: it also involves fear of being far from home, family and friends. The individual is fearful of being in places or situations where escape may be difficult or help unavailable if a panic attack were to occur. Individuals become anxious in anticipation of going out, particularly when unaccompanied, and this may restrict their activities. Avoidance, including an inability to enter shops, usually develops and in its extreme form results in individuals becoming housebound. Not all individuals who develop avoidance have a history of panic attacks, but around two-thirds do. Agoraphobia can either precede or follow panic attacks. Shortness of breath is more common in panic attacks in agoraphobia. Breathlessness, dizziness, feelings of suffocation and fear of dying are common. Individuals with agoraphobia often feel worse the further they are from their home, and when out, they may be better in the company of someone else, unlike in social phobia. In its extreme form, individuals may even be unable to open the front door to retrieve items from the doorstep.

The clinical picture often includes claustrophobia (fear of closed spaces), as well as of crowded places, main roads and public transport. Individuals may abuse alcohol or drugs in an effort to overcome their phobia. Others become depressed as a result of the restrictions on their lifestyle, which in turn further exacerbates the agoraphobia.

Although specific (isolated) phobias are the most common in the general population, agoraphobia is the cause of 60 per cent of the phobic patients seen by psychiatrists. Such individuals often have a history of childhood fears and school phobia. Over two-thirds to three-quarters are female. They are often married and have a high incidence of sexual problems. However, pure agoraphobia is rare compared with co-morbid presentations with panic disorder or major depression.

**Social phobia**

Social phobia is characterized by the persistent fear of situations in which the person is subject to possible scrutiny by others, and also by fears that he or she may act in a humiliating or embarrassing way. Such situations include eating in a restaurant and public speaking. Social phobias may be specific, such as speaking or urinating in public, or generalized, with the individual experiencing distress in any social setting, even speaking on the telephone. Symptoms may include blushing and muscle twitching.

Social phobia can be precipitated by stressful or humiliating experiences, the death of a parent, separation or chronic exposure to stress, or it may have an insidious onset. Twin studies suggest a genetic vulnerability. There is little spontaneous remission, and chronicity is associated with co-morbidity with depression, other anxiety disorders and substance abuse in 75 per cent of cases. Blushing is particularly characteristic of panic attacks in social phobia. Palpitations, trembling and sweating are also common.

Social phobia is more common than previously considered and occurs in 3–4 per cent of the general population. First-degree relatives are three times more likely to be affected. It is associated with panic disorder and other
anxiety disorders, which may have led to its delayed recognition as a syndrome apart from agoraphobia. Social phobics may abuse alcohol or drugs to counter social anxiety before social interaction. Social phobics who may have competent social skills should be differentiated from those with poor social skills that lead to social anxiety. They may as children have had temperaments of behavioural inhibition. Although individuals with social phobia may well have been shy adolescents, this should be distinguished from anxious (avoidant) personality disorder, although there is co-morbidity in 50 per cent of cases of each condition. People with avoidant personality disorder are shy and lack social confidence; people with social phobia show marked anxiety and avoidance. Social avoidance may also be caused by depression, panic disorder, schizophrenia and physical illness. People with schizoid personality disorder lack an interest in socializing. Table 40.6 shows the age of onset, sex ratio, characteristics and treatment response of phobias. Table 40.7 shows factors relevant to the differential diagnosis of social phobia and depression. Table 40.8 shows factors relevant to the differential diagnosis of general social phobia and panic disorder.

High rates of co-morbidity are, however, seen in social phobia, such as with other neurotic disorders, depression, post-traumatic stress disorder and substance abuse.28 On mental state examination in a clinic, an individual with a phobia may appear relaxed and otherwise normal, as the phobic object or situation is not present.

**Aetiology**

There is some limited evidence of a genetic inherited predisposition to develop agoraphobia (heritability 0.30), social phobia and phobia of small animals (heritability 0.47), but not of other phenomena.29 In agoraphobia there is an increased concordance for monozygotic compared with dizygotic twins and an increased family history of panic

disorder and agoraphobia. In social phobia there is an increased concordance rate for monozygotic compared with dizygotic female twins (24.4% vs. 15.3%). For simple or specific animal phobias there is evidence of increased concordance for monozygotic compared with dizygotic twins (25.9% vs. 11%), but not for situational phobias, which seem more environmentally determined. Specific phobias may originate in normal childhood fears. Even 1-year-old babies are fearful of writhing and darting animals and heights, but not, for instance, of manufactured dangerous objects such as guns. Such inborn fears may have been of evolutionary value.

Phobias can perhaps be best understood in terms of behavioural learning theory (Figure 40.7). The Pavlovian classical conditioning model is illustrated by the case of ‘Little Albert’. In 1920 the American psychologist Watson caused Albert, then 11 months old, to develop a fear of his favourite furry toy rat by making a loud noise behind Albert when he attempted to touch the toy. This fear later generalized to a fear of all furry objects, and even to men with beards and his mother’s fur necklace. Pavlovian classical conditioning with generalization might thus explain the development of a phobia that is, in effect, the pairing of a conditioned stimulus – the phobic situation – with an unconditioned stimulus (e.g. unexpected noise) to produce the response of fear. This seems to apply in social phobias where the conditioned fear response may be determined environmentally and triggered by the social situation in which anxiety first occurred. However, only some individuals with specific animal phobias can recall their phobias being precipitated, for instance by being frightened or bitten by such animals in childhood.

Skinnerian or operant conditioning argues that the frequency of a behaviour can be altered by its consequences, such as reward or punishment. For example, avoidance of a phobic situation would be associated with a temporary reduction in anxiety, which is rewarding and thus reinforces the avoidance. This is a maladaptive learning response. The adaptive response would be to confront the phobic situation, even though this would produce a temporary increase in anxiety. The individual would then learn that such fear is excessive and inappropriate, the anxiety level would decrease and the phobia should thereafter be extinguished.

In Freudian psychoanalytical theory, phobic neuroses arise from intrapsychic anxiety caused by emotional conflict being concentrated into a specific situation by the defence mechanism of displacement. This leaves the individual free and able to cope with other situations in life. Other defence mechanisms such as projection and avoidance may also be pertinent. In 1909, Freud described the development of a phobia of horses in a 5-year-old child called ‘Little Hans’. Freud postulated that Hans’ fear of his father, and specifically of castration, was displaced on to horses in general after seeing a male horse urinate in the street. Freud’s assessment, however, was based on information from Hans’ father and not on the basis of an interview with Hans himself. Psychoanalytical explanations conceptualize phobias as symbolic representations of conflict, frequently of a sexual nature, that prevent the individual from going into a situation symbolic of that conflict. In agoraphobia, for example, a road with much traffic may represent sexual intercourse to an individual afraid of developing a sexual relationship. However, in spite of such theories, psychoanalysis is a very ineffective treatment of phobias in general.

The ‘preparedness theory’ suggests that fear of some objects may be evolutionarily adaptive to increase survival of the individual or species and may thus be difficult to extinguish. An ethological theory of an evolutionarily determined genetic vulnerability to unfamiliar territory has also been proposed to account for agoraphobia.

Predisposing, precipitating and perpetuating factors

The development of phobias may follow childhood parental death. Individuals with phobic disorder are also more likely
to have a dependent, emotionally immature and possibly introverted premorbid personality, but this is not invariable. In the case of agoraphobia, although this can arise spontaneously, it is frequently precipitated by traumatic events such as bereavement, illness or divorce. Social phobias are said to develop from adolescence, and more commonly in shy, anxious and avoidant individuals with low self-esteem, and also in people who have experienced parental separation, overcontrolling maternal upbringing and childhood sexual abuse.

Phobias might be prevented by generally encouraging children to face rather than avoid feared situations. Fears may be passed on from one generation to another within a family and, similarly, they vary according to cultural background.

Perpetuating factors may include alcohol and drug abuse, and also the collusion of family members. For instance, an agoraphobic female may obtain from her condition secondary gain from her spouse having to accompany her on outings or do the shopping instead of her, and he may collude in this because of his desire to have his wife be dependent on him. In addition, phobic disorders get worse with intercurrent depressive episodes, which may be in reaction to the phobias and the limitations they impose on the individual, or which may coexist with them or indeed predate them.

Management

Psychological treatment

Behaviour therapy is the treatment of choice for phobias, but it requires the patient’s commitment. It is most effective, in 75 per cent of cases, for specific phobias. Exposure techniques are the most widely used, where the way in which avoidance maintains anxiety is explained and the individual is encouraged to face rather than avoid the phobic situation. This can be done in a graded way, tackling easier situations first and practising this repeatedly before confronting more difficult situations.

Exposure techniques developed from the behavioural technique of systematic desensitization (originally described by Wolpe39), in which relaxation training is combined with gradual exposure to the phobic stimulus over a number of sessions. The stimulus is presented in a progressively more anxiety-provoking form (graded hierarchy), either in fantasy but more effectively in vivo. It is based on the principle of reciprocal inhibition – that is, if a response incompatible with anxiety, such as relaxation, is produced while the subject is exposed to the source of this anxiety, then the fear and avoidance response will be extinguished. Thus, a systematic desensitization programme for an individual with a phobia of spiders (arachnophobia) might involve a graded hierarchy from thinking about spiders to being in the presence of a dead spider in a room, and then a live spider being brought progressively nearer to the individual until, with agreement, the individual might tolerate touching and holding the spider. Treatment goals should be agreed with the individual; for example, the goal for someone with a spider phobia might be merely to be in the same room as a spider, or it may be to hold the spider in the hand. ‘Applied tension’ may be additionally required in phobias of blood and bodily injury in order to counter the bradycardia and hypotension.

Flooding (implosion) is a behavioural technique in which the individual is maximally exposed to the feared stimulus, under supervision, until anxiety reduction or exhaustion occurs. This is based on the assumption that an individual cannot maintain a maximum level of anxiety indefinitely (in fact, beyond about 40 min). For instance, an individual with a phobia of heights may be taken, with consent, to the top of a tower block and asked to remain there with a therapist until the anxiety subsides. Such procedures can, of course, be distressing and the individual must be physically well enough (e.g. with no cardiac disease) to tolerate them. They are probably no more effective than other exposure techniques in the long term.

In modelling, the individual observes the therapist engaging in non-avoidant behaviour in relation to the phobic stimulus. The idea is that the individual should later copy such behaviour. Modelling may sometimes be usefully added to exposure and other behavioural treatments.

Behavioural techniques may be undertaken in groups. For instance, a group of agoraphobic patients may be taken together to the feared situation of a town centre. Such techniques also frequently involve elements of self-help, including homework in which the family members may also have to participate. It is also of note that many sexual dysfunctions have phobic elements and can be treated behaviourally.

Where agoraphobia is accompanied by panic disorder, CBT is the treatment of choice, using graded self-exposure, cognitive therapy or behavioural experiments to test catastrophic beliefs and cease safety behaviours.

For social phobia, CBT is the treatment of choice. This involves explanation, structured exercises for recognizing maladaptive thinking, exposure to simulated situations provoking anxiety, cognitive restructuring of the patient’s maladaptive thoughts, homework assignments and self-administered cognitive restructuring routines. Undertaken in groups, CBT is moderately beneficial. There is no evidence of specific benefit from social skills or relaxation training.

It is important to be aware that the behaviour of family members may reinforce the phobia and obstruct treatment, and that family members may need to be counselled accordingly.

Drug treatments

Agoraphobia and depression sometimes coexist, and antidepressant drugs are often used. SSRI antidepressants and MAOIs such as phenelzine are superior to placebo in specifically relieving symptoms of agoraphobia and social
phobia, perhaps reflecting underlying abnormalities in the serotonergic and dopaminergic systems. Tricyclic antidepressants may be effective in people with depressive features. CBT is the treatment of choice for people with agoraphobia with panic disorder, but high-dose SSRI antidepressants are the second-line treatment, although response may not appear for 6 weeks and reach a maximum level of benefit only after 12 weeks.

Benzodiazepines can be used to prevent the reinforcement of fear through avoidance; diazepam, for instance, can be given 1 h before an individual enters a phobic situation. However, anticipatory anxiety may sometimes be the main reinforcer of a phobia, so that benzodiazepines, for instance, taken 4 h before a phobic situation, may be more effective. Benzodiazepines are, in any case, most effective when used in combination with behavioural techniques, especially in the initial stages (e.g. to allow the individual to enter a phobic situation).

Beta-adrenergic antagonists (beta-blockers), such as propranolol, are effective if somatic symptoms predominate and reinforce a phobia, especially in specific social phobia. They do not work well in generalized social phobia. As they are non-sedative, these drugs can be particularly useful for driving tests, examinations and for people in the acting or music professions, where sedation may impair performance. Beta-blockers have been used by snooker players to steady trembling arms and are certainly preferential to the use of alcohol for the same effect in professional darts players.

Although providing emotional support can be beneficial, psychoanalytical psychotherapy is considered to be very ineffective in the specific treatment of phobias.

**Prognosis**

Animal phobias have the best outcome. Social phobias tend to improve gradually and agoraphobias do worse, with a tendency towards chronicity.

**OBSESSIVE–COMPULSIVE DISORDER**

Obsessive–compulsive disorder is a non-situational preoccupation in which there is subjective compulsion despite conscious resistance. Such preoccupations can be thoughts (ruminations or obsessions) or acts (rituals or compulsions).

Ruminations are like ‘tunes’ stuck in one’s head. The content is often absurd or alien to the individual’s normal personality, such as preoccupations with sex, violence, accidents or death, although such thoughts are recognized as the individual’s own (cf. thought insertion in schizophrenia, where there is a delusional belief that thoughts are externally inserted into the individual’s mind). Ruminations may be recurrent words, thoughts, ideas or mental images that are persistent, unwellcome, egodystonic and intrusive or that may be pointless or abstract. However, in general, patients do not act on their ruminations.

Rituals are akin to the childhood compulsion to walk between cracks in the pavement. They are repetitive and time-consuming and usually cause the patient distress. After an initial decrease in anxiety, rituals tend to increase anxiety further. Examples include obsessive washing or cleaning behaviour, and checking light switches or locks. Checking on three occasions is particularly common and has been related to the Holy Trinity. Individuals may also count to a certain number before undertaking an activity. Although rituals are sometimes referred to as ‘compulsions’, both ruminations and rituals are compulsive.

In obsessive–compulsive disorder, insight is maintained: individuals regard their ruminations or rituals as ‘silly’, but they are unable to stop. This is in contrast to delusional ideas, which may be recurrent and preoccupying, but where insight is lost and the ideas are regarded as true. Also in contrast to rituals, stereotypies are regular repetitive non-goal-directed movements, such as foot-tapping or utterances. These occur in conditions where insight is lost, such as chronic schizophrenia, infantile autism and mental handicap.

Particularly in chronic cases of obsessive–compulsive disorder, resistance to intrusive thoughts frequently abates and, indeed, may be absent and is therefore not an essential component of the disorder. In children, resistance is often absent. However, when conscious resistance is present, it is this that helps to generate the anxiety and tension, which are relieved only by ruminating again or performing the rituals.

Rituals may arise from obsessional doubts (folie de doute) and have been referred to as a small area of organization in the chaos of the individual’s life. It is of note that when one normally checks switches or locks, one does not usually register (i.e. precisely remember) the activity, hence the capacity for obsessional doubting.

It is often helpful to individuals with obsessive–compulsive disorder to point out that anxiety comes first, before the ruminations or rituals, which are seen as a defence against anxiety. The patient may otherwise regard them as evidence of ‘madness’. It should also be noted that depression and anxiety are common in obsessive–compulsive disorder.

So-called ‘illness phobias’ can better be understood as obsessive–compulsive disorders because such individuals ruminate on whether they have, for instance, cancer, acquired immunodeficiency syndrome (AIDS) or venereal disease. These are non-situational preoccupations, as compared with a true phobia, where there is an inappropriate external situational anxiety with avoidance.

The most common pattern involves obsessions about contamination followed by washing.

Individuals with washing rituals are often actually germ-phobic, but as it is not possible to see germs, the patient
becomes dirt-phobic and generates washing rituals, to the extent that they might wash up to 40 times a day.

Screening questions include enquiring about:

- worry about contamination, dirt and germs;
- washing and checking excessively;
- unwanted thoughts of which one cannot be rid;
- doing things slowly in order to do them carefully;
- overconcern about routine, orderliness and symmetry.

Extreme slowness out of proportion to other symptoms (primary obsessional slowness) is rare.

**Epidemiology**

Past estimates of the prevalence of obsessive–compulsive disorder have included 0.5 per cent of the general population, 10 per cent of all patients with neurotic disorders and about 1 per cent of the psychiatric out-patient population. However, the disorder is now considered to be much more common than previously thought, and studies from the USA suggest that 2–3 per cent of the population may have obsessive–compulsive disorder at some time in their lives. Rates across the world are similar, although symptom themes vary. Minor obsessive–compulsive symptoms may be present in up to 17 per cent of the population; 1-month prevalence rates suggest it affects 1 per cent of males and 1.5 per cent of females. Males have an earlier onset. Two-thirds of individuals have an age of onset in the early twenties, before 25 years, with a mean age of about 22 years. It can even begin in childhood, with a peak age of onset of 12–14 years. Patients with checking rituals have an earlier mean age of onset of 18 years compared with other groups, with a mean age of onset of 27 years. The course tends to be chronic with exacerbations.

**Differential diagnosis**

Obsessional symptoms may be seen in up to 20–30 per cent of patients with depressive disorder and also in schizophrenia, where it has been suggested that premorbid obsessional symptoms, arising even in childhood, might represent defences against psychosis. Obsessional symptoms also occur in organic psychoses, including early dementia, and in anorexia nervosa and generalized anxiety disorder. Obsessional ruminations about harming one’s baby occur as part of puerperal psychiatric disorders and, especially in cases of depression, should be taken very seriously in order to prevent them being acted on.

As discussed previously, delusional ideas may be recurrent and preoccupying, but insight is lost and they are regarded as true. Similarly, insight is lost in stereotypes, unlike obsessional rituals.

It is clinically useful to distinguish between the compulsions of obsessive–compulsive disorder and the impulsive behaviour of people with low impulse control and lack of resistance, such as individuals with psychopathic or eating disorders, disorders of sexual preference or gambling addiction.

**Aetiology**

The aetiology of obsessive–compulsive disorder is some way from being understood, and it is probable that its aetiology is different from other neurotic disorders. There is an increased genetic predisposition in first-degree relatives (3–7%) and a greater concordance between monozygotic (50–80%) compared with dizygotic (25%) twins. However, types of rumination and ritual are not always the same in different affected family members. There is also a genetic association between Tourette’s syndrome, chronic motor tic disorder and obsessive–compulsive disorder. Indeed, up to 20 per cent of individuals with obsessive–compulsive disorder may have tics, which in turn are suggestive of basal ganglia disorder.

There is an increased incidence of obsessive–compulsive disorder in people with brain injury, for example due to head injuries, encephalitis, including encephalitis lethargica, or syphilis. Neuropsychological studies show abnormalities in executive function. Evidence for a neurobiological basis has been accrued from positron-emission tomography (PET) and magnetic resonance imaging (MRI) techniques, in which orbitofrontal and cingulate cortices and basal ganglia abnormalities have been found, as have reductions bilaterally in the size of the caudate nuclei and retrocallosal white matter. These findings all suggest structural abnormalities in the brain in at least some cases of obsessive–compulsive disorder. Increased glucose metabolism in the caudate nucleus and orbitofrontal cortex has also been found. There is also evidence for abnormalities in serotonin (5-HT) transmission or in its interaction with dopamine (DA) in the central nervous system. Some children and adolescents develop obsessive–compulsive disorder and motor tics after beta-haemolytic streptococcal infections, suggesting a cell-mediated autoimmune aetiology against basal ganglia peptides affecting the corticostriatal-thalamic-cortical circuits.

A premorbid anankastic (obsessive–compulsive) personality disorder is said to predispose to the subsequent development of obsessive–compulsive disorder but is present in only 15–35 per cent of cases. Some studies suggest that a majority of patients have a premorbid anankastic personality, while others suggest that it is only a minority who do. People with an anankastic personality are characteristically obsessional, rigid, orderly, punctual and stubborn. However, they do not resist their obsessionality and their thoughts are not alien to them. Certain obsessional personality traits, such as conscientiousness, can be useful unless they result in insecure dithering and indecisiveness.

In Freudian psychoanalytical theory, anankastic personality disorder originates at the anal training stage of development (e.g. due to harsh toilet training). Obsessive–compulsive disorder is seen as a regression back from the...
Oedipal to the anal-sadistic phase of development. Magical thinking (the belief that thinking about an event can cause that event) is also cited [omnipotence of thought]. Obsessional symptoms are considered to arise from intrapsychic anxiety due to emotional conflicts being expressed via the defence mechanisms of displacement, reaction formation and undoing (e.g. checking to feel secure). Obsessive–compulsive disorder may represent a defence against anxiety associated with sexual and aggressive impulses, and also a defensive regression to the anal stage of development.

Learning theory cannot account fully for obsessive–compulsive disorder, but it does aid cognitive-behavioural treatment. Anxiety comes first; obsessions follow. The latter give rise to more anxiety, which leads to compulsions to reduce the feared consequences of the obsession and level of anxiety, but this is only short-lived and serves only to reinforce the compulsion.

**Management**

In the treatment of obsessive–compulsive disorder, any depressive component or other co-morbid intercurrent mental illness should also be treated effectively. The most common cause of ruminations is depression, not primary obsessive–compulsive disorder.

**Psychological treatment**

Supportive psychotherapy may be of value in pointing out to the individual that he or she is not ‘going mad’ and that anxiety comes before symptoms, which are seen as a defence against anxiety. However, psychoanalytical psychotherapy is ineffective, as the patient shows poor free association and may unprofitably ruminate during therapy, although people with an anankastic personality may benefit. This ineffectiveness may be further evidence in favour of a neurobiological basis for the condition.

CBT is, however, effective. This involves graded self-exposure and self-imposed response prevention of the ‘undoing’ of obsessions through compulsions, and/or cognitive therapy.

In general, rituals are easier to treat than ruminations. One behavioural approach for rituals is response prevention, whereby individuals learn to cope with the increasing tension associated with resistance when they are prevented from undertaking their rituals. Prevention is by distraction, discussion and, occasionally, mild physical restraint. In-patient treatment may be required for such treatment to be effective. Modelling can also be useful.

An alternative to response prevention is mass practice, in which the individual is told to keep repeating the rituals to a degree beyond what even he or she would wish to undertake voluntarily, until the anxiety reduces and the compulsion subsides.

Ruminations are less easy to treat. The technique of thought-stopping can, however, be helpful. In this, an individual is asked to relax and ruminate, whereupon the therapist will shout ‘Stop!’, at which point the patient must alter the content of those thoughts. Shouting of the word ‘stop’ is later replaced by the individual merely thinking of the word. This technique is repeated until the individual can learn thought control and to employ the technique as required. Smelling salts have also been used as an aversion technique to achieve thought-stopping. Individuals have also been taught to restrict their ruminating to a fixed period each day and thereafter to get on with their everyday lives.

**Drug treatments**

SSRI antidepressants at high doses are the drug treatment of choice. Their use developed from the observation that the tricyclic antidepressant clomipramine (the tricyclic with the most powerful 5-HT reuptake inhibition) was helpful over months (e.g. 8–16 weeks) in 40–60 per cent of cases. Their beneficial effect is not dependent on their antidepressant properties. They are superior to other tricyclic antidepressants, although these too have produced improvement, perhaps because they treat the often-associated depression. Clomipramine causes significant anticholinergic side effects and sexual difficulties and can produce seizures at high doses. Clomipramine may be marginally superior, but SSRIs are better tolerated.

Low-dose atypical antipsychotic medication appears to be more effective than benzodiazepines, possibly because of its effect on conditioned responses. However, the use of atypical antipsychotics is as an adjunct in cases resistant to SSRI antidepressants, not as a monotherapy. Benzodiazepines may be helpful in the short term.

Placebo response rates in studies are low (about 50%) compared with other psychiatric disorders.

Overall, for severe cases of obsessive–compulsive disorder, it is usual in the UK to combine CBT with SSRI alone, but the combination may be superior.

**Psychosurgery**

In severe, intractable, chronic and incapacitating cases, where all other treatments have failed, stereotactic sitespecific brain surgery has been reported to be successful, although there is a lack of adequate trials and such procedures carry stigma. Radioactive yttrium implants and, more recently, non-invasive proton, electron and X-ray techniques have also been used.

Anterior cingulotomy, capsulotomy and limbic leucotomy have been found to be effective in 25–30 per cent of such cases. Cingulotomy carries a 1 per cent risk of epilepsy. All these procedures involve a separation of the frontal cortex from the deep limbic structures. A prerequisite for any such surgery is a stable premorbid personality, as patients with a history of antisocial behaviour and alcoholism may be further disinhibited in their behaviour as a result of the procedure. In England and Wales, under the Mental Health Act 1983, Section 57, neurosurgery for this
condition requires both the consent of the patient and the agreement of a second opinion in addition to that of the patient’s responsible clinician (consultant). Neurosurgery is banned for this purpose in some other countries.

**Prognosis**

Obsessive–compulsive disorder can now be treated effectively in up to 70 per cent of cases. The more reasonable the preoccupation, the worse the prognosis tends to be – for example, checking that the house is locked before leaving home has a poorer prognosis than pointless rituals such as walking between the cracks in the pavement. Other poor prognostic factors include early age of onset, the coexistence of obsessions and rituals, low social function at baseline, magical obsessions and rituals.44

Table 40.9 summarizes the treatments for generalized anxiety disorder, panic disorder, phobic disorders and post-traumatic stress disorder.

**NEUROTIC DISORDERS IN ELDERLY PEOPLE**

In people aged over 65 years, the incidence and prevalence of neurotic disorders are reduced (generalized anxiety disorder 4%, simple phobia 4%, agoraphobia ≤8%, social phobia 1%, obsessive–compulsive disorder ≤0.8%). The onset of panic disorder in old age is unusual, and depression and underlying physical disorders should be excluded.45 In elderly people, anxiety symptoms are often associated with depression and may be secondary to physical disorders or to prescribed drugs. Hypochondriacal symptoms are prominent.46

**Reactions to severe stress and adjustment disorders**

ICD-10 provides a classification for a group of disorders that are a direct consequence of exceptionally stressful life events, producing acute stress reactions, or significant life changes leading to continued unpleasant circumstances, which result in adjustment disorders. Whereas psychosocial stresses can precipitate the onset or contribute to the presentation of many psychiatric conditions, the disorders in this group would not occur without the impact of such stresses. They can be regarded as maladaptive responses to severe or continued stress, in that they interfere with successful coping mechanisms and lead to impaired social functioning. Acts of self-harm, most commonly self-poisoning by a prescribed medication, may be associated closely in time with the onset of either an acute stress reaction or adjustment disorders.
**Acute stress reaction/disorder**

Acute stress reaction in ICD-10 or acute stress disorder in DSM-IV is a transient disorder that develops in an individual with no other apparent mental disorder in response to exceptional physical or mental stress; it usually subsides within hours or days. The stress may be an overwhelming traumatic experience involving serious threat to the patient or a loved one, or an unusually sudden and threatening change in their social position or network, such as multiple bereavement or a domestic fire. The risk of developing this disorder is increased if physical exhaustion or other organic factors are present. Clearly, individual vulnerability and coping capacity are important, as not all people exposed to exceptional stress develop such a disorder. There is a mixed and usually changing picture of symptoms, typically including an initial state of ‘daze’, followed by depression, anxiety, anger, despair, overactivity (flight reaction or fugue) or withdrawal. No one symptom predominates for a long time, and the condition resolves rapidly within a few hours at most when the patient is removed from the stressful environment. When the stress continues or cannot be reversed, symptoms usually begin to diminish after 24–48 h and are usually minimal after 3 days.

This disorder was originally introduced into DSM-IV in 1994 to identify people who would develop post-traumatic stress disorder. However, only about half of cases do so, and the condition may be removed from DSM-V.

**Post-traumatic stress disorder**

This is a common reaction of normal individuals, usually within 6 months, to an extreme trauma (‘an exceptionally threatening or catastrophic experience’) that is likely to cause pervasive distress to almost anyone, such as experiencing a natural or manmade disaster, being involved in combat or a serious accident, witnessing the violent death of others, or being the victim of torture, terrorism, rape or other crime. Manmade disasters are more likely than natural disasters to cause post-traumatic stress disorder. Although predisposing factors such as personality traits and a previous history of neurotic or affective illness may lower the threshold for the development of the syndrome or aggravate its course, they are neither necessary nor sufficient to explain its occurrence. The syndrome is characterized by five elements:

- Experience of a major trauma
- Intrusive recollections in the form of thoughts, nightmares and flashbacks
- Sense of numbness and emotional blunting, which represent an attempt to avoid reminders of the trauma
- Increased arousal and hypervigilance, with an enhanced startle reaction and insomnia
- Onset follows trauma with a latency period of a few weeks to months, but not more than 6 months, and the condition lasts for at least 1 month.

Note that incomplete memory of the trauma can occur but is not characteristic.

The condition is seen as arising from the overwhelming and overloading of normal emotional processing. Emotional numbing/dissociation following traumatic events is predictive of post-traumatic stress disorder at 6 months.49

**Epidemiology**

The lifetime prevalence has been estimated as 7.8 per cent in the USA, with women twice as commonly affected as men. It occurs after a traumatic event in 8–13 per cent of men and 20–30 per cent of women. In men the traumatic event is more likely to be that of combat, while in women it is more likely to be rape. The exposure rates for significant traumatic events are much higher (60.7% of men, 51.2% of women).49

**Neurobiology**

Abnormalities in the hypothalamic-pituitary-adrenal axis, including hypocortisolaemia and supersuppression in the dexamethasone suppression test, the opposite to that seen in depression, together with abnormalities in regional blood flow in the basal ganglia and orbitofrontal cortex, as seen in obsessive–compulsive disorder, have been found, as have increased noradrenergic and serotonergic central activity. Reduced hippocampal volume was reported in post-traumatic stress disorder in Vietnam veterans. The hippocampus mediates conscious memory, including of traumatic events, while the amygdala mediates unconscious memories, for example autonomic aspects of trauma. Decreased medial prefrontal and anterior cingulate areas have been found in neuroimaging studies, which correlate with increased activity in the amygdala, resulting in hypersensitivity to external threats, which is seen in post-traumatic stress disorder.50

Co-morbid psychiatric diagnoses are present in up to 80 per cent of patients. Anxiety and depression are commonly associated, and suicidal ideation may also occur. Both major depression and dysthymia may develop. The condition may be complicated by drug or alcohol abuse. Rarely, there may be dramatic acute episodes of fear, panic or aggression, triggered by stimuli that arouse a sudden recollection or a re-enactment of the trauma, or of the original reaction to it. Simple phobias, agoraphobia and social phobia may also develop.

Post-traumatic stress disorder, although not always referred to by that term, has been recognized throughout history. During the Second World War it was known as ‘shell shock’, but it was the Vietnam War that provided the major impetus for research into and description of the condition,51 and since 1980 a number of natural disasters have led to its increasing recognition.

**Prevention**

Primary prevention has been attempted through stress inoculation in high-risk groups (e.g. exposure to dead bodies).
Secondary prevention strategies that have been found to be of value in aiding early emotional processing include early meetings of groups of survivors, within 1–2 days if possible, where group discussion can set the individual’s emotional reactions within the normal range, and critical incident debriefing. The long-term efficacy of such measures is, however, unproven, and inappropriate and ill-timed interventions or interventions that lead to inappropriate rumination on the trauma can be harmful. NICE in the UK does not recommend brief single-session interventions.

Management
Many cases go undetected owing to the individual’s reluctance to discuss symptoms and seek help. A high level of clinical suspicion is therefore required. Making the diagnosis can be reassuring to the individual, who often feels that no one can understand what he or she has been through. Specific treatment is indicated where symptoms have persisted for more than 6 months and social handicaps are significant. Self-help and mutual support groups, such as Rape Crisis Centres, can be of benefit. Central to most treatment approaches is the rehearsal of the ‘trauma story’, either in a cognitive-behavioural approach, which may include imaginal or in vivo exposure and may be combined with adjunctive anxiety management, or in a technique called ‘testimony’. The aim is to rehearse the trauma and reawaken associated emotions, but in a way that can be tolerated and processed without leading to avoidance. Verbal recall represents behavioural exposure to a traumatic event, and the aim is to achieve habituation to it. Audiotape desensitization using the individual’s own account of the trauma may also be of value. For survivors of torture, the pain is often compounded by guilt and fear, for instance over actions they may have been forced to carry out. They are encouraged to reframe their thinking and to see that such actions were due not to their betrayal of others but to the conditions to which they were subjected.

In the UK, NICE has made recommendations for sequential treatment in primary and secondary care settings and recommended either a CBT approach or eye movement desensitization processing (EMDR). EMDR involves rapid and rhythmic eye movements induced by the patient visually tracking the therapist’s finger moving back and forward for about 20 s, during which time the patient focuses on the traumatic image and associated negative emotions, sensations and thoughts, and discusses such associated emotions. Once the distress begins to reduce, reference to positive thoughts for the event are encouraged. However, eye movement may not, in fact, be necessary, with the procedure perhaps merely inducing desensitization.

Antidepressant medication, although not recommended as a routine first-line treatment, has also been found to be effective in the management of post-traumatic stress disorder, treating the commonly associated depression, facilitating sleep and reducing intrusive memories. SSRIs at high doses for 5–8 weeks have been cited as especially beneficial for core symptoms. Tricyclic antidepressants help the intrusive symptoms of anxiety and depression. However, the MAOI phenelzine may be better than the tricyclic imipramine. Response may be delayed for up to 8 weeks. NICE recommends the noradrenergic and specific serotonergic antidepressant (NaSSA) mirtazapine or the SSRI paroxetine. Benzodiazepines should be avoided because of their high dependency potential, especially in the first 2 weeks following the trauma, as their use may interfere with the memory processing necessary to reduce symptoms.

Hospital disaster plans should also take into account the psychological responses of victims.

Adjustment disorder
Adjustment disorders are states of emotional distress and disturbance, usually interfering with social functioning, arising in a period of adaptation to a significant life change or stressful life event such as bereavement or separation. Onset is usually within 1 month of the event and the symptoms do not usually last more than 6 months. In contrast to an acute stress reaction, individual predisposition or vulnerability plays a greater role in the risk of developing such a disorder and in shaping its manifestations. However, it is assumed that the condition would not have arisen without the stress. There may be a brief or prolonged depressive reaction, a mixed anxiety and depressive reaction, or disturbance of conduct, for example in adolescence. Other predisposing factors include culture shock and hospitalization in children. As a condition, it has been little researched. Its management has been informed by the treatment of other conditions with similar symptomatology. It may respond better than major depression to antidepressant medication.
● Anxiety is more often associated with other psychiatric disorders, such as depression, than generalized anxiety disorder, especially when the onset is after the age of 35 years.

● Cognitive therapy and anxiety management techniques are effective treatments for generalized anxiety disorder.

● Benzodiazepines should not be prescribed as hypnotics for more than 10 nights, or for anxiolytics for more than 4 weeks, due to the risk of dependency.

● Panic attacks are discrete periods of intense fear or discomfort caused by acute psychic and somatic anxiety symptoms, which are unexpected and not triggered by situations.

● Panic disorder is effectively treated by cognitive-behavioural approaches.

● Antidepressants, especially the SSRIs and clomipramine, are also beneficial in panic disorder.

● A diagnosis of mixed anxiety and depressive disorder is made when symptoms of both anxiety and depression are present but neither symptom is severe enough to justify a separate diagnosis.

● Neurotic disorders do not include depression if this is the predominant symptom. It is instead classified under mood (affective) disorders as a depressive episode.

● Fear is a normal prudent situational anxiety.

● A phobia is an inappropriate situational anxiety with avoidance.

● Specific (isolated) phobias, such as of animals, are the most common phobias, but agoraphobia, a fear not only of open spaces but also of crowds and difficulty in making an easy escape, is the phobia most commonly seen by psychiatrists.

● Exposure techniques are the psychological treatment of choice for phobias and may involve homework assignments.

● SSRIs and MAOI antidepressants such as phenelzine specifically relieve symptoms of agoraphobia and social phobia.

● Obsessive–compulsive disorder involves non-situational preoccupations with subjective compulsion despite conscious resistance. The preoccupations may be thoughts (ruminations/obsessions) or acts (rituals/compulsions).

● Insight is maintained in obsessive–compulsive disorder: ‘It’s silly, but I can’t stop it.’

● Obsessional symptoms are common in depressive disorder, and any depressive component should always be treated adequately.

● Cognitive-behavioural therapy treatments for obsessive–compulsive disorder include thought-stopping for ruminations and response prevention for rituals.

● SSRIs and clomipramine specifically treat obsessional symptoms.

● Post-traumatic stress disorder is a reaction of normal individuals to a major trauma. Intrusive recollections, emotional numbing, increased autonomic arousal and hypervigilance occur.

● Meetings of groups of survivors and critical incident debriefing within 1–2 days may be preventive of post-traumatic stress disorder.

● Self-help and mutual support groups are helpful for people with post-traumatic stress disorder.

● Psychological treatments for post-traumatic stress disorder include rehearsal of the ‘trauma story’, such as ‘testimony’.

● Antidepressant drugs are effective in the treatment of post-traumatic stress disorder, although their main effect may be on the associated depressed mood.

2. Whytt T (1768) Observations of the nature, causes and cure of those disorders which are commonly called nervous, hypochondriac, or hysteric: to which are prefixed some remarks on the sympathy of the nerves. In R Whytt (ed.) The Works of Robert Whytt, 3rd edn. Edinburgh: Balfour.

INTRODUCTION

This chapter deals with the various types of neurotic and stress-related disorder previously included under the term 'hysteria'. This now redundant term referred to physical or mental symptoms not of organic origin and created and maintained for unconscious psychological motives.

The term 'hysteria' has now been replaced by the terms 'dissociative disorders' (mental and sometimes neurological symptoms for which no organic cause can be found) and 'somatoform disorders' (physical symptoms with no apparent organic basis). The term 'conversion' refers to medically unexplained symptoms affecting voluntary motor or sensory function, for example limb paralysis or psychogenic blindness or deafness, where mental stress has been converted into a physical symptom.

The term 'hysteria' has been in use for 2000 years and stems from the Greek word for womb, *husteria*. The ancient Greeks believed that the womb could wander through the body and cause malfunction in various organs by pressing on them. The term has been used in psychiatry with many and varied meanings, and it is still used today in some circumstances.¹

The old hysterical neurosis is now described in the tenth revision of the *International Classification of Diseases* (ICD-10) under the term ‘Dissociative (Conversion) Disorders’ (Box 41.1) and includes the following concepts:

---

**Box 41.1** Dissociative (conversion) disorders as described in ICD-10

### COMMON THEMES

- Partial or complete loss of normal integration between memories of the past, awareness of identity and immediate sensations and control of bodily movements
- The term 'conversion' is applied to some of these disorders and implies that unresolved problems and conflicts are transformed into symptoms, e.g. paralysis and anaesthesias
- Denial of problems and difficulties that are obvious to others
- No evidence of physical disorder that might explain symptoms
- Evidence of psychological causation in form of association in time with stressful events and problems or disturbed relationships.

### SPECIFIC DISORDERS

- **Dissociative amnesia**: loss of memory (partial or complete) for recent events of a traumatic or stressful nature
- **Dissociative fugue**:
  - Features of dissociative amnesia
  - Purposeful travel beyond everyday range
  - Maintenance of self-care and simple social interactions with strangers
- **Dissociative stupor**: profound diminution or absence of voluntary movement and normal responsiveness to external stimuli
- **Trance and possession states**
- **Dissociative disorders of movement and sensation**: e.g. loss of ability to move all or part of limb(s); sometimes accompanied by calm acceptance (la belle indifférence)
- **Dissociative convulsions** (pseudo-seizures)
- **Other dissociative and conversion disorders**: e.g. Ganser's syndrome, multiple personality.
• **Conversion hysteria**, in which there is a loss of or change in bodily function due to the conversion of unconscious intrapsychic anxiety, caused by emotional conflict, to physical bodily symptoms of symbolic significance (e.g. paralysis or anaesthesia of the limbs).

• **Dissociative states**, in which there is dissociation of the normally integrated functions of consciousness such that one mental activity may be dissociated from another, for example dissociative (hysterical) amnesia, in which stressful or traumatic events cannot be recalled while other memories, such as those required for everyday living, may be preserved.

---

**Box 41.2 Varied meanings of the term ‘hysteria’**

**HYSTERIC NEUROSIS**

This is now described in ICD-10 under the term ‘Dissociative (Conversion) Disorders’.

**HYSTERICAL SYMPTOMS**

These may occur in other mental illnesses, such as depression and anxiety, and may also complicate organic disease.

**EPIDEMIC (COMMUNICABLE) HYSTERIA OR MASS HYSTERIA**

In this condition, there may be a widespread outbreak of particular hysterical or other symptoms, such as fainting, hyperventilation, emotional distress and abdominal pain. This often occurs among young females and in institutions such as schools. There is often a background of tension or apprehension, and the initial symptoms may appear in an influential or powerful figure and then spread, by suggestion, to younger or less influential individuals, while excluding outsiders or more intellectually able people. Food or chemical poisoning or infection may initially be suspected, which only increases the emotional tension. In the Middle Ages, dancing mania swept through Europe, although alternative explanations have been given for this in terms of an infective neurological disorder causing limb restlessness.

**HYSTERICAL OR HISTRIONIC PERSONALITY DISORDER**

Such individuals have overemotional and overdramatic personality traits. They may crave attention and be manipulative. Under stress they have an increased vulnerability to developing dissociative (conversion) disorders and are also prone to parasuicidal acts.

**HYSTERICAL (HISTRIONIC) BEHAVIOUR**

This term is used frequently, not only by the general public, to refer to behaviour where there is ‘acting out’ of problems and also loss of or poor control of impulses. Such behaviour occurs particularly in people with histrionic or psychopathic personalities. It is useful to distinguish the conscious motivation for such behaviour from the unconscious motivation underlying hysterical symptoms in dissociative (conversion) disorders.

**HYSTERICAL PATIENT**

This is a term of abuse often applied by doctors to patients, usually female, when the doctor is irritated because of a belief that the patient may be exaggerating her symptoms or the doctor has a feeling of being manipulated. Similar male patients tend to be labelled ‘psychopaths’. The use of the term ‘hysterical’ in this way usually reflects an unsatisfactory doctor–patient relationship.

**ST LOUIS HYSTERIA (BRIQUET’S SYNDROME)**

Also known as ‘somatization disorder’, this refers to individuals with recurrent and multiple unexplained physical symptoms commencing before the age of 30 years and of chronic duration.

**HYSTERICAL PSYCHOSIS OR HYSTERICAL PSEUDOPSYCHOSIS**

This is a group of pseudopsychotic disorders, with pseudodelusions and pseudohallucinations, which occur suddenly after severe emotional stress and usually end abruptly within a few days. Such pseudohallucinations are experienced as arising within the mind, rather than being perceived by actual sense organs. They are a form of vivid imagery, located in subjective rather than objective space, but not subject to conscious control. Included in such disorders are a number of culture-bound disorders, such as ‘running amok’ in South-East Asia and, from history, the Vikings ‘going berserk’. It has been suggested that Joan of Arc had an hysterical psychosis.

**ANXIETY HYSTERIA**

This is a psychoanalytical term for phobic anxiety.
Box 41.2 shows the varied meanings of the term ‘hysteria’ used in the present and the past.

There are, however, significant interrelationships between the varied concepts of hysteria. For instance, people with a hysterical personality disorder are more likely than normal to develop conversion symptoms, conversion disorders and somatization disorder, and are more likely to be the influential figure instigating mass hysteria in others. Also, many females with St Louis hysteria, or Briquet’s syndrome, have conversion symptoms. In addition, nearly all those in the above categories are prone to irritate their doctors and develop unsatisfactory doctor–patient relationships.

In ICD-10, the category of dissociative (conversion) disorders includes conversion disorder (previously hysterical neurosis, conversion type). In the fourth revised edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR), the category of dissociative disorders does not include conversion disorder, which is subsumed under the category of somatoform disorders. Table 41.1 compares the nomenclature for these disorders in ICD-10 and DSM-IV.

For clarity, dissociative disorders will be described here separately from the conversion disorders. However, both dissociative and conversion disorders are usually temporarily related to a trigger and are of sudden onset; the link between psychological stress and resulting symptoms is not consciously known to the patient, and both disorders are increased in females, in people under age 40 years and in people with vulnerable personalities.

### DISSOCIATIVE DISORDERS

These disorders are characterized by a psychogenic (psychologically caused) alteration in an individual’s state of consciousness or personal identity. Box 41.1 summarizes the description of dissociative disorders in ICD-10.

Dissociation is a state in which two or more mental processes coexist without becoming integrated. Emotional conflict and distress are thus segregated from normal consciousness, as in dissociative amnesia, or even to a separate distinct personality, which may take control of the person’s behaviour, as in multiple personality disorder. Historically, Janet particularly emphasized the defence mechanism of dissociation following traumatic experiences in cases of hysteria. Doubts, however, remain about the definition and measurement of dissociation.

#### Dissociative amnesia

In this condition, the severity of loss of memory (whether partial or complete) for recent events of a traumatic or stressful nature contrasts with the otherwise very good preservation of other cognitive functions and the individual’s ability to utilize memories that are not of a personal nature. Complete recovery may occur within a few days once the precipitating stress is removed. In contrast to amnesia of organic aetiology, dissociative amnesia may respond to anxiolytic medication. Included in the differential diagnosis would be transient global amnesia due to temporal lobe ischaemia caused by vertebrobasilar insufficiency.

Classically, in dissociative amnesia, episodic memory is present and does not involve problems in procedural memory or in memory storage, as in Wernicke–Korsakoff syndrome. The amnesia is reversible, including by hypnosis. The memory loss is for discrete periods of time, ranging from days to years, and usually for traumatic or stressful events, which it follows. Onset may be gradual or sudden, and people in the third or fourth decades of life are most often affected. Usually only one episode is involved, but multiple periods of lost memory are seen. Co-morbidity occurs with conversion disorders, depression, alcohol abuse and bulimia nervosa; personality disorders of histrionic, dependent or borderline type occur in a minority of patients with dissociative amnesia.

#### Dissociative fugue

In this condition, in addition to the features of dissociative amnesia, there is purposeful travel beyond the usual everyday range and maintenance of basic self-care. Simple social interactions with strangers are usually preserved. The unconscious motivation (primary gain) may be to avoid
arrest for criminal activities or intolerable stresses at home or at work.

This is effectively amnesia with wandering and an inability to recall personal past history, sometimes combined with a partial or new identity. Memory of recent traumatic or stressful events may be lost. The differential diagnoses include organic fugue, where basic self-care and activities of daily living are not characteristically preserved, and postictal states, where there is an absence of current stressors and travel is without purpose.

**Dissociative stupor**

In this disorder, voluntary movement is severely reduced but the individual responds to external stimuli in a normal way. In spite of apparent reduction in consciousness, the individual is neither sleeping nor unconscious.

**Other dissociative disorders**

Included in this ICD-10 category is Ganser’s syndrome, which is characterized by approximate or ridiculous answers to questions (e.g. Elizabeth III is the queen of England; a horse has five legs) and which occurs in the setting of diminished consciousness (a hysterical twilight state). There may also be somatic conversion signs and pseudo-hallucinations. The condition was described by Ganser in 1898 in three prisoners. It is considered to be very rare nowadays.

Also included in this category is multiple personality, or, in DSM-IV, dissociative identity disorder, where there exist within the person two (the most common type) or more distinct personalities or personality states, at least two of which recurrently take full control of the person’s behaviour. Switches between personalities are usually rapid. No personality has any awareness of any of the others. Sometimes a personality will be that of the individual at an earlier age. Multiple personality has been recognized since the early 1900s and was well described in the 1957 film *The Three Faces of Eve* (based on a book by Drs CH Thigpen and HM Cleckley). Patients may have a past history of childhood abuse. Some patients meet the criteria for dissociative personality disorder. Other patients have a history of substance abuse. It remains a controversial diagnosis and is made more often in the USA than in the UK. It can be iatrogenic if reinforced during psychotherapy.

Reflecting the influence of culture, dissociative trance and possession disorder are more common in the East.

**Predisposing and precipitating factors**

Predisposing factors include severe childhood emotional trauma and abuse (often sexual), and a borderline personality disorder. The condition is usually triggered by severe psychological stress.

**CONVERSION DISORDERS**

Conversion disorders are characterized by loss of or alteration in bodily function arising from psychological conflict or need and are not explicable by a medical disorder. Symptoms are typically neurological, affecting the voluntary nervous system. Typically, one or two neurological symptoms are seen. They are not, however, under voluntary control, as the individual is not conscious or aware of their psychological basis – that is, the individual is not intentionally producing symptoms or otherwise malingering. Such symptoms arise via the unconscious defence mechanism of displacement. This group of disorders was central in the history of the development of psychoanalytical theory.

Classically, symptoms in dissociative (conversion) disorders are of symbolic significance and have an unconscious motivation or primary gain, such as relief from intolerable intrapsychic conflict or the reduction or loss of anxiety, which may present as a calm acceptance (*la belle indifférence*) of what appears to be a serious disability. Internal conflicts are kept away from awareness. The gain is primary psychological, not financial, legal or social. Thus, an individual who is fearful both of battle and of being thought a coward may solve this conflict unconsciously by developing paralysis of the lower limbs, thus symbolizing the conflict. Similarly, individuals who unconsciously do not wish to see or hear what is going on may develop hysterical blindness or deafness. In the past, ‘hysterical fits’ (dissociative seizures) in females were related to sexual ‘frigidity’. Individuals may also achieve secondary gain from their symptoms, such as attention, care and affection from others, including relatives, by the manipulation of relationships and by avoiding unwanted everyday tasks or situations – that is, adopting the advantages of the sick role.

Theoretically, in dissociative and conversion disorders the motivation is unconscious, whereas in malingering it is conscious. In clinical practice, however, such a differentiation may be less clear cut and it is often better to assess the degree of unconsciousness of motivation, which itself may vary over time.

Family and early background, and cultural factors, may determine the choice of hysterical symptoms, which may be modelled closely on symptoms experienced during a childhood illness, when the rewards of attention resulting from the sick role may have been learned. Similarly, an individual may develop a conversion symptom when a close relative develops similar symptoms, such as paralysis of one side as the result of a stroke.

In the past, hysterical fainting by females was common, but this is now a rare event. Similarly, in developing countries, gross paralysis of the limbs is now less common, while more subtle neurological conversion symptoms are more apparent. Gross conversion symptoms, however, still occur frequently in some developing countries.

Neurophysiological studies show that although an
individual with a conversion disorder may say that no feeling in an area is experienced, corresponding cortical evoked responses to tactile stimulation may be detected in the brain using an electroencephalogram. Individuals with conversion disorder (e.g. with limb paralysis) are suggestible and may ‘take up their bed and walk’ upon suggestion from a respected other. Alternatively, they may respond to physiotherapy, thereby unconsciously saving face.

**Epidemiology**

The age of onset is usually in adolescence or early adulthood, but the disorder may appear for the first time during middle age or even later. However, it should be emphasized that symptoms suggestive of a conversion disorder occurring in middle age or beyond are very likely to be due to organic illness. Although conversion disorder was considered common several decades ago, it is now encountered much more rarely. It is considered to be more common in women than in men. Most cases are seen in neurological or orthopaedic practice, and in military settings, especially at times of war. It may be more common in lower socioeconomic groups. The incidence is falling in developed countries, but it remains high in developing countries.

**Clinical features**

To summarize the above, symptoms have a primary gain that reduces anxiety and helps to resolve emotional conflict. They may be associated with secondary gain (e.g. attention of others), and symptoms may be symbolic and determined by, or modelled on, cultural, family or early background factors. Classically, symptoms may be calmly accepted (*la belle indifférence*), although in practice this is not seen frequently. However, the diagnosis is not dependent on the demonstration of gain or indifference. There is usually only one conversion symptom present in one episode of conversion disorder. Symptoms include the following:

- **Sensory symptoms:** these are incompatible with peripheral or central nervous system disorders and may include anaesthesias and paraesthesiae, especially of the extremities, e.g. ‘stocking and glove’ anaesthetic areas of the hands and feet (Figure 41.1).
- **Special sense organ symptoms:** these may include deafness and either unilateral or bilateral blindness or tunnel vision.
- **Motor signs:** see Figure 41.2.

Conversion symptoms may be distinguished from organic symptoms by their variability, their nature (which often reflects the individual’s concept of anatomy and physiology) and their inconsistency with known anatomy and physiology (e.g. areas of stocking and glove anaesthesia). For example, individuals with hysterical aphonia are able to use the same muscles to cough that they would normally use to speak, while individuals with hysterical blindness may avoid colliding with objects. Areas of anaesthesia may be increased by suggestion from a doctor during an examination. Apparently paralysed extensor muscles of one leg may contract when the individual is asked to lie supine and raise the opposite leg.

History taking should concentrate on eliciting precipitating stress factors. A close relative or friend should also be interviewed, as this may help to elucidate, among other matters, the individual’s use of the sick role. Physical examination and investigations should be completed quickly...
and, if normal, the physical symptoms themselves ignored thereafter.

**Differential diagnosis**

This includes any undiagnosed physical disorder, especially one that presents with vague multiple somatic symptoms, such as systemic lupus erythematosus (SLE) or multiple sclerosis. Undiagnosed physical disorders may be either difficult to diagnose (e.g. haemangioblastoma of the cerebellum or tumours of the foramen magnum) or not routinely considered (e.g. myasthenia gravis, acute intermittent porphyria). One classic study carried out at the National Hospital for Nervous Diseases in London on 85 patients diagnosed as having hysteria showed that after a follow-up period of 9 years, the diagnosis of hysteria had been replaced in one-third by that of an organic disorder. For example, hysterical pain had been replaced by a diagnosis of trigeminal neuralgia or basilar artery migraine; hysterical paraesthesia and weakness by Takayasu’s disease; and symptoms of classical and, more rarely, in schizophrenia.

Other diagnoses to be considered include hypochondriacal disorder and malingering, where symptoms are consciously produced.

**Aetiology**

**Predisposing factors**

There is little evidence in favour of a genetic predisposition to conversion disorders.

Freud initially used the term ‘conversion’. He had observed the French neurologist Charcot producing conversion hysteria in susceptible individuals by the use of hypnosis and even suggestion. The mechanisms underlying this condition have been sought, unsatisfactorily, ever since. Freud saw these disorders as arising from mental or psychological energy and anxiety being repressed and converted into physical symptoms, which were often suggestive of a neurological disease and which resulted in avoidance of emotional conflict and thus a reduction in intrapsychic anxiety. The conflict is between instinctual impulses, for example aggressive or sexual, and inhibition against their expression.

A premorbid histrionic, dependent, passive–aggressive or antisocial personality disorder may be present in up to one-fifth of cases. Traits of suggestibility and increased capacity to dissociate may predispose towards the development of conversion symptoms.

Learning theory explains conversion disorders in terms of classical conditioning.

Previous physical disorders or exposure to such disorders in other people may be a predisposing factor by providing a model for the choice of conversion symptom. For instance, dissociative convulsions (pseudoseizures) are more likely to occur in people with epilepsy, as this provides a model for their symptoms; they have also learned the advantages of the sick role as a result of their condition.

The increased incidence of conversion disorder in young and immature people may reflect the fact that they have emerged only recently from the privileged dependent state of childhood. Similarly, it has been suggested that the greater proportion of women with the disorder apparent in the past perhaps reflected their overall greater dependence on men. In keeping with this theory, the ratio of females to males with the disorder has fallen considerably in recent decades.

**Precipitating and perpetuating factors**

Precipitating factors include severe stress, such as the recent death of a close relative, whose physical symptoms may be modelled by the patient, and at times of war. In fact, experience of warfare suggests that all individuals are capable of developing a conversion disorder. Head injury and temporal lobe epilepsy have also been suggested as precipitating factors. Impaired action generation with decreased activity in the left dorsolateral prefrontal cortex has also been found.

The condition is perpetuated by secondary gain and the advantages of the sick role (see above).

The possibility of financial gain, such as in compensation neurosis, may also perpetuate the disorder. Table 41.2 summarizes the aetiology of conversion disorders.

**Management**

Most cases remit with non-specific supportive measures, particularly if suggestion is used. To prevent secondary
gain, chronicity or relapse, early resolution of symptoms is important. Physical investigations should be undertaken only if indicated, not merely as reassurance. In the absence of any abnormalities, the patient should be firmly reassured that there is no serious illness present and that the symptoms are familiar to the doctor and will remit. Any associated psychiatric disorder should be treated in its own right. Relaxation training, hypnosis and anxiolytics may also be of value.

If the symptoms do not remit, or precipitating or perpetuating factors continue, then it is necessary to help the patient to recognize these and to take action to counter them in order to prevent chronicity. Cognitive-behavioural therapy (CBT) has been found to be the most effective specific treatment. Cognitive-behavioural and physiological factors interrelate. Therefore, cognitive-behavioural treatments can result in physiological changes. Behaviour therapy alone has clinically been found to be effective. Psychotherapy may be indicated to gain insight into and explore the origins of the symptoms (e.g. by linking them to mood). However, the severe stresses may prevent the individual from discussing these problems.

Abreaction may also be indicated. This is the recall to consciousness of the underlying and causative repressed trauma, with the simultaneous re-experiencing of the emotion that originally accompanied it. Methods of achieving abreaction (catharsis) include psychotherapy alone, hypnosis and the use of drugs, most safely with intravenous diazepam, although intravenous barbiturates and amphetamines have also been used.

Secondary gain may need to be countered by behavioural therapy and environmental manipulation. The advantages of the sick role should be minimized and those of health maximized. The involvement and help of family members and other individuals important to the patient may have to be enlisted.

**Prognosis**

In general, the prognosis for most patients is good, with complete and rapid recovery either spontaneously or upon removal of the precipitating factors. Good prognosis is associated with acute onset and a clear and resolvable emotional conflict. If the condition persists after 1 year, the course is likely to be more intractable. Intractability is also associated with personality difficulties and poor motivation. About one-quarter of patients will have another conversion symptom within 6 years.

The prognosis is also better for a sustained disabling conversion disorder, such as paralysis, than for the intermittent use of symptoms such as dissociative convulsions (pseudoseizures), or where the symptom produces little disability in everyday life.

### SOMATOFORM DISORDERS

ICD-10 divides the somatoform disorders into somatization disorder, hypochondriacal disorder and persistent pain disorder (Table 41.3). DSM-IV-TR also includes conversion disorder, which has already been described, and body dysmorphic disorder (dysmorphophobia) (Box 41.3).

#### Hypochondriacal disorder (hypochondriasis or hypochondriacal neurosis or severe health anxiety)

This is characterized by a persistent belief in the presence of one or more serious physical illnesses underlying the presenting symptom or symptoms, even though repeated examination and investigations have identified no adequate physical explanation. There is a persistent refusal to accept

the advice and reassurance of doctors that no such physical illness exists.

Hypochondriacal disorder can thus be defined as an excessive concern about having a serious disease and morbid preoccupation with one’s body or state of health, which is out of proportion to actual medical morbidity and is present for a major part of the time. Characteristic features include the following:

- Somatic (bodily) symptoms without medical explanation
- Disease conviction (belief in an occult medical illness, which is, in fact, not present)
- Disease fear
- Bodily preoccupation.

The term ‘hypochondriasis’ is also used to refer to a personality trait or a symptom in a number of psychiatric disorders (e.g. depression). Hypochondriacal symptoms are, in fact, most often seen as a feature of depressive disorder. The term ‘hypochondriasis’ originates from the ancient belief that it was associated with physical disorder of the organs below (hypo-) the costal margin (chondrica).

**Epidemiology**

This disorder can begin at any age but most commonly between the ages of 20 years and 30 years. It occurs slightly more commonly in males, or at least equally to females, in contrast to other somatoform disorders, which are more common in women. Its exact prevalence in the general population is unknown, and this is compounded by the fact that hypochondriacal complaints occur more commonly as part of another psychiatric syndrome, such as depressive disorder. Although hypochondriacal disorder is commonly seen in general medical practice (estimates of 4–15%), such individuals often refuse referral to mental health services and so are not frequently seen in psychiatric facilities.

Primary hypochondriacal disorder is said to occur more often in lower social classes, very young people, elderly people, Jewish people and people associated with disease, including medical students. It may be more common in non-European cultures, where depressive disorder presents more commonly with hypochondriacal/somatic features.

**Clinical features**

Individuals experience symptoms that strongly suggest disease to them but not to their examining doctors. Even if organic disease is present, symptoms will be disproportionate and typically refer to a number of anatomical locations and organs. Individuals are very concerned as to the exact significance of the symptoms and their aetiology, and also with their authenticity being accepted by others. They are convinced that they have a serious disease that is yet to be detected, and they cannot be persuaded otherwise, in spite of adequate reassurance, negative investigation results and a benign course of their condition over time.

Patients have a disease fear that is intense and persistent. They are vigilant to the slightest indication of illness, which alarms them greatly. Their bodily preoccupation is profound and extends to their general health status. They scrutinize themselves intensely. They habitually visit general practice and hospital clinics and accumulate a long history of medical contact. Ultimately, they always remain dissatisfied by their contact with the medical profession, whom they often
criticize and blame for their continuing complaints, and a deteriorating doctor–patient relationship is common.

**Differential diagnosis**
This includes true organic disease, especially the early stages of neurological disorders such as multiple sclerosis, endocrine disorders such as thyroid or parathyroid disease, and also disorders that frequently affect multiple body systems (such as SLE). The presence of true organic disease does not, however, rule out coexisting hypochondriacal disorder.

Hypochondriacal symptoms are most often seen, in up to 80 per cent of cases, in depressive disorder. Somatic delusions of physical disease may be present in psychotic disorders, including depression and schizophrenia. In hypochondriacal disorder, beliefs are characteristically not of delusional intensity, in that the individual will accept the possibility that the disease may not be present, although such distinctions may be difficult to make, especially initially. Hypochondriacal concerns may also be present in generalized anxiety disorder, panic disorder and somatisation disorder. In somatization disorder, the preoccupation is with the symptoms rather than the fear of having a specific disease or diseases.

**Aetiology**
Hypochondriasis is a polythetic disease – that is, it has numerous interacting causes. It has been argued that it is a variant form of other mental illnesses, such as depression or anxiety disorder, rather than a primary neurotic disorder. However, the validity of primary hypochondriasis has been confirmed. Hypochondriacal symptoms are most often seen, in up to 80 per cent of cases, in depressive disorder. Somatic delusions of physical disease may be present in psychotic disorders, including depression and schizophrenia. In hypochondriacal disorder, beliefs are characteristically not of delusional intensity, in that the individual will accept the possibility that the disease may not be present, although such distinctions may be difficult to make, especially initially. Hypochondriacal concerns may also be present in generalized anxiety disorder, panic disorder and somatisation disorder. In somatization disorder, the preoccupation is with the symptoms rather than the fear of having a specific disease or diseases.

**Predisposing factors**
Past experience of true organic disease, especially in childhood, in either oneself or a family member, predisposes to the development of this disorder (e.g. by modelling or reinforcement). Illness may have been a particular focus of attention and source of concern for family members of such patients.

Psychodynamic theory holds that hypochondriacal symptoms and associated suffering are assumed to have an unconscious meaning and gratification for an individual. Hypochondriacal disorder has been viewed as a somatic expression of oral dependency needs, including nurturing, attention, physical contact and sympathy. It has also been viewed as a transformation, through repression and displacement, of aggressive and hostile wishes arising from the past towards other people in the present, to whom such individuals make numerous and persistent physical complaints.

Hypochondriacal disorder has been seen as a hypochondriacal personality disorder. It has also been viewed as a non-verbal communication from individuals with interpersonal problems. For an individual feeling overwhelmed by apparently insoluble problems, such complaints may represent a request to be placed in the sick role, in order to avoid normal obligations, postpone unwelcome events, and attract support and sympathy with no implications of blame.

**Precipitating and perpetuating factors**
Precipitating factors are usually significant psychosocial stresses. The condition is perpetuated by the persistence of such stresses, unresolved psychodynamic factors and the advantages of the sick role.

**Management**
This is usually undertaken by a general practitioner (GP), as such individuals often do not find psychiatric referral acceptable. Organic disease should be excluded, and any primary psychiatric disorder, such as depression, should be treated vigorously.

Specific psychiatric treatment may be of benefit if the individual can acknowledge emotional difficulties underlying the physical complaints. Psychiatric treatment is better undertaken in a non-psychiatric medical setting, with an emphasis on the reduction of psychosocial stresses and education about the role of psychological factors in the development of symptoms, and how to cope with such symptoms. The psychodynamic meaning of the symptoms should be sought, as should their relationship to the family and social situation. However, one should be cautious if it is clear that the symptoms are acting as a last-ditch powerful psychological defence.

CBT is the specific treatment of first choice. Misinterpretations should be identified and challenged and realistic interpretations substituted. Graded exposure to illness cues and illness related situations with response prevention should be undertaken, and core illness beliefs modified. Such an approach can result in up to 75 per cent symptom reduction.

Antidepressant medication, particularly of the selective serotonin reuptake inhibitor (SSRI) type, is recommended by some for all such patients, particularly as most hypochondriacal symptoms in the general population are secondary to depression, which may explain the response. Antidepressant treatment is certainly the second-line treatment of choice if CBT fails or if there is significant co-morbidity or severe symptoms.

Group psychotherapy is the psychotherapeutic approach of choice, although the primary aim is usually supportive rather than curative. The evidence for this and for individual insight-oriented psychotherapy is lacking.

Overall, it is worth remembering that the patient is symptomatic for psychological and social reasons, and no specific medical or surgical intervention will cure the need to be sick. The aim is to concentrate on the person as a whole. The patient should be seen regularly and attention given to any social and personal factors from which the complaints are considered to arise.

Specific medical interventions should be kept to a mini
mum, for example a simple physical examination. The main treatment is the physician’s personal attention. Elaborate and invasive diagnostic and therapeutic procedures should be undertaken only when there is objective evidence for their use, and incidental abnormalities and equivocal findings should not be treated.

**Prognosis**
The prognosis is often poor, with individuals having chronic mild disability for most of their adult life. The more chronic the condition, the worse the prognosis. Where symptoms are associated with depressive or generalized anxiety disorder, the prognosis is better.

**Somatization disorder (Briquet’s syndrome, St Louis hysteria)**
This is a chronic syndrome of multiple somatic (physical) symptoms, which have persisted for several years with no adequate medical explanation associated with psychosocial distress, impairment and medical help-seeking. There is no autonomic overstimulation. The alternative terms of ‘Briquet’s syndrome’ and ‘St Louis hysteria’ arose from Briquet’s 1859 concept of hysteria, which was revived by psychiatrists at Washington University, St Louis.

The ICD-10 description of somatization disorder is given in Table 41.3. It will be seen that at least 2 years of multiple and variable physical symptoms are required for diagnosis. DSM-IV-TR criteria for somatization disorder indicate that the disorder should begin before the age of 30 years, must be of several years’ duration, must not be caused or resulted in significant impairment of social, occupational or other important areas or functions. For the diagnosis to be made, the individual must have had:

- two gastrointestinal symptoms, e.g. vomiting;
- four pain symptoms, e.g. pain in extremities;
- one sexual symptom other than pain;
- one pseudo-neurological symptom, e.g. amnesia or difficulty in swallowing.

These symptoms must not be intentionally produced or feigned (as in, respectively, factitious disorder or malingering).

**Epidemiology**
This disorder is diagnosed very rarely in males; for females, prevalence rates of up to 2 per cent have been found. Women have been found to outnumber men with this condition 5- to 20-fold. Symptoms begin in the teenage years or, rarely, in the twenties, usually before the age of 30 years.

**Clinical features**
Patients have long and complicated medical histories, with many diagnoses having usually been considered. Even if some benign organic disorders have been diagnosed, the complaints and disabilities are excessive and the individual is severely disabled. The majority are unable to work and may spend up to one-quarter of each month in bed. They may consult a number of doctors, at a number of institutions, even at the same time.

Associated features include the following:
- Anxiety, depression, threats of suicide and parasuicide attempts
- Increased incidence of antisocial personality disorder, and alcohol and drug abuse
- Interpersonal discord.

History-taking often reveals poor childhood adjustment, school difficulties, a disturbed adolescence, menstruation difficulties and dysmenorrhoea from menarche, sexual activity from an early age with sexual problems common, interpersonal discord, unstable relationships, a number of marriages, and inconsistent or neglectful parenting of any children.

**Differential diagnosis**
Physical disorders should be ruled out, particularly those with vague, multiple or confusing somatic symptoms, such as hyperparathyroidism, porphyria, multiple sclerosis and SLE. Multiple physical symptoms of late onset in life are almost always due to physical disease. In somatization disorder, there is an early onset of multiple symptoms involving a number of body systems and a long but benign course without the development of serious medical illnesses.

Unlike hypochondriasis, in somatization disorder there is less disease conviction, less disease fear and less bodily pre-occupation. In addition, somatization disorder primarily affects females, whereas in hypochondriacal disorder males are affected at least equally.

The differential diagnosis also includes conversion disorder, depressve disorder, panic disorder and schizophrenia with multiple somatic delusions. Such disorders may coexist with somatoform disorder, particularly depression, and increase physical symptoms and negative appraisal of them.

**Aetiology**
Genetic and environmental factors probably both have a role. Monozygotic compared to dizygotic twin concordance in somatoform disorders was found to be 29 : 10 in one study. Somatization disorder occurs in 10–20 per cent of first-degree female relatives. First-degree male relatives, however, have an increased incidence of alcoholism, drug abuse and antisocial personality disorder. Such genetic predisposition is in contrast to its absence in conversion disorder. Abnormal regulation of the cytokine system has also been hypothesized. Parental example may lead to behavioural learning of this condition, and physical illness in childhood may result in somatic rather than emotional responses for attention, care and countering hostility in adulthood.
Management
Ideally, the diagnosis should be made early and unnecessary organic investigations and interventions avoided, as these are likely to result in further complaints arising from complications of the procedures, side effects of medication and iatrogenic disease. Medical practitioners are reluctant to diagnose somatoform disorder but are inclined to search for rare medical illnesses. The gallbladder, uterus, appendix and teeth may all be needlessly removed. The aim should be to direct attention to the associated psychosocial stresses in the patient’s life and away from the symptoms. ‘Doctor shopping’ should be discouraged, and instead an attempt should be made to engage the patient in a long-term supportive therapeutic relationship with the GP, who can be advised, as required, by a psychiatrist as to the nature of the disorder and the feasible goals of treatment. Although the goal is to move the patient beyond somatization, a complete elimination of symptoms is unlikely, and general support and care of the patient is more important. Specific CBT may assist, by leading to the reattribution of physical symptoms, for example through behavioural experiments with hyperventilation. Fixed beliefs by patients that their physical symptoms are due to environmental hypersensitivity and Candida are, however, difficult to alter. Psychodynamic psychotherapy has also been used. Psychotropic medication and analgesics tend not to be effective and such patients often concentrate on the resulting side effects.

Prognosis
This is generally poor, with a chronic course, repeated recurrences of symptoms, and disability persisting for most of the patient’s life. Symptoms do tend to be more florid in early adult life, but the course is often fluctuating. Spontaneous remission is very rare. It is unlikely that such individuals will go more than 2 years without medical attention.

Dissociation, conversion and somatization have been integrated into a unified model of medically unexplained symptoms, including as regards its treatment.

Persistent somatoform pain disorder (psychogenic pain)
The essential feature of this disorder is the preoccupation with persistent, severe and distressing pain in the absence of adequate physical findings to account for the pain or its intensity. Pure psychogenic pain is, in fact, rare compared with psychological elaboration of pain associated with existing or previous injuries.

Pain always has a psychological component to it and has been defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. Psychiatric consultation is often requested for people with chronic pain, which is not an uncommon complaint. Although many patients may have a past history of injuries, they often show no current evidence of tissue or nerve damage. In normal circumstances healing takes place within 3 months, or more rarely up to 6 months, and the correlation between pain and injury is poor after that period.

Epidemiology
The disorder is considered to be common in general medical practice. It is diagnosed almost twice as frequently in females as in males. Onset can occur at any age but is most frequent in the thirties and forties.

Clinical features
The normal course is for pain to appear suddenly and to increase in severity over a few weeks to months. Such pain is inconsistent with the anatomical distribution of the nervous system. Characteristically, the pain is continuous for much of the day, may cause difficulty in getting off to sleep but does not cause wakening, and has symbolic significance, for example chest pain in an individual who had a relative who died from a heart attack.

The common sites of pain are summarized in Figure 41.4. There is limited insight into associated psychological factors and patients characteristically respond less well to analgesics than to psychotropic medication. Persistent pain

Figure 41.4 Common sites of psychogenic pain
disorder may be accompanied by local sensory and motor changes, such as paraesthesiae and muscle spasm. ‘Doctor shopping’ and excessive use of analgesics without relief are often seen. A past history of conversion symptoms is common, as is an associated depressive disorder.

The pain solves a psychological problem for the patient and may be ameliorated by psychological and environmental changes. It also corresponds to ideas held by the patient about the condition. The degree of resulting disability reflects these beliefs rather than the severity of any previous injury or organic disease. The more uncertain the patient is of the cause of this pain, or the greater the belief that the pain will endure, the worse the disability and the associated demoralization. The complaint often increases following extensive investigations with negative results, which merely frustrates the patient.

The history may reveal a vulnerable hypochondriacal personality with a low pain threshold. Getting a history from an informant is also useful and previous hospital records will need to be examined. The previous psychiatric history may reveal similar episodes, including similar causes and precipitants.

Physical examination is required, not only to exclude organic disease but also to gain credibility in the patient’s eyes and to appreciate more fully the complaints. Persistent pain disorder is characterized on examination by overreaction to the examination itself, diffuse superficial tenderness, and weakness of all muscle groups in the region.

Investigations might also include requesting the patient to complete a diary of pain and associated behaviour and activities. This may reveal, for instance, that the pain is worse if the patient’s partner is present and being sympathetic. Following assessment, it may be harmful to continue with a diary, as this may merely increase the patient’s attention to the pain.

Differential diagnosis
True organic pain may be dramatically presented, particularly in patients with a histrionic personality. A physical cause is suggested if the pain is characteristically described as ‘sore, boring or nagging’ and wakes the patient at night, and also if it is localized to a particular dermatome.

Atypical facial pain, which may be as severe as trigeminal neuralgia, should be differentiated from temporomandibular joint (TMJ) syndrome. In atypical facial pain, the pain usually lasts minutes to hours, sometimes being continuous. The pain is aching, dull, burning or crushing, although occasionally it is sharp or knife-like. In TMJ syndrome there is focal tenderness of the TMJ, aggravated by talking, chewing or lateral jaw movement; this requires referral to an oral surgeon.

Other psychiatric illnesses should be excluded, in particular depressive disorder and somatization disorder, but pain rarely dominates the clinical picture of these conditions, although patients often complain of aches and pains. Some psychotic individuals, such as those with schizophrenia, may have a delusional pain syndrome. Generalized anxiety disorder may present with muscle pain and tension headaches. Malingering should also be excluded. Individuals dependent on narcotics may complain of pain in order to obtain opioids.

Aetiology
Predisposing factors
Patients with this disorder are more likely to have begun working at an unusually early age, held jobs that were physically strenuous or overly routinized, or been workaholics and rarely taken time off. In many cases, however, the pain is shaped by organic, psychological, personal and cultural factors.

A pain-prone personality profile has been proposed. Such personalities court injuries and unsuccessful surgery. However, such a profile, for example the inverted V profile on the Minnesota Multiphasic Personality Inventory (MMPI) (high scores for hypochondriasis and hysteria and a low score for depression), is often secondary to the impact of chronic pain.

A further theory suggests that such individuals come from an abusive parental family background, where the child is subject to physical abuse from parents who subsequently show remorse and comfort, so that the child grows up associating parental love with pain and suffering. However, such a background is infrequently seen in clinical practice, although an increased history of childhood physical and sexual abuse has been identified. Some ethnic and cultural groups, such as Asians, are said to somatize problems more frequently.

Precipitating and perpetuating factors
These include physical trauma, which occurs in about half of cases, and dissatisfaction with employment before injury.

A background of litigation with a view to compensation makes the resolution of the pain very unlikely while litigation is in progress. Even after a satisfactory legal settlement, a number of patients will continue to complain of chronic pain.

This disorder has also been considered as a variant of depressive disorder.

Management
Organic disease should be excluded and, if it cannot, a full evaluation of the degree and extent of physical pathology and its contribution to the presentation of pain should be made.

Adequate medical treatment of any organic basis to pain is essential. Multidisciplinary pain clinics, with an anaesthetist, psychiatrist and physician present, may facilitate management. Current psychosocial stresses will need to be resolved. Antidepressants that affect both serotonin and noradrenaline reuptake, such as amitriptyline, are more effective than those that act mainly on noradrenaline uptake. Tricyclic antidepressants also have an analgesic action of faster onset than, and that is independent of, their
Body dysmorphic disorder (dysmorphophobia)

This is a distressing preoccupation with some imagined or slight defect of appearance in a normal-appearing person. If a slight physical anomaly is present, the person’s concern is grossly excessive. However, there is no correlation between body dysmorphic disorder and the degree of deformity. The belief in the defect is not of delusional intensity, although in clinical practice this distinction is often difficult to make and may not be valid, as the belief may vary from an overvalued idea to a delusion. The term ‘dysmorphic’ originates from the Greek word for ‘ugliness of face’. Although patients do often fear ridicule, and even fear upsetting others and thus show avoidance, the European term ‘dysmorphophobia’ is not used in the American DSM-IV-TR, as it is argued that there is no pure phobic avoidance. In ICD-10, both dysmorphophobia and body dysmorphic disorder are included under the category of hypochondriacal disorder.

Epidemiology

The most common age of onset is from adolescence through to the third decade. Psychiatrists see only a small proportion of cases, and the disorder may actually be more common than thought previously. Women are affected slightly more often than men. Patients are more likely to go to a plastic surgeon or dermatologist than to a psychiatrist. Studies of US college students have suggested that a quarter may meet DSM-IV-TR criteria for body dysmorphic disorder.

Clinical features

The most common imagined defects are of the face, including wrinkles, the shape of the nose, excessive facial hair and facial asymmetries. More rarely, the complaint involves the feet, hands, back, breasts or genitals. Any preoccupation with the genitals and breasts must be more than is normal. Women are more preoccupied with breast and legs and are more likely to use make-up as camouflage and check their appearance in the mirror. Men are more preoccupied with their genitals, height and excess body hair. There is never a disturbance of the whole body image, as is seen in anorexia nervosa, but more than one imagined defect in appearance may occur at one time, or a series may occur over time. The disorder can be markedly disabling, resulting in repeated visits to plastic surgeons or dermatologists in an effort at ‘correction’. There is avoidance of social or occupational situations because of anxiety and fear of attention. Worry, dysphoria and depressive disorder frequently occur. Co-morbidity is frequent; in women this is often with generalized anxiety disorder, panic disorder and bulimia, while in men there is a lifetime co-morbidity increase in bipolar disorder. The individual’s whole lifestyle may be affected: they become socially isolated, restrict their activities and are usually unmarried. They may frequently check their appearance in the mirror and may often change their hairstyle to alter their appearance.

Feeling grossly disfigured, such individuals often fear seeking help or present to a plastic surgeon or dermatologist before a psychiatrist. They may also fear being viewed as vain about their appearance. They are very sensitive to, and feel confused about, their internal, ideal and actual self-image. They may become socially isolated, unemployed and suicidal. One-quarter of the patients attempt suicide.

Differential diagnosis

Anorexia nervosa or transsexualism do not fulfil the diagnostic criteria for body dysmorphic disorder, as these two conditions are characterized by a disturbance of the whole body image and not some imagined defect in appearance. Concern about minor defects in appearance, such as acne, is common but not grossly excessive in normal adolescence. Individuals may exaggerate defects in appearance in major depression, as may individuals with an anxious (avoidant) personality disorder and social phobia, but such symptoms are not the predominant disturbance.

In delusional disorders, an individual’s belief in a defect of appearance is of delusional intensity, which by definition is not the case in body dysmorphic disorder. Studies have suggested that up to 50 per cent of people complaining of a large nose and requesting plastic surgery are ‘neurotic’, but an increased incidence of schizophrenia and depression has also been found.

Aetiology

There is little definitive information on predisposing factors of body dysmorphic disorder. In psychodynamic theory, body dysmorphic disorder has been considered to represent an unconscious displacement on to body parts of sexual or emotional conflicts, or more general feelings of inferiority, poor self-image or guilt. Alternatively, the disorder may be used to explain the individual’s failures with, and suffering in relation to, the opposite sex. In Freud’s classic case history of ‘the Wolf Man’, the patient is described as neglecting his daily life and work because of his perception of a defect in appearance of his nose.

Some individuals have a sudden onset of body dysmorphic disorder precipitated after distressing experiences, including abandonment by their partner.

Increased family history of affective disorder and obsessive-compulsive disorder and high co-morbidity with antidepressant effects. Cognitive-behavioural methods of treatment have also been found to be of value.

Prognosis

In most cases the symptom has persisted for many years by the time the individual comes to the attention of psychiatrists. Patients who express emotional distress with physical symptoms tend to do poorly, whereas those who are able to accept the pain and appreciate that their own efforts to improve the quality of their life are of the utmost importance tend to do better.

Somatoform disorders 677

Part 4: Mental health problems and mental illness
depressive disorder are seen. The pathophysiology may involve serotonin, given the response of the condition to SSRI antidepressants.

**Relationship with other psychiatric disorders**

A relationship between body dysmorphic disorder and a number of other psychiatric disorders has been postulated, including mood disorder, obsessive–compulsive disorder and schizophrenia. It has been suggested that body dysmorphic disorder may, in fact, be only a non-specific symptom of such conditions. The links appear to be greatest with obsessive–compulsive disorder, but in that disorder preoccupying thoughts are more intrusive and unnatural than in body dysmorphic disorder.

The condition may also be related to delusional disorders, although by definition the defect is not of delusional intensity in body dysmorphic disorder. Where the belief is of delusional intensity, the terms ‘monosymptomatic hypochondriasis’ and ‘monosymptomatic hypochondriacal psychosis’ have been used. In fact, the delusional intensity of such beliefs can vary with time, and thus the clinical picture overlaps with body dysmorphic disorder.

**Management**

Although CBT and psychodynamic psychotherapy have been described as being of benefit, and CBT should be the first-line treatment of choice, with proven benefit over 2 years, it appears that the best results may be obtained by using SSRI antidepressants. Surgery is not generally effective, as patients often express dissatisfaction with the results, requesting and obtaining repeated operative procedures. However, where there is a slight physical anomaly and the defect in appearance is well circumscribed, some studies have shown good results from plastic surgery alone (e.g. rhinoplasty for a large nose).

**Prognosis**

The course is often chronic, persisting for several years, and often worsens over time in spite of treatment.

---

**OTHER ASSOCIATED CONCEPTS**

**Undifferentiated somatoform disorder**

This category, included within the somatoform disorders in DSM-IV-TR, is for individuals whose clinical picture does not meet the full criteria of somatization disorder. There may be either single circumscribed symptoms, such as difficulty in swallowing or, more commonly, multiple physical complaints, such as fatigue, loss of appetite or gastrointestinal problems. The duration of disturbance must be at least 6 months in order for this diagnosis to be made. The main categories of somatoform disorders are narrow, and most patients in clinical practice will be in this residual subcategory, a reflection of the current unsatisfactory classification, or, alternatively, have another primary psychiatric disorder, such as depression or anxiety.

**Medically unexplained physical symptoms**

Most patients in clinical practice with such symptoms will, as described previously, have either undifferentiated somatoform disorder or another primary psychiatric disorder, such as anxiety, producing real somatic anxiety symptoms due to autonomic hyperactivity, or depression, producing for example, facial pain, (a depressive equivalent that is sometimes considered psychodynamically to equate to an emotional ‘slap in the face’). The various terms used to refer to symptoms with no organic cause are listed in Box 41.4. Such terms are often used loosely and overlap.

About one in five new consultations in primary care will be with medically unexplained symptoms. This latter term avoids making assumptions about their cause. Many symptoms are transient, but one-third persist and cause distress and disability. They result from interactions between biological, psychological, social and cultural factors. All patients should be asked about low mood and biological symptoms of depression, their beliefs about their symptoms.
(e.g. fear of cancer), why they are seeking help now, and the relationship between symptoms, mood and social factors, with a view to the patient re-attributing the cause of their symptoms (e.g. relating overbreathing to anxiety or lower pain threshold to depression). The reality for patients of their symptoms should be accepted and an explanation of these should be provided if possible.

CBT can be of benefit, as can antidepressants for chronic pain and associated poor sleep, even in the absence of depression.

Somatization and medically unexplained symptoms

Somatization, from the Greek word soma ('body'), is a helpful concept in understanding patients with medically unexplained symptoms. It is a tendency to experience physical distress and symptoms unaccounted for by pathological findings, to attribute them to physical illness, to communicate them and to seek medical help for them. It may be an earlier phenomenon than psychologization, which is especially prevalent in developed countries.

Individuals in general may characteristically view symptoms as having physical, psychological or external causes. There may be a spectrum in the way individuals experience stress (Figure 41.5): at one extreme, this may be with pure psychic symptoms, such as worry about the stress; further along the spectrum, certain individuals may have free-floating anxiety, with both psychic and somatic symptoms; at the other extreme, individuals experience only somatic symptoms, which may be anxiety or depressive equivalents. The latter patients do not perceive such symptoms as having a psychological basis, which leads to their resisting psychological help and rather seeking a medical explanation. Somatization may be facultative and cease when help is received, or it may be a chronic true somatization of psychosocial distress.

![Figure 41.5 Spectrum of stress response](image)

Autonomic hyperactivity accounts for the genuine somatic anxiety symptoms. In conversion disorders, physiological changes can be demonstrated in the voluntary nervous system. In hypochondriacal disorder, individuals are abnormally sensitive to normal sensations in the body.

Patients with medically unexplained physical symptoms exert disproportionately high financial and service burdens on health and social services. In any one week, 60–80 per cent of healthy people experience bodily symptoms, but only a small proportion of these will visit their GP; in 20 per cent, the physical symptoms will be due to minor emotional disorders. Patients who visit their GP may then be referred to hospital specialists, despite the absence of any abnormal physical findings on examination. Up to 40 per cent of patients seen by hospital medical specialists have medically unexplained physical symptoms and receive no organic diagnosis.

Such patients are resistant to any psychological interpretation, which they perceive as implying that their symptoms are not real but ‘all in the mind’. However, it is important to remember that the causes of such symptoms do not have to be either physical or psychological – that is, if no organic disorder is found, it does not therefore have to be assumed to be a purely psychological problem. A medical model of disease does not, and should not, have to be restricted to organic or biological causes alone. Often psychiatric disorders are not looked for if any possible organic causative factor is found. In contrast, another investigation can always be proposed if no causative organic factor has been identified.

It is always important to consider not only the symptoms but also the patient’s understanding of any illness and anxieties about it (i.e. thoughts) and the way the patient’s daily life is affected by the symptoms (i.e. behaviour). A good doctor–patient interaction can be achieved only if the patient feels understood. With this in mind, it is possible to work with such patients’ thoughts and behaviours via CBT.

![Figure 41.6 Pathophysiological mechanisms proposed for specific medically unexplained symptoms](image)
### Box 41.5 Interaction between psychiatric and physical disorders

#### ORGANIC MENTAL DISORDERS

Physical illness has direct effect on brain function:
- Delirium/acute confusional state/organic psychosis, e.g. liver failure
- Dementia/chronic organic psychosis
- Postoperative psychosis.

#### MALADAPTIVE PSYCHOLOGICAL REACTIONS TO ILLNESS

- Depression, e.g. amputation, mastectomy (due to loss)
- Guilt, e.g. fear of burden on relatives
- Anxiety, e.g. before operation, unpleasant procedure
- Paranoid reaction, e.g. if deaf or blind
- Anger
- Denial
- Preoccupation with illness
- Prolongation of sick role (fewer responsibilities, more attention).

#### PSYCHOSOMATIC DISEASE

Multiple (i.e. biopsychosocial) causes. For example life events/stress on physically and emotionally vulnerable, lead to changes in nervous, endocrine systems, etc. and disease. For example, bereavement may precipitate a heart attack, or stress may precipitate asthma, eczema or peptic ulcer.

#### PSYCHIATRIC CONDITIONS PRESENTING WITH PHYSICAL COMPLAINTS

- Somatic (physical) anxiety symptoms due to autonomic hyperactivity, e.g. palpitations
- Conversion disorders (via voluntary nervous system)
- Depression leading to facial pain, constipation, hypochondriacal complaints and delusions, e.g. of cancer, venereal disease
- Hypochondriacal disorder: excessive concern with health and normal sensations
- Somatization disorder
- Monosymptomatic hypochondriacal delusions, e.g. delusions of infestation or smell; other psychotic disorders, e.g. schizophrenia
- Münchausen (hospital addiction) syndrome
- Alcoholism, leading to liver disease
- Self-neglect.

#### PHYSICAL CONDITIONS PRESENTING WITH PSYCHIATRIC COMPLAINTS

- Depressive disorder precipitated by cancer, e.g. of pancreas
- Anxiety in hyperthyroidism
- Postviral depression, e.g. post-hepatitis, glandular fever, influenza.

#### MEDICAL DRUGS LEADING TO PSYCHIATRIC COMPLICATIONS

- Antihypertensive drugs leading to depression
- Corticosteroids leading to depression, euphoria.

#### PSYCHIATRIC DRUGS LEADING TO MEDICAL COMPLICATIONS

- Overdose
- Chlorpromazine leading to jaundice.

#### COINCIDENTAL PSYCHIATRIC AND PHYSICAL DISORDER
Pathophysiological mechanisms proposed for specific medically unexplained symptoms

Figure 41.6 shows the proposed pathophysiological mechanisms for some specific medically unexplained symptoms.

Emotional arousal may lead to increased paravertebral muscle tension, which can be detected by an electromyogram, and results in chronic low back pain. Pelvic vein dilation may result in pelvic pain in females. Hyperventilation, with resetting of respiratory control mechanisms to a reduced Pco₂, may result in breathlessness or hyperventilation syndrome (HVS; also known as da Costa’s Syndrome, cardiac neurosis, effort syndrome and circulatory neurasthenia). About one-quarter of patients with HVS have symptoms of panic disorder; 50–60 per cent of those with panic disorder or agoraphobia have symptoms of HVS. Inactivity, which reduces the capacity for further activity, and increased muscle tension may result in fatigue. Psychological stress produces irregular contractile activity of the smooth muscle in cases of altered bowel habit.

Box 41.5 outlines the interactions between psychiatric and physical disorders. Box 41.6 gives some examples of the factors influencing a patient’s response to a physical illness.

Psychological defensiveness, such as having a repressive coping style, may be associated with lower rates of psychopathology and psychiatric disorder, but this is counterbalanced by a restriction in self-awareness and interpersonal and social functioning, and a trade-off in physical ill-health, for example increased blood pressure and heart rate reactivity, reduced cell-mediated and humoral immunity responses, and possibly even progression of certain tumours, such as breast cancer.

Chronic fatigue syndrome

This is covered in detail in Chapter 51. In brief, chronic fatigue syndrome is characterized by the onset of unexplained physical and often mental fatigue, and heightened awareness of this, lasting for over 6 months and not related to ongoing exertion or alleviated by rest.35 Prevalence is about seven in 100,000. It usually presents between 20 years and 50 years of age. Biopsychosocial factors contribute to the aetiology, and there is some evidence of genetic vulnerability.36,37 Many patients relate the onset to an infection, which may indeed trigger the condition. In some cases, it may be a variant of the less chronic postviral infection fatigue. Some cases follow immunization. Evidence of Epstein–Barr virus infection is present in 10 per cent of cases. Most severe viral infections are associated with immunological abnormalities, especially in T-cell-mediated immunity.

Sixty per cent of patients have no previous psychiatric history, but one-half to two-thirds have a current co-morbid psychiatric disorder, especially minor depression in 40–50 per cent of these cases, anxiety and somatization disorder. Diagnosis is based primarily on clinical history. The differential diagnosis includes depression. Co-morbidity with depression may be due to primary depression or depression secondary to chronic fatigue syndrome itself. Some authors argue that the condition is synonymous with the ICD-10 diagnosis of neurasthenia.38 However, patients and their families frequently fear the stigma of a psychiatric diagnosis.

The condition is exacerbated, often a day or two later, by increased activity and by alcohol consumption. The essence of treatment is early paced activity management, avoiding over- and underactivity, and gradual rehabilitation with emotional support. CBT incorporating a rehabilitation approach and graded exercise can be offered as a more formalized approach and has been recommended by the National Institute for Health and Clinical Excellence (NICE).39 Biofeedback approaches, self-help groups (attendees at these have a poorer prognosis), and psychodynamic therapy have also been used. Patients with chronic fatigue syndrome are sensitive to drug side effects, but low doses of tricyclic antidepressants can be helpful in improving sleep and alleviating pain. SSRI antidepressants in contrast may not be helpful unless depression is present. There is some evidence that treatment with essential fatty acids may be beneficial. Poor outcome is associated with personality disorder and prolonged convalescence.

Psychosomatic disorders

Rheumatoid arthritis, ulcerative colitis, bronchial asthma, essential hypertension, thyrotoxicosis and peptic ulcer have all been described as psychosomatic disorders, a category
developed in the 1950s by analysts in the USA.40 These are physical disorders aggravated or precipitated by psychological factors. Past theories that there are direct causal links between specific unconscious conflicts, psychological methods employed by individuals in coping with them and the development of specific organic diseases have now fallen into disrepute, for example for asthma,41 and a more general theory has evolved, linking psychological stress in people with a vulnerable personality and an inherent vulnerability of certain of their bodily systems, leading to autonomic, endocrine or immunological changes, which in turn precipitate an organic disease to which they are predisposed. For instance, life events may precipitate a myocardial infarction, although the underlying coronary artery disease would already have been present. An increased vulnerability to cardiovascular conditions has been demonstrated in the first year after the death of a spouse. A link has also been suggested between coronary heart disease and type A personality (ambitious, aggressive and competitive, with a chronic sense of time urgency). Some authors also regard obesity and anorexia nervosa as psychosomatic disorders.

Other concepts and disorders related to physical complaints

These are described here for comparison, but are not by definition somatization disorders.

Monosymptomatic hypochondriacal psychosis

Those conditions where hypochondriacal delusions occur may take various forms.42 There may be a delusion of insect infestation of the skin (Ekbom’s syndrome),43 delusions of lumps under the skin, delusions of internal parasitosis and a delusion that the individual is emitting a foul smell. Delusionaly believing that there is a physical cause, the patient attempts to gather evidence for this and seeks multiple medical opinions, perhaps with themselves suggesting bizarre treatments. Although such patients may become paranoid and angry towards their doctors, there may be an otherwise encapsulated systematized hypochondriacal delusional system. Such individuals are difficult to manage and may be resistant to treatment, although the antipsychotic oral medication pimozide has been found to be especially effective. Some patients have also been reported to respond to antidepressant medication; in other cases, the disorder is part of a paranoid psychosis, depressive disorder or organic brain disorder.

The sick role

This was described by Parsons in 1951 and derived from learning and role theories.44 If an individual adopts the sick role, there are two rights (exemption from normal social responsibilities and not being held responsible for one’s condition) and two obligations (the obligation of wanting to recover and an obligation to seek appropriate help, usually from a doctor, and to cooperate with such help). An individual is liable to find the sick role attractive and adopt it when its advantages outweigh its disadvantages. For instance, an individual may be unable to respond adequately to the demands of daily life or may otherwise feel that adopting the sick role is the only way to receive sufficient sympathy, attention and love. Patients who as children had indulgent parents may find the sick role particularly attractive, due to their having learned that status and power can be achieved by manipulative behaviour strategies. Individuals may be especially prone to adopt the sick role at times of increased responsibility and stress (see also Chapter 11).

Illness behaviour

Illness behaviour is the way in which symptoms are perceived, evaluated and acted on.45 Factors such as religion and social class affect how an individual responds to these symptoms, for example the tendency to seek, and the threshold for seeking, medical advice. Such behaviour may be judged inappropriate, given the individual’s degree of disability and the situation. It may then be referred to as ‘abnormal illness behaviour’.46 Figure 41.7 illustrates the suggested relationship between organic disease and illness behaviour.

Accident neurosis

This condition overlaps with post-traumatic neurosis, which is often used to refer to neurotic symptoms following head injury (post-concussional syndrome). True malingering is uncommon following head injury. Gross ‘neurotic’ symptoms
are inversely related to the severity of the head injury and occur most often when the cause of the injury is perceived by the individual as someone else’s fault or if financial compensation is possible. It is more likely to occur in males of lower social class following industrial injuries. Sexual dysfunction may be marked. It is now realized that even in cases of so-called ‘compensation neurosis’, symptoms may persist independent of seeking and achieving compensation, and the resulting disability is often underestimated. However, the longer compensation disputes continue, the worse the prognosis.

Factitious disorders

The term ‘factitious’ means not genuine, real or natural, and such disorders are characterized by physical or psychological symptoms that are intentionally produced or feigned, associated with a psychological need to assume the sick role, as evidenced by the absence of external incentives for such behaviour, such as economic gain, better care or physical wellbeing. This contrasts with malingering, where symptoms are also produced intentionally but for an external goal that is obviously recognizable when the environmental circumstances are known, for example financial compensation. Examples of physical symptoms in factitious disorders include self-inflicted injuries to the skin and symptoms arising from the acceptance of medication, despite the individual being aware of having an abnormal sensitivity to the drug. It usually begins before the age of 30 years. The main treatments used have been psychological, either confrontatory or non-confrontatory. Table 41.4 summarizes the differences between somatoform, conversion, dissociative and factitious disorders and malingering.

Münchausen syndrome (hospital addiction syndrome)

This is the best-studied form of factitious disorder with physical symptoms. It was described by Asher in 1951, who coined the term after a fictional German cavalry officer, described by Raspe in 1785, Baron Karl von Münchausen, who harmlessly lied about his extraordinary military exploits. Patients feign illness to bring about paramedic employment, and experience of medical for no obvious gain. Although symptoms are consciously produced, motivation is largely unconscious but directed to achieving the sick role. It is an abnormal illness behaviour, a disorder of both illness behaviour and sick role. The patients simulate symptoms suggestive of serious physical illness and deceive medical staff. Men appear to be affected more than women. Patients’ histories are often plausible but overdramatic. Patients may inflict injuries on themselves or simulate symptoms in a bizarre way, such as swallowing needles. Abdominal symptoms are the most common. Pathological lying (pseudologia fantastica) is often present. Variants include presenting with psychiatric complaints, including a false history of bereavement. Patients may seek analgesic drugs and, more generally, attention. The condition is conceptualized as histrionic or hysterical behaviour in a severely disordered, sometimes masochistic, personality. Such individuals become impostors as a defence against feelings of inferiority and may masochistically play out a game with staff involving aggressive and sexual elements, perhaps to counter unconscious guilt and the psychological disintegration of the individual. Their behaviour may induce a sadistic response from staff. However, physical illness may predispose, coexist with or result from Münchausen syndrome.

When their feigning comes to light, such individuals may abscond from hospital but then travel to another hospital (‘peregrination’) and present with the same clinical scenario. Patients frequently change their names and the hospitals they approach, and they have a characteristic lack of visitors. Consistent management is thus made very difficult, with considerable associated costs, morbidity and even mortality. Patients who wander usually have a longer history, are more often men, often are unemployed or frequently change jobs, and are more likely to present with abdominal or psychological symptoms, to have abused drugs and alcohol, and to have criminal convictions. Non-wanderers tend to be female, to be more stable socially, to be nurses, and to have less dramatic symptoms.

Aetiological factors may include parental abuse, neglect, early experience of chronic illness or hospitalization, paramedic employment, and experience of medical

mismanagement with an associated grudge. Organic mental disorder should be excluded.

Treatment of coexisting depressive disorder may sometimes be of benefit. Psychological treatment is the ideal treatment of choice, either non-confrontatory or confrontatory.

A further variant is Münchausen by proxy, in which physical symptoms are intentionally produced in others, for instance by a mother in her child. Such children do not show symptoms when in the care of others or when the mother is supervised. There may be a similar history of unexplained symptoms or even death in a sibling of the child. The mother may have medical experience, such as being a nurse, and have an emotionally distorted relationship with her partner. Through her behaviour, the mother becomes the centre of attention and herself receives care, which may underlie the motivation for such behaviour. Such women rarely ever admit to having produced physical symptoms in their children, often due to underlying feelings of deep humiliation.

**Malingering**

This is the conscious production of physical or psychiatric symptoms for external gain, for example to avoid prison, to obtain benefits or to avoid military service. It is not a mental disorder in ICD-10 or DSM-IV, although the latter describes it as an ‘additional condition that may be the focus of clinical attention’.

---

**KEY POINTS**

- ‘Hysterical’ symptoms occur not only in dissociative (conversion) disorders but also in other psychiatric disorders, such as depression and anxiety, and true organic disease.
- In epidemic (communicable) or mass hysteria, there is often a background of tension in an institution. Initial symptoms appear in an influential figure and spread to others by suggestion.
- Histrionic personality disorder is associated with an increased vulnerability to dissociative (conversion) disorders.
- Hysterical (histrionic) behaviour is consciously motivated, unlike the unconscious motivation underlying symptoms in dissociative (conversion) disorders.
- In dissociative states, such as amnesia or fugue (unexpected journeying with amnesia), there is partial or complete loss of normal integration between two or more mental processes.
- In conversion disorders, there is loss or change in bodily function, usually affecting the voluntary nervous system, such as paralysis or anaesthesia.
- Dissociative and conversion disorders have an unconscious motivation to resolve intrapsychic conflict and may show the following features:
  - Primary gain, e.g. to resolve conflict or reduce anxiety
  - Secondary gain, e.g. the attention of others

- Symptom choice may be symbolic of the conflict and reflect modelling of symptoms that the individual or others have experienced.
- La belle indifférence (calm acceptance of symptoms).
- Hypochondriacal disorder is a disease conviction in spite of medical reassurance. There is intense persistent fear of disease and a profound preoccupation with body and health status.
- In hypochondriacal disorder, the patient is abnormally sensitive to normal physical signs and sensations and has a tendency to interpret them as abnormal.
- Hypochondriacal symptoms are most frequently secondary to depressive illness.
- Somatization disorder is a chronic syndrome of multiple physical symptoms not explainable medically.
- There is an increased incidence of somatization disorder in first-degree female relatives.
- In somatization disorder, first-degree male relatives have an excess of alcoholism, drug abuse and antisocial personality disorder.
- Unlike in hypochondriacal disorder, in somatization disorder there is less disease conviction, less fear of disease and less bodily preoccupation.
- Somatization disorder occurs primarily in females, compared with the at least equal incidence in males of hypochondriacal disorder.
- Somatization disorder has an onset before 30 years of age and has a long course without serious medical illness emerging.
- In body dysmorphic disorder (dysmorphophobia), there is a preoccupation with some imagined defect in appearance in a normal-appearing person that is not of delusional intensity.
- In clinical practice, most medically unexplained symptoms are due to undifferentiated somatoform disorder or to another primary psychiatric disorder, e.g. somatic anxiety symptoms, facial pain in depression.
- Somatization is the tendency to experience somatic (physical) symptoms unaccounted for by organic causes, to attribute such symptoms to physical illness and to seek medical help.
- Psychosomatic disorders are physical conditions aggravated or precipitated by psychological factors, e.g. bronchial asthma, peptic ulcer, ulcerative colitis.
- In monosymptomatic hypochondriacal psychosis, there are hypochondriacal delusions, such as skin infestation by insects or an emission of a foul smell.
- Adopting the sick role exempts an individual from normal responsibilities and from being held responsible for their condition.
- Illness behaviour refers to the way in which symptoms are perceived and acted upon by an individual.
- Accident neurosis overlaps with post-traumatic neurosis. Post-concussional syndrome refers to neurotic symptoms following a head injury.
- In cases of compensation neurosis, symptoms may persist after compensation.
- In malingering, symptoms are consciously produced for an obvious goal, which is lacking in factitious disorders.
- Münchausen (hospital addiction) syndrome is a factitious disorder in which patients repeatedly present at and get admitted to hospitals with feigned symptoms suggestive of serious physical illness.
REFERENCES

**INTRODUCTION**

It is often easier to say what eating disorders are not rather than what they are. People with eating disorders do not have a problem with their eating. They can chew or eat their food as well as anyone else. People with anorexia nervosa do not have anorexia; indeed, they are usually ravenous. Despite the repeated claims in the media, anorexia nervosa is not a ‘slimmer’s disease’; nor does it develop because people want to look attractive.

The diagnosis of anorexia nervosa is at three levels. First, there needs to be a behaviour, such as dieting, overexercising or self-induced vomiting, that leads to weight loss. Second, the weight loss has to be sufficient that the person (if a woman) stops menstruating and, irrespective of gender, has a low sexual drive. Third, the thinking of people with anorexia nervosa changes: they are terrified of being at a normal weight.

It is a common clinical mistake to believe that the patient with anorexia nervosa is attempting to avoid ‘being fat’; rather, she has a phobia of being at a normal weight, and this is the pathognomonic feature of anorexia nervosa. None of the other eating disorders have, strictly speaking, pathognomonic features; the behavioural features occur in other clinical conditions, particularly the mood states and disorders of personality.

Bulimia nervosa involves frequent binge eating coupled with compensatory behaviours designed to avoid gaining weight. People with bulimia nervosa do wish to weigh less, and this view is more entrenched than in the general population, but it does not have the intensity of anorexia nervosa.

Patients with bulimia nervosa feel out of control – a feeling that often extends beyond the eating behaviour itself. They feel unsure about social and interpersonal matters. They are sad and apprehensive, but the dominant emotion is anger – anger towards themselves or to a particular person, such as their mother or partner. Their feelings and the eating disorder fluctuate. A large minority are multi-impulsive; that is, their eating disorder has become mixed with addictive and self-damaging behaviour.

Anorexia nervosa invariably begins in adolescence, while bulimia nervosa is usually a condition of adulthood. People with bulimia nervosa are at normal weight, whereas people with anorexia nervosa are emaciated. Anorexia nervosa has a specific psychopathology, while people with bulimia nervosa, although wishing to be slim, rarely lose much body weight and certainly do not maintain a low weight.

There have been attempts to arrange people with eating disorders into one diagnostic group. There is logic to this, as there is some overlap and sometimes patients can move from one diagnosis to another. Many clinicians have resisted this, however, because although eating-disordered individuals share a number of commonalities, such as overevaluation of control of eating, shape and weight, there are differences in the demographics, pathogenesis and treatment approaches of the main syndromes.

In addition to anorexia nervosa and bulimia nervosa, other diagnostic groups include binge-eating disorder (BED) and eating disorder not otherwise specified (EDNOS). BED involves frequent binge eating without any compensatory behaviours; it is usually associated with obesity. Apart from body weight, the disorder is similar to bulimia nervosa, but not all obese patients binge eat. EDNOS is a range of eating disorders including BED and other eating disturbances that show some, but not all, of the features of anorexia and bulimia nervosa.

The treatment of eating disorders has been the subject of much research. Somewhat flippantly, it has been suggested that there are only three significant findings: first, that bulimia nervosa responds to a cognitive-behavioural approach; second, that family-based treatments are to be recommended for adolescents with eating disorders; and third, that some patients with bulimia nervosa benefit from antidepressant medication. We do not know what will get any particular person with anorexia nervosa better, although there are complex multidisciplinary treatment approaches that benefit many. Unfortunately, severe and enduring anorexia is becoming an increasing problem, as is the multi-impulsive form of both anorexia and bulimia nervosa.
**DIAGNOSIS**

**Anorexia nervosa**

*International Classification of Diseases, 10th revision (ICD-10) (F50.0)*

The disorder is characterized by a deliberate weight loss associated with specific psychopathology, and resulting in malnourishment, with endocrine and medical disturbances. It occurs mostly in young women and girls, but men and adolescent boys may also be affected by anorexia nervosa.

- Weight loss leading to a body weight at least 15 per cent below the normal/expected for age and height body weight (or Quetelet’s body mass index (BMI) at 17.5 kg/m² or less, used for age 16 years and over). Prepubertal patients may show failure to make the expected weight gain during the period of growth.
- Weight loss self-induced by avoidance of ‘fattening foods’ and other methods such as excessive exercising, use of appetite suppressants or diuretics, and purging behaviours such as self-induced vomiting or laxative misuse.
- Distorted body image: self-perception of being too fat and intrusive dread of fatness persisting as intrusive, overvalued ideas, which leads to self-imposed low weight threshold.
- Endocrine disturbances of hypothalamic–pituitary–gonadal axis (HPA), manifesting as amenorrhoea in women and loss of sexual interest and potency in men.
- In prepubertal onset, the sequence of pubertal events is delayed or arrested (e.g. growth, breast development and primary amenorrhoea in girls; juvenile genitals in boys). With recovery, puberty is often completed normally but menarche is late.²

**Diagnostic and Statistical Manual of Mental Disorders, 4th edition, text revision (DSM-IV-TR)**

- Refusal to maintain minimally normal body weight (< 85%).
- Fear of gaining weight.
- Disturbance in perception of shape or size of body.
- Amenorrhoea (absence of three or more menstrual cycles).³

**Subtypes**

- **Restrictive:** predominant features – dieting, fasting or excessive exercising.
- **Binge eating/purging:** regular bingeing or purging; very likely to have other impulse-control problems.

NB: anorexia nervosa ‘trumps’ the diagnosis of bulimia nervosa.

**Bulimia nervosa**

*ICD-10 (F 50.2)*

- Recurrent episodes of overeating, when large amounts of food are consumed in short periods of time.
- Persistent preoccupation with eating, and strong desire/compulsion to eat (craving).
- Attempts to counteract the ‘fattening’ effects of food by one or more of the following:
  - Self-induced vomiting
  - Self-induced purging
  - Alternating periods of starvation
  - Use of medications (appetite suppressants, diuretics, etc.).
- Morbid dread of fatness, usually normal weight, may be a history of anorexia nervosa or obesity.²

**DSM-IV-TR**

- Recurrent episodes of binge eating, characterized by:
  - Eating in a discrete period of time an amount of food that is larger than for most people under the same circumstances
  - Feelings of lack of control over eating during the episode.
- Recurrent behaviours to prevent weight gain (e.g. self-induced vomiting, misuse of laxatives/diuretics/enemas/other medications, fasting or excessive exercise).
- All above occurs, on average, at least twice a week for 3 months.
- Self-evaluation unduly influenced by body shape and weight.
- Disturbance not occurring exclusively during episodes of anorexia nervosa.³

**Subtypes**

- **Purging:** regular self-induced vomiting or misuse of laxatives, diuretics or enemas during the current episode.
- **Non-purging:** compensatory behaviours such as fasting or excessive exercising used, but no regular self-induced vomiting or use of laxatives/diuretics/enemas.

**Eating disorder not otherwise specified**

This category in DSM-IV represents eating disorders of clinical severity, psychopathology and presence of social impairment that are similar to other eating disorder diagnoses but that do not meet all diagnostic criteria for either anorexia nervosa or bulimia nervosa.³ For example, there could be a weight marginally above the diagnostic criteria for anorexia nervosa, or frequency of binge eating could be below that required by DSM-IV.³ The main ICD-10
equivalents would be atypical anorexia nervosa (F50.1) and atypical bulimia nervosa (F50.3): disorders that meet some but not all of the criteria for anorexia nervosa and bulimia nervosa, respectively, and where the overall clinical picture does not justify the diagnosis (e.g. lack of amenorrhea or significant weight loss or does not meet the frequency criteria for bingeing and vomiting). There should not be a weight loss secondary to a known physical illness.

EDNOS is the most common eating disorder in the outpatient setting and is widely used by clinicians, and yet it is not as well researched as other eating disorders. Perhaps the most well researched subcategory is BED – recurrent episodes of binge eating, in the absence of the regular use of compensatory behaviours aimed at weight control that are characteristic of bulimia nervosa and anorexia nervosa. People with BED usually have a BMI above the normal range of 20–25.

Some clinicians point out that there are certain problems of nosology that would need to be addressed when formulating diagnostic criteria for the fifth edition of the DSM. EDNOS is the most widely seen eating disorder in clinical practice, and yet it has the ‘residual’ category in the major classification systems. Some proposals for DSM-V involve changing diagnostic criteria for anorexia nervosa (e.g. to drop amenorrhea as a criteria, or to upwardly adjust the weight threshold for anorexia nervosa); reclassifying EDNOS to several categories in their own right; and even creating one dimensional category of eating disorder, including all types and subtypes.

EPIDEMIOLOGY

The incidence of anorexia nervosa is approximately 8 cases per 100,000 population per year and is highest in women aged 15–19 years, who account for approximately 40 per cent of all diagnosed cases. Incidence rates of anorexia nervosa in men have been reported less frequently, at below 0.1 cases per 100,000 population per year. According to Hoeken, the average prevalence rate for anorexia nervosa is 0.3 per cent, although it has varied in studies between 0 per cent and 0.9 per cent, with an average point prevalence of 0.29 per cent in young women. There is less information about the incidence rates for men, but it has been reported at less than 1 per 100,000 population per year (around 10% of cases).

The incidence of bulimia nervosa is 12 cases per 100,000 population per year, with a prevalence rate of 1 per cent. The average age of onset is 19 years – slightly older than in anorexia nervosa.

In a community setting, eating disorders tend to be divided into 60 per cent EDNOS, 14.5 per cent anorexia nervosa and 25.5 per cent bulimia nervosa.

AETIOLOGY

There is no single cause for the development of an eating disorder. There seems to be a genetic predisposition/vulnerability, which, together with adverse life events and other environmental influences, could manifest as inappropriate dieting or emotional difficulties. This vulnerability may also predispose to particular personality traits or affective disorder (particularly associated with binge eating/purging). All the factors described below play an important role in the predisposing, precipitating and maintaining aetiological factors for eating disorders and will commonly interact as part of one complex aetiological model.

Genetic factors

Family studies have shown that there is an increased incidence of eating disorders in first-degree relatives by 7–12 times. Several studies have shown an increased concordance ratio for monozygotic and dizygotic twins, with Holland and colleagues showing a concordance ratio of 56 : 5. The heritability of binge eating was estimated to be 50 per cent and broad bulimia nervosa 60 per cent, with the remaining variance attributable to individual specific environment.

Sociocultural factors

Assimilation to a new culture with a higher prevalence of eating disorders may play a mediating role in the development of anorexia nervosa in a vulnerable person. This may occur as a result of the pursuit of thinness seen as ideal in Western cultures. In vulnerable individuals, internalization of this ideal may result in feelings of discrepancy between self and ideal, which in turn can lead to body-image dissatisfaction and dietary restriction. Experimental evidence suggests that media exposure or social pressures to the idealized thin can increase body-image concerns, at least in the short term. It could be considered a causal factor in models and media industries, but there is no evidence that it is so in a general population. Dieting, which may be culturally driven, is often a trigger for eating disordered behaviour in a vulnerable individual. Ethnic background does not appear to be a protective factor. Urbanization seems to be a risk factor for bulimia nervosa but not for anorexia nervosa. There have been studies to suggest that anorexia nervosa is more common in people from higher socioeconomic groups, but no such association has been found in people with bulimia nervosa or in studies combining people with all eating disorders.

Family factors

Family studies, such as those by Minuchin, were very influential in the 1970s and 1980s. Certain parenting styles (’anorexogenic mother’) were thought to increase the risk
for anorexia nervosa. These findings, however, are not supported in the newer studies, and current research suggests that patterns observed within the family, for example enmeshment, may be a result of the eating disorder rather than the cause of it. Blair and Freeman found that disordered eating may cause family disturbances.14

**Sexual, physical and emotional abuse**

Early studies focused predominantly on the role of sexual abuse in the development of eating disorders. Connors and Worse found a 30 per cent rate of sexual abuse in patients with eating disorders,15 although many studies that have looked into associations between eating disorders and reported sexual abuse did not find a strong specific relationship. The generally held view is that sexual abuse is no higher in the eating disorders than in other neurotic conditions, save for the multi-impulsive form – that is, where the eating disorder occurs in conjunction with addictive or self-damaging behaviours. Later studies have highlighted the importance of examining sexual, physical and psychological abuse, particularly as it is often the case that more than one form of abuse will be present.16 All forms of abuse may be seen as moderators of other factors, which may predispose an individual to develop an eating disorder, rather than as being a sufficient factor alone to cause the eating disturbance.17 It has been suggested that the experience of emotional abuse may lead to a number of related manifestations, such as difficulties in tolerating distress, which are later implicated in the development of the eating disorder.17

**Personality**

Personality factors have been considered with regard to onset and manifestation of symptoms, maintenance of eating disorders and treatment response. Perfectionism is a risk factor for anorexia nervosa and bulimia nervosa, whereas obsessive–compulsive personality disorder has been found to be a risk factor only for anorexia nervosa.18 Cluster C personality disorders (obsessive–compulsive, dependent, avoidant) are the most common among individuals with eating disorders, followed by cluster B (borderline, histrionic, narcissistic, antisocial).

**Biological factors**

Hypothalamic dysfunction and neuropsychological deficits (e.g. visuospatial processing) have been studied. Some of the deficits, for example cognitive functioning, improve with weight gain. However, there are some studies suggesting non-nutrition-related brain changes. For example, Gordon and colleagues found unilateral temporal lobe hypoperfusion demonstrated by a regional cerebral blood flow isotope scan.19

---

**PATHOGENESIS**

Few people would accept that the eating disorders have a single pathogenesis. The differences in demography, symptomatology and age of presentation for each disorder belie this. There are, however, certain personal and social cultural factors that are common. Low self-esteem, perfectionism, rigidity and negative affect are frequent, but these are probably secondary rather than primary to the disorder. Some authors have noted a season of birth affect (April and June), and being slightly overweight before the illness. More relevant for anorexia nervosa is an early puberty, which leaves the girl without peers who are going through a similar experience. Family factors, particularly family dieting or disordered eating, or a family history of neurosis or addictive behaviour, are described by a few authors. Sexual abuse is not thought to be associated specifically with eating disorders, apart from the multi-impulsive form of bulimia nervosa.20,21 A first-degree relative with an eating disorder has been implicated, as has chromosome 10 for bulimia nervosa and chromosome 1 for anorexia nervosa.22

The overwhelming biological feature, however, is that primarily girls and women have these conditions. Further, the conditions occur in adolescence in anorexia and in early adulthood in bulimia.

Hilde Bruch was the first to attempt to explain the development of anorexia nervosa.23 She emphasized the severe disturbance of body image rather than disordered eating. She related the development to the changing role of women after the Second World War. She saw anorexia nervosa occurring in those women who were casualties of the social, economic and political freedom that followed universal opportunities, expectations and the contraceptive pill. They were, she said, within ‘a golden cage’ where contradictions were played out. Their disorder seemed to control them, and yet they in turn had control over their families and starving bodies.

Crisp was influenced by Bruch, although he emphasized the powerful effect of the anorectic patient’s own pubertal hormonal changes. In his model, the future person with anorexia nervosa found the passage to adult expectations and sexuality difficult.24 Certain events – social, medical, familial – provided the seeds of the disorder around the age of 13 years, but the precipitating event would occur anytime in the following 5 years. Restriction would lead to weight loss and what Crisp referred to as ‘pubertal regression’, by which he meant that emotionally the patient returns to a prepubertal state. Further, she becomes trapped by her own biology, which is the hormonal status associated with low body weight. Crisp identified a threshold weight of approximately 40–42 kg above which plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) can be stimulated. These hormones are associated with libido. The patient with anorexia nervosa, terrified of her low weight, attempts weight gain. On reaching this
threshold, she becomes aware again of adult feelings and the unresolved conflicts that she experienced around puberty. Unsurprisingly, she seeks safety below the threshold. It is for this reason that most people with anorexia nervosa can be cajoled to gain some weight and reach approximately 40 kg. Beyond that, Crisp said it was only those patients who received a sophisticated psychotherapy, coupled with practical therapies, who could make the full journey to recovery and normal body weight.

The implications of this model are that the disorder is egosyntonic and that the patient rarely seeks change. Any weight gain is minor and the therapeutic task of the clinician is to achieve emotional maturity. Crisp said:

Whatever the patient's chronological age, her psychological age has been arrested at or been regressed to, a pre-pubertal level since the onset of the illness. Her target-weight should represent this fact.

The implications of this are that the family needs empowerment and their involvement is essential. It was from Crisp that the core role of family therapy developed.

Cognitive-behavioural models of the eating disorders have developed over time and tend to focus on the maintenance of the disorders, while acknowledging the importance of aetiological factors. Fairburn and colleagues propose that once attempts to restrict eating begin, these are reinforced through three main feedback mechanisms that vary in influence over time. First, dietary restriction enhances the sense of being in control. Second, aspects of starvation encourage further dietary restriction, through the physiological and psychological changes bought about by starvation (including impaired concentration, intense hunger and heightened sense of fullness), which all threaten the individual's sense of control. Third, control over shape, weight and eating become inextricably bound up in the individual's perception of their self-worth. The individual engages in behaviours such as hypervigilant body-checking or avoidance, further reinforcing distorted beliefs and assumptions regarding eating, shape and weight. Biases in information-processing contribute to these distorted beliefs. Thus, the overvaluation of control of eating, shape and weight is seen as the core maintaining mechanism of the eating disorder. Among individuals with bulimia nervosa, the vicious cycle of restriction, bingeing and purging serves further to undermine sense of control and contribute to sense of failure. Therefore, it is suggested that the onset of the disorder may be related to a need for self-control in general. In patients with a restrictive presentation this may be a result of an interaction between the individual's perfectionism and long-standing low self-esteem, while in more bulimic presentations the need may be for control over intolerable emotion.

As described below, cognitive-behavioural theory forms the basis of a successful range of treatments, particularly for bulimia nervosa. As researchers have become aware of the importance of deeper, core beliefs, the cognitive-behavioural therapy (CBT) model has been extended. Waller and colleagues have developed a schema theory model for eating disorders, based on good data. Schemas are extremely stable, negative, rigid and global core beliefs that develop during childhood and that are expanded upon throughout an individual's lifetime. When a schema is triggered, the individual experiences intense affect such as a high level of anger, anxiety, shame or sadness. The model proposes two processes by which individuals attempt to avoid this intolerable affect. In people with a restrictive presentation, primary avoidance of affect, whereby the individual uses compensatory schema (e.g. perfectionism, emotional inhibition) to avoid triggering early maladaptive schema, is prominent. In people with a bulimic presentation, secondary avoidance of emotion occurs, in which the individual uses recognized behaviours (e.g. bingeing, vomiting) to escape or block the intolerable emotion.

TREATMENT OPTIONS FOR EATING DISORDERS

National Institute for Health and Clinical Excellence (NICE) guidelines recommend the following:

Anorexia nervosa

- Most people with anorexia nervosa should be managed on an out-patient basis, with psychological treatment provided by a service that is competent in giving that treatment and assessing the physical risk of people with eating disorders.
- People with anorexia nervosa requiring in-patient treatment should be admitted to a setting that can provide the skilled implementation of refeeding with careful physical monitoring (particularly in the first few days of refeeding) in combination with psychosocial interventions.
- Family interventions that directly address the eating disorder should be offered to children and adolescents with anorexia nervosa.

Bulimia nervosa

- As a possible first step, patients with bulimia nervosa should be encouraged to follow an evidence-based self-help programme.
- As an alternative or additional first step to using an evidence-based self-help programme, adults with bulimia nervosa may be offered a trial of an antidepressant drug.
- Cognitive-behavioural therapy for bulimia nervosa (CBT-BN), a specifically adapted form of CBT, should be offered to adults with bulimia nervosa. The course of treatment should be for 16–20 sessions over 4–5 months.
• Adolescents with bulimia nervosa may be treated with CBT-BN, adapted as needed to suit their age, circumstances and level of development, and including the family as appropriate.

Atypical eating disorders

• In the absence of evidence to guide the management of atypical eating disorders (EDNOS) other than BED, it is recommended that the clinician considers following the guidance on the treatment of the eating problem that most closely resembles the individual patient’s eating disorder.
• Cognitive-behavioural therapy for binge-eating disorder (CBT-BED), a specifically adapted form of CBT, should be offered to adults with BED.

All eating disorders

• Family members, including siblings, should normally be included in the treatment of children and adolescents with eating disorders. Interventions may include sharing of information, advice on behavioural management and facilitating communication.

A systematic review of treatments for anorexia nervosa found serious weaknesses in the literature for psychological treatments. The authors concluded that there was some evidence to suggest that CBT may be superior to nutritional counselling after restoration of weight, but that it was unclear whether CBT was useful in the acute phase of illness in very underweight patients. The authors of the review found one unreplicated study that showed that manual-based non-specific clinical management (NSCM) was more effective than CBT or interpersonal psychotherapy (IPT) in improving global outcome in an out-patient setting. They also reported that there was no significant evidence for family therapy in adults, although the evidence is supportive for family therapy in children and adolescents, as indicated in the NICE guidelines. A study looking at psychoanalytical psychotherapy, cognitive analytical therapy (CAT) and family therapy with a control group of ‘routine’ management, in out-patient management of anorexia nervosa, found that psychoanalytical and family therapies were superior to routine management in terms of weight gain.

Many studies have small sample sizes and high dropout rates, and it is difficult to come to firm conclusions about the efficacy of one psychological treatment over another. However, it is clear that treatment with a psychological therapy in a specialist eating disorder setting is superior to no treatment or a non-specialist treatment. Establishing a positive therapeutic alliance is perhaps the most important factor in terms of engagement and outcome for psychological therapies for anorexia nervosa. More research is needed to look at the specific benefits of psychoanalytical psychotherapy, CBT, IPT, CAT, NSCM, motivational enhancement therapy and family therapy in the treatment of anorexia nervosa. Most patients should be treated in an out-patient setting, although day-hospital and in-patient settings are suitable for patients who need more intensive or emergency treatment.

The aims of psychological treatment for anorexia nervosa vary, depending on the motivational stage of change: many patients are ambivalent about change and may not have sought help independently. It may be that motivational enhancement work and help to improve quality of life are all that the patient can manage at the moment, particularly in patients with severe and enduring anorexia nervosa, although it is important to persist with instilling the hope of recovery for all patients. For patients aiming at full recovery from anorexia nervosa, the aim will be to look at the underlying psychological predisposing, precipitating and maintaining aetiological factors for the eating disorder psychopathology and behaviours, as well as reintroducing regular eating and avoided foods and encouraging weight gain. Different psychological and behavioural issues may arise at each stage of recovery, and patients continue to need intensive out-patient psychological support for at least a year after weight restoration has been achieved, whether as an in-patient, day patient or outpatient. Weight

PSYCHOLOGICAL INTERVENTIONS FOR ANOREXIA NERVOSA

Much research into eating disorders has been done since the 1970s. However, the research has concentrated largely on delineating the bulimia nervosa syndrome and determining and testing treatment approaches to it. Little has meaningfully changed in the treatment of anorexia nervosa, and yet this remains the mental illness with the highest mortality. Treatments for multi-impulsive eating disorders are reasonably promising on an in-patient basis, but outpatient treatments have yet to be developed. Overall, the treatment response of anorexia nervosa is erratic. The treatment for the acute phases of anorexia nervosa and for severe and enduring anorexia nervosa must be the highest priority.

The evidence base for the psychological treatment of anorexia nervosa is poor. The NICE guidelines for eating disorders found that the strength of evidence for psychological therapies was level C (expert committee reports or opinion or clinical experiences of respected authorities, or extrapolated from indirectly related randomized controlled trials (RCTs) or other well-designed studies) in the hierarchy of evidence, except for family therapy that directly addresses the eating disorder for children and adolescents with anorexia nervosa, which was graded as level B (well-conducted clinical studies but no RCTs).
gain without psychological input is unlikely to achieve full and sustained recovery.

PSYCHOLOGICAL INTERVENTIONS FOR BULIMIA NERVOSA

In contrast to anorexia nervosa, treatment for bulimia nervosa has been well researched and a number of modalities have some empirical support. Indeed, the only level A recommendation for adults with eating disorders in the NICE guidelines is for CBT-BN.27 For individuals with bulimia nervosa, a stepped-care approach, in which treatments are provided sequentially, according to need, is recommended.27

Self-help

The vast majority of patients with bulimia nervosa can be treated as out-patients. The first step of psychological treatment is self-help, which can be guided or unguided. Self-help has a number of advantages, including being more disseminable and less costly than individual treatments.13 Guided self-help appears promising in the treatment of bulimia nervosa. In guided self-help, the patient is typically given a treatment manual and invited for a few brief outpatient appointments, where their progress is reviewed.

A systematic review identified four self-help trials for bulimia nervosa.34 Outcomes are generally positive, with guided self-help demonstrating short- and long-term improvements. Although some studies appear to suggest that dropout may be higher in guided self-help than with face-to-face treatments,15 others report no such difference.36 An RCT of 121 patients entered into self-help with minimal guidance, self-help with face-to-face guidance, self-help with telephone guidance or waiting list demonstrated improvements in those who received additional guidance, particularly face to face.33 Self-help with minimal guidance was not superior to the waiting-list condition. New technologies such as Internet-assisted self-help are also showing promise.38

In summary, it is likely that a subgroup of patients will respond well to guided self-help and may not need further intervention.33 Guided self-help may therefore be most appropriate as part of a stepped-care approach within a primary care setting or as a cost-effective first response to patients presenting to a secondary care service, particularly if the alternative is a long wait for one-to-one therapy.17

Face-to-face therapy

There is general agreement within the field, supported by NICE,27 that CBT is the treatment of choice for bulimia nervosa, delivered in group or individual format.39–41 The aims of CBT are to modify behaviours and cognitions that maintain the eating disorder, focusing on the implementation of regular eating and reduction of the core pathology, the overevaluation of eating shape and weight. Food-monitoring diaries, cognitive restructuring and behavioural experiments are key strategies.

Despite this endorsement, the rates for complete remission are low,19 leaving a substantial number of patients with continued difficulties. Thus, there is still need to improve current therapies and to develop sequential or alternative treatments. Fairburn and colleagues are developing a new enhanced form of CBT, building on existing theory by incorporating four additional maintaining mechanisms – clinical perfectionism, interpersonal differences, core low self-esteem and mood intolerance.1 This treatment relates to a transdiagnostic model of eating disorders and highlights the use of individualized formulations. One trial compared 20 sessions of two types of enhanced CBT: focused, which focuses exclusively on modification of eating disorder symptomatology, and broad, which also addresses the four maintaining mechanisms, as relevant for the individual patient, with waiting-list controls for all eating-disorder patients with BMI above 17.5.42 Both enhanced CBT treatments were found to be superior to waiting-list controls and earlier CBT treatments. Such changes were well maintained across the substantial 60-week follow-up period – important, as eating disorders are prone to relapse.

IPT is the only therapy that has been demonstrated to provide outcomes comparable to CBT, although the speed of response is slower.39 Adapted for bulimia nervosa, IPT was originally developed as a short-term psychotherapy for depression. The focus is in assisting patients to identify and modify current interpersonal problems that may be maintaining the disorder. Thus, IPT may be appropriate for people with interpersonal difficulties or who are reluctant to engage in or are unsuccessful with CBT. A further treatment that shows promise is dialectical behaviour therapy (DBT),43 an affect-regulation treatment originally developed for borderline personality disorder. An RCT comparing DBT with waiting-list controls demonstrated significant decreases in bingeing and purging.44 A small case series provides preliminary support for a time-limited integrative psychodynamic behavioural approach, with significant reductions in bulimic symptoms.45 Treatment studies have focused on women and therefore little is known about outcomes for men; clinicians are advised to adopt current models as appropriate.

In contrast to the adult literature, evidence-based treatment trials for adolescents with bulimia nervosa are largely absent.46 The success of family-based therapy with adolescent patients with anorexia suggests that this may be applicable. An RCT comparing family-based therapy and supportive psychotherapy with 80 adolescents with bulimia nervosa found that family-based therapy showed a clinical and statistical advantage over supportive psychotherapy at post-treatment and 6 months follow-up.46 Another trial compared family-based therapy with cognitive-behavioural
guided self-care (GSC) and found GSC to be superior in terms of cessation of binge-purge episodes at 6 months, although patients in both treatment groups showed significant improvement over time and were indistinguishable at 1 year follow-up. A small body of case series supports the use of CBT with adolescents with bulimia nervosa, and NICE recommends CBT-BN, adapted to suit the circumstances.

Research into bulimia nervosa is beginning to focus on the identification of predictors of treatment response, with Fairburn and colleagues demonstrating early change in frequency of purging as the best predictor of response at treatment end and 8 month follow-up. More recently, there has been a focus on disseminating CBT for bulimia nervosa to routine clinical settings using individualized formulations, demonstrating outcomes comparable to those found in research trials.

Psychological treatments for EDNOS

With the exception of BED, there is an absence of research for EDNOS. Treatments for BED are often similar to those for bulimia nervosa, and self-help is recommended as the first step. Research suggests that, for some patients, self-help is effective in reducing binge-eating episodes and psychological features associated with BED and in promoting abstinence from binge eating. With regard to face-to-face contact, a number of studies provide support for both group and individualized CBT, and this is recommended as the treatment of choice. DBT also shows promise, leading to greater reduction in binge days and in weight, shape and eating concerns. IPT has also been demonstrated to significantly reduce binge days at end and 4 month follow-up. Treatment of BED is often complicated by co-occurring obesity and associated medical concerns. It is of note that none of the studies has found significant reduction in BMI, and NICE advises that patients should be warned that all psychological treatments for BED have limited impact on weight.

For the remaining EDNOS disorders, it is suggested that the clinician considers following the guidance for the disorder that the patient’s presentation most closely resembles. This is supported by data on patients with BMI above 17.5. A case series design study that included patients with atypical bulimia nervosa found that the majority of these patients responded to CBT as well as those with bulimia nervosa, with the exception of those with normal-weight purging disorder.

Summary of psychological treatments for eating disorders

Since the original description of bulimia nervosa, significant progress has been achieved in the development and evaluation of evidence-based psychological treatments for the eating disorders. Most notably, CBT is recognized as the treatment of choice for bulimia nervosa and BED, and there is evidence for family therapy with adolescents with anorexia nervosa. However, many challenges remain. Substantial numbers of patients fail to get better with these treatments, and the lack of research regarding anorexia nervosa and EDNOS is remarkable. Adolescent, EDNOS, male and chronic patients remain poorly researched. The enhancement of current therapies and development of newer therapies is highlighted above.

Models of service delivery are also important, with the UK favouring a stepped-care model. The research does not inform as to which patients will benefit from which, if any, of the treatments detailed above – for example, which patients are suitable for guided self-help compared with individual treatment. A potential limitation of this model is patients becoming demoralized as they step further up the care pathway. Reliable predictors of treatment outcomes also remain unclear.

PHYSICAL PRESENTATION AND MANAGEMENT

Eating disorders, particularly anorexia nervosa, have one of the highest standardized mortality rates (SMRs) of any psychiatric disorder.

Patients with an eating disorder may present to healthcare professionals from many different medical specialties due to the fact that the physical consequences affect many different organ systems. Organic causes for unexplained weight loss should be excluded, but all clinicians should have knowledge of eating disorders sufficient to recognize likely cases and to refer on appropriately.

An initial physical examination and investigations should be carried out, but physical risk assessment in patients with eating disorders must be a longitudinal process. A general medical history and examination should be carried out, of which the specific elements will be described below.

Body mass index (normal 20–25 in adults)

BMI should not be used alone to assess physical risk, due to factors such as patients falsifying their weight through practices such as water-loading or carrying heavy objects in their clothes. A BMI below 17.5 meets the criteria for anorexia nervosa, and immediate risk to patients increases significantly as the BMI falls below 13. However, speed of weight loss increases risk, particularly if it is more than 1 kg a week. Other behaviours such as purging and overexercise also exacerbate the risk of a low BMI. The BMI is less useful in children and adolescents (in whom standard growth charts may be used instead), in pregnancy and in people with a height at the limits of normal. Co-morbid
physical illness may also increase physical risk, such as omission of insulin to cause weight loss in patients with diabetes mellitus.\textsuperscript{59}

**Proximal myopathy**

Starvation will eventually cause breakdown of muscle for energy, and increasing proximal myopathy is a good indicator of weight loss and may be useful if a clinician suspects weight falsification. It can be assessed by using the squat test or sit-up test.\textsuperscript{57,58}

**Core temperature**

Inadequate autonomic response to temperature variations in anorexia nervosa can cause low core temperature, which if below 34.5°C is an indicator of significant physical risk.

**Blood tests**

**Full blood count**

Mild, usually normocytic (occasionally macrocytic) anaemia is common in patients with anorexia nervosa, although haemoconcentration due to dehydration may mask it. Anthrocytosis has been reported in anorexia nervosa and results in a low erythrocyte sedimentation rate (ESR). A low white cell count may occur, particularly neutropenia, which is concerning in anorexia nervosa. Severe infection may occur as a result of this and other immunological factors. Mild thrombocytopenia may also occur. Bone-marrow changes such as fat-cell depletion have a significant effect on haemopoiesis and are likely to be a major cause of haematological complications in patients with anorexia nervosa.\textsuperscript{60}

**Urea, creatinine and electrolytes**

A raised urea and creatinine in patients with eating disorders may be due to dehydration, either through restriction of fluids or through purging behaviours. Regular vomiting usually causes a hypokalaemic, hypochloaemic metabolic alkalosis, with varying disturbances of sodium. Laxative and diuretic misuse can also cause hypokalaemia, with disturbances of pH, sodium and chloride. Hypokalaemia can cause cardiac arrhythmias, muscle weakness, cramps, renal and gastrointestinal disturbances, tetany and absent reflexes.\textsuperscript{61} Oral supplements may be used but, if the serum potassium is less than 3, particularly alongside electrocardiogram (ECG) changes, hospital admission may be necessary. Purging commonly causes hypovolaemia, which activates the angiotensin–renin–aldosterone system. Sudden cessation of purging can cause rebound oedema and consequent rapid weight gain. The oedema usually settles with conservative management, although short-term potassium-sparing diuretics are occasionally used in persistent oedema.\textsuperscript{62} Malnutrition, purging behaviours, alcohol misuse and refeeding syndrome may also cause hypophosphatemia, hypomagnesaemia and hypocalcaemia. Water-loading can cause hyponatraemia and, in the most serious cases, may result in clinical symptoms of water intoxication, which include confusion, ataxia, seizures, coma and occasionally death as a result of brainstem coning due to cerebral oedema.\textsuperscript{63}

**Liver function tests**

Starvation can adversely affect liver function tests (LFTs), possibly associated with fatty infiltration of the liver.\textsuperscript{64} Initial refeeding in patients with anorexia nervosa or co-morbid alcohol misuse may also affect LFTs.

**Albumin**

Together with severity of weight loss, low serum albumin (due to starvation or severe infection) is a predictor of death in anorexia nervosa.\textsuperscript{27,65}

**Glucose**

Starvation-induced hypoglycaemia may be asymptomatic, but rarely, in the most serious cases, it can cause coma and death. Dumping syndrome – excessive insulin production in response to food – may cause hypoglycaemia during refeeding. Vomiting following bingeing may also result in hypoglycaemia, therefore maintaining the binge–purge cycle, as hypoglycaemia may precipitate bingeing.\textsuperscript{61}

**Endocrine**

Thyroid functions tests are useful to rule out hyperthyroidism as a differential for weight loss, co-morbid thyroid dysfunction or thyroxine misuse. Eating disorders, particularly anorexia nervosa, affect the thyroid axis; the common pattern is low tri-iodothyronine (T3; thyroxine (T4) is sometimes low) and normal thyroid-stimulating hormone (TSH). Eating-disorder-related abnormalities should normalize with weight gain and will not need treating routinely. Raised growth hormone and cortisol with normal or low adrenocorticotropic hormone (ACTH) may also occur but do not need to be checked routinely unless there is concern about an endocrine disorder as a differential for anorexia nervosa.\textsuperscript{61} Reproductive hormones may need to be measured alongside other investigations, following weight restoration, if the female patient does not begin menstruating.

**Cardiac**

**Blood pressure**

Starvation or hypovolaemia due to fluid restriction or purging commonly causes postural hypotension, and blood pressure should be monitored regularly. Concerning features are a blood pressure below 90/70 mmHg and a postural drop of more than 10 mmHg.\textsuperscript{58}
Electrocardiogram: prolonged QTc interval
Prolongation of the QTc interval and QT variability are good predictors of life-threatening ventricular arrhythmias. Prolonged starvation with a low BMI, causing atrophy and histological changes in cardiac muscle and collagen fibres, and purging behaviours, resulting in hypokalaemia and hypomagnesaemia, may be directly arrhythmogenic or may prolong the QTc interval in patients with eating disorders. A genetic or medication-related prolonged QTc interval may increase this risk, and medications (many psychotrophic) should be used with caution in patients with eating disorders.

Bradycardia
Bradycardia is a common feature in patients with anorexia nervosa, possibly due to electrolyte disturbances, atrophy and reduced glycogen content of cardiac tissue cells, and thyroid dysfunction. It is particularly concerning if the pulse rate is less than 40 bpm, due to the consequent risk of arrhythmias. Resting tachycardia is an unusual and concerning feature in anorexia nervosa and should be investigated appropriately. Reduced variability of heart rate can also occur in anorexia nervosa and may be a predictor of sudden death, especially in patients with pre-existing cardiac disease.

ECG: ST segment and T-wave abnormalities
ST segment and T-wave changes are usually related to the effects on cardiac muscle of starvation, hypothermia or electrolyte abnormalities and should be investigated and treated appropriately.

Echocardiography
Patients with anorexia nervosa often have reduced left ventricular mass with reduced cardiac output. Mitral valve prolapse and pericardial effusion are other cardiac complications associated with eating disorders. Ipecac, an emetic sometimes used by patients with bulimia nervosa, causes potentially fatal toxic cardiomyopathy.

Bone mineral density
Osteopenia and osteoporosis are serious complications of anorexia nervosa and are not fully reversible. Bone metabolism is a continuous dynamic process, and oestrogen normally inhibits certain cytokines that encourage excessive bone resorption. The teenage years are a peak time for bone mineral to be laid down, similar to the time of onset for anorexia nervosa. The consequent amenorrhoea is therefore involved in the aetiology of osteoporosis or osteopenia in anorexia nervosa as well as other factors, including reduced levels of insulin growth factor (which normally promotes bone formation), increased cortisol levels and other nutritional deficiencies. Dual-energy X-ray absorptiometry (DEXA) is used to measure bone density at the hip and spine. It is probably appropriate to carry out DEXA scans on patients who have been amenorrhoeic for 1 year or more due to weight loss, as significant deterioration of bone density will take this long to occur. Scanning may be motivational in some patients, and knowledge of the current fracture risk may be useful in terms of lifestyle planning. Significant changes to bone density are likely to take at least 2 years, and therefore more frequent scanning is thought to be unnecessary.

Weight restoration is the key intervention to preventing further deterioration and partly improving bone mineral density. Weight-bearing exercise may improve bone density in a person of normal weight but can be detrimental to bone health in an underweight patient due to the fracture risk, contributing to further weight loss and continued amenorrhoea. Bisphosphonates should not be used in young women due to the potential for serious side effects such as teratogenicity (based on animal studies). They also have a poor evidence base for the treatment of premenopausal osteoporosis associated with anorexia nervosa. Other medications sometimes used in osteoporosis associated with anorexia nervosa are hormone-replacement therapy (HRT), the oral contraceptive pill (OCP), and calcium and vitamin D supplements, but the evidence base for these treatments is weak. Children should not be given hormone replacement, as there is a risk of stunted growth due to premature closure of the epiphyses.
Gastroenterological complications

Gastroenterological complications are very common in patients with eating disorders. Delayed gastric emptying in anorexia nervosa may cause bloating after meals, early satiety and reflux symptoms. Constipation is common in all eating disorders and may be related to poor food intake and colonic transit. Hypokalaemia is also a cause of constipation and paralytic ileus. Self-induced vomiting can cause complications such as Mallory–Weiss tears, reflux symptoms, oesophagitis and hiatus hernia. Gastric or oesophageal dilation/rupture due to bingeing and vomiting is rare. Haematemesis is relatively common as a result of a mild tear, but serious causes must always be excluded. Rare but serious complications of refeeding include acute gastric dilation, rupture of the stomach and acute pancreatitis. Patients with eating disorders are also more prone to functional gastrointestinal disorders such as irritable bowel syndrome. Chronic laxative misuse may also resemble a functional gastrointestinal problem. Misuse of stimulant laxatives may cause serious abnormalities in electrolyte and fluid balance; in order to prevent rebound oedema, patients are advised to wean off laxatives slowly. Bulk laxatives may be required during the weaning-off process, but a regular dietary structure and appropriate exercise should help to restore normal bowel function. Most complaints improve with recovery from the eating disorder.

Neurological complications

Neuroimaging in patients with anorexia nervosa has consistently shown widening of the sulci and ventricular enlargement. These generally appear to be reversible with recovery from the eating disorder, but certain functional abnormalities remain, which are possibly due to primary deficits. Electrolyte abnormalities can cause neurological complications and should be monitored and managed appropriately. Thiamine deficiency from malnutrition or alcohol misuse may cause Wernicke’s encephalopathy, and vitamin B12 and folic acid deficiency can rarely result in subacute combined degeneration of the spinal cord. During initial refeeding of patients with eating disorders, a general multivitamin supplement is usually sufficient. Specific supplementation with thiamine or vitamin B compound should be given in Wernicke’s encephalopathy (medical emergency), alcohol misuse, and cases of severe and enduring malnutrition.

Dermatological manifestations

Lanugo hair (hypertrichosis lanuginose) is common in anorexia nervosa – there is soft downy hair, usually on the lower back, abdomen and forearms (Figure 42.1). Russell’s sign (calluses/abrasions on the back of the hands) is an early sign in patients who induce the gag reflex with their fingers (Figure 42.2). Patients with anorexia nervosa may develop acne, particularly during weight restoration; acne may also be associated with polycystic ovarian syndrome in bulimia nervosa. Peripheral oedema during starvation or refeeding may cause skin changes. Changes to hair and nail structure, acrocyanosis, dermatitis, carotenoderma and dryness of the skin may also occur in patients with eating disorders.

Oral manifestations

Enamel erosion is a very common oral problem in patients who chronically induce vomiting, although salivary pH and flow and acidity of diet may influence the development of erosion. Eating disorders may also cause problems with oral
mucosal and gingival tissues through poor oral hygiene, nutritional deficiencies, infection and self-induced vomiting. Self-induced vomiting can cause non-inflammatory hypertrophy of the salivary glands, most commonly the parotids, and also disturb the gag reflex. Advice concerning oral health should be given to patients in order to limit oral damage. This includes using a non-acid mouth wash and fluoride toothpaste; rinsing the mouth with water and delaying brushing teeth after vomiting; reducing the amount of acidic foods and fluids in the diet; and regular check-ups with a dentist.

Compulsory treatment

It is preferable that a patient with anorexia nervosa enters into treatment through their own free will. However, when a patient has become so seriously physically and mentally unwell that they lack the capacity to make an informed decision about life-saving treatment, it is the responsibility of the clinician to appropriately assess the need for refeeding under the Mental Health Act.

Treatment under the Mental Health Act should be considered before it is too late to start refeeding in a patient in a life-threatening condition. Intervention in children may be particularly urgent, as they will reach a dangerous physical state faster than adults, due to having fewer fat reserves. A treatment section can be used in patients with anorexia nervosa in order to refeed, because the physical deterioration is related directly to the psychopathology that characterizes the disorder. Compulsory refeeding is often initiated with nasogastric tube feeding, which can be emotionally and physically demanding for nursing staff. Patients need one-to-one nursing care on a specialist eating disorders unit or medical ward. If control and restraint are necessary, local or national guidelines should be followed. Mild sedation may be necessary, but BMI and cardiovascular and respiratory functioning must be taken into consideration when calculating the dose.

Refeeding and refeeding syndrome

Refeeding syndrome is most common in patients with a BMI below 12, recent rapid weight loss of more than 1 kg a week, alcohol misuse, bingeing and purging, and co-morbid physical illness. Endogenous energy stores are catabolized during starvation as a means of providing energy, and insulin production is reduced. Despite sometimes normal serum levels, intracellular electrolyte levels, particularly phosphate, are often low. Insulin production increases on refeeding, in response to the move to exogenous carbohydrate metabolism. Insulin stimulates electrolyte uptake into cells, which may result in a sudden drop in serum electrolytes, most importantly phosphate. Peripheral oedema that usually settles with conservative management may occur during refeeding, but cardiac failure should be excluded.

Oral or intravenous phosphate supplementation may be used if necessary. Serum phosphate levels below 0.5 mmol/L may cause the most serious clinical features of refeeding syndrome. These comprise acute haemolysis, hypotension, cardiac failure, arrhythmias, rhabdomyolysis, respiratory failure, seizures, coma and sudden death. Calorie intake during initial refeeding should be below the patient’s basal metabolic requirements and should be increased gradually to reduce the risk of refeeding syndrome. Refeeding syndrome may also occur in patients at particular risk who are refeeding in an out-patient department. Careful monitoring of daily blood tests and diet are necessary for all high-risk patients in the initial stages of refeeding.

Further refeeding involves a gradual increase in dietary intake to encourage weight gain of approximately 1 kg a week on an in-patient unit and 0.5–1 kg a week in outpatients and day patients. To gain 1 kg a week, a patient will need approximately 1000 extra calories a day, on top of their normal requirements. This will mean a diet of approximately 2500–3000 calories/day, depending on the stage of weight gain, and should be achieved as far as is possible with a normal oral diet. Supplement high-calorie drinks are sometimes used for patients who are not aiming at full recovery from their eating disorder and are struggling with a full oral diet.

PHARMACOLOGY FOR EATING DISORDERS

One systematic review found that no medications trialled (antidepressants, hormonal and nutritional supplements) made a significant impact on weight gain in patients with anorexia nervosa. Appropriate use of vitamin and electrolyte supplements and other medications to prevent or reduce physical risk is described above (see Physical presentation and management).

Olanzapine has been used for patients with anorexia nervosa in an attempt to reduce the intensity of the anorectic psychopathology, particularly fear of normal body weight and overvalued ideas about weight and shape. A literature review found that the limited evidence suggests that olanzapine at doses of 2.5–15 mg daily may be helpful in reducing anorectic psychopathology and helping weight gain. However, more research is needed to clarify these findings, and refeeding alongside psychological therapies should be the mainstay of treatment for anorexia nervosa. Antidepressants may be used to improve mood in a patient with co-morbid depression, but low mood is common as a result of weight loss and malnutrition and may improve with refeeding.

Fluoxetine, a selective serotonin reuptake inhibitor (SSRI), has been licensed for the treatment of bulimia nervosa and is thought to help to reduce the urge to binge and vomit. A study found that fluoxetine 60 mg once a day is helpful in the treatment of bulimia nervosa, irrespective of
the presence of co-morbid depression, and therefore suggested that its effect on the eating-disorder symptoms is not only secondary to the antidepressant effect.\textsuperscript{78} SSRIs may also be useful in improving symptoms such as aggression, instability of mood, rejection sensitivity, anger, sexual disinhibition, illicit substance misuse and impulsive spending\textsuperscript{79} and therefore may be helpful in treating symptoms in patients with multi-impulsive eating disorders.

Topiramate, an anticonvulsant, has been suggested as a treatment for BED in obese patients. A study found that CBT efficacy improved with added topiramate (at a maximum dose of 200 mg) compared with CBT and placebo, with significantly reduced bingeing and increased weight loss in the short term, and found that topiramate was well tolerated in terms of adverse effects.\textsuperscript{80} More research is needed, particularly to look at whether the benefits are sustained in the longer term.

Medication is usually used in eating disorders alongside psychological therapies and aimed at specific symptoms rather than the core disorder.\textsuperscript{81} When using medications in patients with eating disorders, particular care needs to be taken with regard to physical monitoring and dosage.

**Course and outcome**

### Anorexia nervosa

A systematic review of the literature looked at outcomes of eating disorders.\textsuperscript{82} It found that case series studies have shown that 24–82 per cent of patients have recovered at 5–15 years’ follow-up. Two case series with comparison groups showed 27 per cent and 30 per cent recovery at 10 years and 12 years’ follow-up, respectively, and a prospective cohort study with comparison group showed 59 per cent recovery at 5 years’ follow-up. There were also concerns that, despite ‘recovering’ from their eating disorder, many patients continued to have significant concerns about weight and appearance, higher scores in the eating attitudes test, and dietary restriction. In all studies, up to 24 per cent of patients continued to have anorexia nervosa and many had traversed eating-disorder diagnoses or relapsed after a period of remission. Predictors of poor outcome in various studies included greater family hostility; extreme compulsion to exercise; poor social relationships before illness onset; psychiatric co-morbidity, particularly cluster C personality disorders, obsessive-compulsive disorder (OCD), autism-spectrum disorders, depression and substance misuse (associated with binge–purge subtype); more bingeing and purging behaviours; longer duration of disorder before presentation; older age at presentation; longer duration of amenorrhoea; and low albumin levels and lower BMI, haemoglobin and alkaline phosphatase at follow-up. The review also found higher rates of recovery for binge–purge subtype than for restrictive subtype at 4 years but no difference at 8 years; those patients who had the illness longer were more likely to have the binge–purge subtype. This fits with the finding that 52 per cent of patients with restrictive subtype were found to develop binge–purge subtype, usually within the first 5 years of follow up.

Berkman and colleagues also looked at mortality outcomes. The SMR for anorexia nervosa ranged from 1.36 to 30.5 and the SMR for suicide was 58.1 in one study.\textsuperscript{83} Crude mortality rates vary from study to study but have been found to be as high as 20 per cent over 20 years. Predictors for death in anorexia nervosa in various studies included weight below 35 kg at presentation; more than one inpatient admission; a history of psychiatric hospitalization for anorexia nervosa; substance and alcohol misuse; longer duration of illness at start of treatment; poor social adjustment; hospitalization for an affective disorder; and suicidality associated with co-morbid mental illness.\textsuperscript{82}

### Bulimia nervosa and multi-impulsive eating disorders

A study showed that, at 12-year follow-up after in-patient treatment (common in Germany), 70.1 per cent of patients with an original diagnosis of bulimia nervosa had no eating disorder diagnosis (most of whom had a BMI below 30), 10.8 per cent had bulimia nervosa, 1.8 per cent had anorexia nervosa, 1.8 per cent had BED, 1.8 per cent had anorexia nervosa and 13.2 per cent EDNOS.\textsuperscript{84} In a systematic review of the literature,\textsuperscript{82} predictors for poor outcome in bulimia nervosa were found to be substance misuse, poor impulse control, premorbid obesity, lifetime history of anorexia nervosa, older age at illness onset, co-morbid affective disorder and poor social adjustment. Many studies showed that BMI increased over time but remained largely within the normal range. The SMR for patients with bulimia nervosa was similar to that of the general population, throughout the studies.

Patients with multi-impulsive eating disorders have been found to have a poorer outcome, although there have been relatively few outcome studies. A study found that impulsive behaviours such as alcohol or substance misuse, recent suicide attempt, bingeing or stealing were the strongest predictor of a poor prognosis for patients with both anorexia and bulimia nervosa over a 4- to 6-year follow-up.\textsuperscript{85}

### Binge eating disorder and other EDNOS

There is a limited literature for outcome in BED. A study looked at 12-year outcome after in-patient admission for BED and found that 67.2 per cent of patients had no diagnosable eating disorder at 12 years (although 53.4 per cent of these had a BMI above 30), 7.8 per cent had BED, 9.4 per cent had a diagnosis of bulimia nervosa, none had anorexia nervosa and 12.5 per cent had other EDNOS.\textsuperscript{84} Co-morbid psychiatric illness, high presenting BMI, a history of sexual abuse and impulsivity appear to be poor prognostic indicators. The SMR for BED is unclear.
There is a very limited literature on outcomes in other EDNOS. However, one study found that patients with atypical anorexia nervosa, who lacked the intense fear of normal body weight and body image disturbance, had a better outcome than those with typical anorexia nervosa.86

CONCLUSION

Eating disorders have high morbidity and mortality rates especially anorexia nervosa. They have a complex aetiology and pathogenesis. Although there are clearly distinct eating disorder syndromes, many patients traverse diagnoses over the course of their illness. Psychological treatment for bulimia nervosa is well researched, with cognitive-behavioural psychotherapy being the gold standard. The evidence base for psychological treatment for anorexia nervosa is less clear, perhaps due to factors such as difficulty engaging patients in treatment and high attrition rates. All patients with eating disorders need careful physical investigation and monitoring over time. Early detection and treatment are important, as this may lead to better prognosis.

KEY POINTS

- Eating disorders have a complex and multifactorial aetiology and pathogenesis.
- Most people with eating disorders should be treated in an outpatient setting.
- Day-patient or in-patient treatment may be required, particularly for patients with anorexia nervosa.
- CBT is the recommended treatment for bulimia nervosa.
- Psychological treatment in any modality should be offered to patients with anorexia nervosa and EDNOS.
- Anorexia nervosa has the highest standardized mortality rate of any psychiatric disorder.
- Patients with any eating disorder may present with high physical morbidity.
- All organ systems may be affected, and careful physical monitoring should be carried out in all patients with eating disorders.
- Treatment for an eating disorder should aim for the patient to gain or stabilize weight within the normal BMI range and deal with underlying psychological problems contemporaneously.

REFERENCES

INTRODUCTION

Personality disorders are odd. They are common (affecting around 7–10% of the population\(^1,2\)), have a major influence on society\(^3\) and yet are almost universally neglected in ordinary psychiatric practice. It is also odd that they are the least stable diagnoses in psychiatric practice\(^4\) and yet regarded as conditions that are stable, arising in late adolescence and persisting to late middle or old age. This is also an essential element in their general description: people with personality disorder have an ‘enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual’s culture’\(^5\). This dissonance between the notional lay impression of personality as the bedrock of psychic functioning that make the person’s sense of ‘self’, and empirical data that suggest the diagnosis is unstable, is one of the major puzzles behind the diagnosis, and perhaps helps to explain why its measurement is such a perennial issue for psychiatrists and psychologists within and outside the research area. This is why researchers and clinicians are very much involved in questioning the reliability of personality disorder, and in this context the lay meaning of ‘reliable’ becomes the same as the statistical one of agreement. If people cannot agree on what constitutes personality disorder, then there is little confidence in those who are diagnosed as having the condition. For psychiatrists in training, it is important to start with the existing classification, to explain why it fails and what is likely to be offered as an alternative that is better suited to clinical practice. The course and treatment of these conditions is then discussed in the light of both new and old classifications, and readers can then come to their own conclusions as to which is superior.

CURRENT CLASSIFICATION

There are four elements that underpin the classification of personality disorders: (i) they are primarily disturbances of behaviour, not symptoms; (ii) they are persistent; (iii) they are associated with poor interpersonal relationships; and (iv) they create problems for both society and the individual. It will be apparent immediately that these features are not necessarily confined to personality disorders alone, and there has long been debate over the dividing line between mental state disorders (Axis I in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) classification) and personality disorders (Axis II). The current classification systems of personality disorder in the *International Classification of Diseases*, 10th revision (ICD-10)\(^6\) and the fourth edition of DSM (DSM-IV)\(^5\) both describe personality disorders as forming in childhood and adolescence and continuing through adulthood. A formal diagnosis of personality disorder cannot be made before the age of 18 years.

The clinician making an assessment of personality disorder is advised to make the diagnosis in two stages: (i) the identification of the condition as a personality disorder, and (ii) the categorization of the disorder into one of nine or ten categories – paranoid, schizoid, dissocial, emotionally unstable (borderline and impulsive), histrionic, anxious, dependent and anankastic in ICD-10, and paranoid, schizoid, schizotypal, antisocial, narcissistic, borderline, histrionic, avoidant, dependent and obsessive–compulsive in DSM-IV. In practice, most clinicians tend to plump for the categories first because they are so seductive and then try to justify the general criteria for general personality disorder second. Unfortunately, because the categories are not very good and there is a great deal of overlap between them, the diagnosis of personality disorder not otherwise specified (PD-NOS) is often chosen as the most appropriate diagnosis\(^7,8\). The four characteristics needed for the diagnosis of personality disorder in ICD-10 are evidence that:

- the ‘individual’s characteristic and enduring patterns of inner experience and behaviour deviate markedly from the culturally expected and accepted range in one of more of the following areas – (a) cognition (ways of perceiving and interpreting things, people and events; forming attitudes and images of self and others), (b) affectivity (range, intensity and appropriateness of emotional arousal and responses), (c) control over impulses and gratification of needs, (d) manner of relating to others and of handling interpersonal situations’;
- the deviation is pervasive as ‘behaviour that is inflexible, maladaptive or otherwise dysfunctional across a broad range of personal and social situations’;
the disorder creates personal distress or an ‘adverse effect on the social environment attributable to the deviant behaviour’;

- the deviation is stable and long standing, with ‘onset in late childhood or adolescence’.

In addition, there are two exclusion criteria: the condition cannot be explained as a manifestation or consequence of other mental disorders, and organic disorders should be excluded as these may give rise to personality change (e.g. in dementia) but are not personality disorders.

**PROBLEMS WITH THE EXISTING CLASSIFICATION**

The main problems with the existing classification are that

(i) the specific diagnosis is temporally unreliable;
(ii) there is too much overlap with other personality disorders;
(iii) the characteristics defining the disorder (operational criteria) are not specific to each disorder (one of the reasons for the overlap);
(iv) there appears to be reluctance, probably amounting to stigma, to use the diagnosis; and
(v) the high use of PD-NOS as a diagnosis suggests that what clinicians identify as personality disorder cannot be fitted easily into the present classification.

The unreliability of the diagnosis is clearly shown in service statistics, and this might be thought to be due to sloppy recording or inadequate assessment. However, even when assessors have been trained with interview schedules that are recommended for the assessment of personality disorder, diagnostic agreement is only at a level of around 0.45–0.50 (kappa). The reason for this seems to be that formal personality assessment pretends that it can assess personality status over a period of years, but in practice only present personality status, or personality function, is measured, and this changes from month to month.

The problem with overlap is that although each individual personality disorder appears to have face validity, the descriptions of each disorder are somewhat stereotyped and rarely exist alone. Factor analysis of the criteria for the different DSM personality disorders reveals a completely different structure from that postulated by the DSM system.

In an attempt to reduce this overlap, the personality disorders have been separated into three clusters in many research studies assessing personality disorder. These have now passed into common parlance, but it is worth stressing that the clusters are not actually described in the ICD-10 system of classification. The three clusters are the odd and eccentric group (cluster A), the flamboyant or dramatic group (cluster B) and the anxious and fearful group (cluster C) (Table 43.1).

A fourth group, the obsessional or rigid cluster (cluster D), is also sometimes identified, but formally this is included within cluster C, in spite of good evidence that a four-group model is similar to the classification of normal personality variance in the community.

However, even the cluster system does not remove overlap greatly, for when there is severe personality disorder it is possible to satisfy the criteria for almost all those present in the classification. What is somewhat surprising is that as personality disorder gets more severe in terms of its impact on the individual and on society, the numbers of personality disorders also seem to increase, and this is accommodated in a classification of severity (Table 43.2).

This classification of severity is not an accepted one, but as there is no alternative available it can be regarded as a working option until another is found to be superior.

**DIMENSIONAL VERSUS CATEGORICAL ASSESSMENT OF PERSONALITY DISORDER**

Box 43.1 shows the DSM-IV criteria for antisocial personality disorder.

DSM-IV, Diagnostic and Statistical Manual of Mental Disorders, 4th edn; ICD-10, International Classification of Diseases, 10th revision.
Serious consideration is being given to dimensional systems of classification in all parts of psychiatry, but it is particularly strong with personality disorder. There are many advantages of dimensional systems, not least of which is that when there is no clear distinction between the presence and absence of a disorder, then a dimensional system gives steadily better levels of agreement up to seven groups with no gain in reliability subsequently. But better reliability does not necessarily mean better validity, and there is also some doubt as to whether clinicians would use a dimensional classification. It seems likely that if a dimensional system does enter either the ICD-11 or DSM-V classification in 2012–13, then it will show some similarity to the cluster system described above.

One main advantage of dimensional systems is that they remove the stigmatic label of personality disorder. The reluctance of clinicians to use the diagnosis is not only because it is unreliable; the reluctance to use the diagnosis in only about 10 per cent of the population who qualify for significant personality abnormality suggests that the stigma attached to the diagnosis is the main reason, so that a clinician might baulk at crossing the dividing line between two of the criteria in Box 43.1 and three criteria, which qualifies the person for the diagnosis of antisocial personality disorder.

### Natural History of Personality Disorder

Psychiatrists seldom have the opportunity to study the natural history of the disorders they treat, but this is not so true of personality disorders. Until recently no specific treatments were available, and so long-term follow-up studies of personality disorder were, in effect, a record of the natural course of these conditions. In almost every study in which long-term follow-up has taken place, there has been a steady fall in the number of people having the disorder, with a gradual reduction in the prevalence over time. This can be a dramatic reduction, with more than half failing to reach the criteria for a personality disorder diagnosis after 5 years or more. There is some variation in the course of different disorders. Disorders in the cluster B group tend to manifest earlier in life, with onset in late childhood, almost always diagnosed as conduct disorder, and have earlier resolution, whereas disorders in clusters A and C arise later but persist for longer (Figure 43.1). There are also suggestions that cluster A disorders may become more prominent later in life.

No good explanation exists for this variation. The aetiology of cluster B disorders includes childhood abuse,
physical, mental and sexual, and this is said to be particularly prominent in borderline personality disorder. Despite this claim, the prospective follow-up of populations necessary to test this hypothesis has not revealed a marked preponderance of borderline personality disorder as opposed to other personality disorders. Part of this problem is related to the severity of disorder. As noted above, when personality disorders become very severe, the people concerned satisfy the criteria for a large number of personality disorders, and so it is difficult to know which is primary. There has long been interest in the notion of psychopathy as a core element of antisocial personality. Oddly, it does not appear in the official psychiatric classifications, but it shows great overlap with antisocial personality disorder. Robert Hare invented the Psychopathy Checklist, which itself was derived from the descriptions in a celebrated book by Hervey Cleckley, called *The Mask of Sanity* because Cleckley believed that behind the glib, charming, remorseless front of the true psychopath was a serious mental flaw, or disorder. The revised form of the Psychopathy Checklist (PCL-R) is now in common use in the assessment of both risk and personality disorder.

The most serious form of personality disorder in the UK is dangerous and severe personality disorder (DSPD). Although this originally masqueraded as a diagnosis, it now describes the DSPD programme in England. The programme allows for the detention of individuals in a secure setting if they satisfy all three of the following characteristics:

- They are more likely than not to commit an offence within 5 years that might be expected to lead to serious physical or psychological harm from which the victim would find it difficult or impossible to recover
- They have a significant disorder of personality
- They are more likely than not to commit an offence

The risk presented appears to be functionally linked to the significant personality disorder.

Three hundred people are currently being treated in the programme in two high-security prisons (HMP Whitmoor and Frankland) and two special hospitals (Broadmoor and Rampton) in England. The assessment procedure has been defective in many respects and expensive, and the long-term feasibility of this initiative is far from certain.

**TREATMENT**

The successful treatment of personality disorder is probably the key to it being accepted as a proper diagnosis in psychiatry. As Kendell puts it:

If, therefore, the psychiatrists and politicians who maintain that ‘antisocial personality disorder’ has as good a claim to being accepted as a mental disorder as schizophrenia can demonstrate that it responds to some form of treatment that is not simply a disciplined environment, it is likely that the opposition will melt away, and the same will be true for other types of personality disorder.

It is fair to say that we do not yet have a satisfactory treatment for any form of personality disorder and so have not approached this point. Some of the reasons for this are apparent from our poor understanding of the genesis of normal personality and the reasons why its variation tends to be self-correcting.

**Drug treatments**

Every psychotropic drug has been used to treat personality disorder at some time in practice, and this only serves to reinforce the interpretation that nothing works. It is true that many drug trials have been carried out with some positive results, the results of which are summarized below (Tables 43.3 and 43.4), but the total evidence base is very slim and as most of the studies have been industry funded the positive ones with only small numbers should be viewed with some scepticism, particularly when they have not been replicated. One of the main problems is that most of those with personality disorder are very poor at adhering to drug therapy so even when a treatment may be effective, it is only under conditions of supervised adherence that it is effective. Because of the risks of drug treatment and only marginal advantage there is no strong reason for prescribing drugs except as a crisis measure. Unfortunately in practice a very large number of people with borderline personality disorder take these drugs, and it is likely that much of this polypharmacy is counter-productive.

**Psychological treatments**

In general, psychological treatments have been preferred to all others in the treatment of personality disorder. This
preference is largely supported by the evidence from data and is perhaps a natural consequence of personality disorder being a complex disorder with an allegedly prolonged course with much variation. Psychodynamic, both individual and group, transference-focused psychotherapy, cognitive-behavioural therapy (CBT), schema-focused therapy, social problem-solving therapy and nidotherapy are the most commonly used treatments that have some degree of evidence base, but there are many variations of these treatments that are practised with conviction and enthusi-

asm. Although there are many treatments and, with a recent surge, many more randomized trials, the standard method of summarizing the results, combining data in the form of meta-analysis, is not very satisfactory. Although several meta-analyses have been published, the most influential being that of Leichsenring and Liebing, in the National Institute for Health and Clinical Excellence (NICE) guideline for borderline personality disorder there was too much disparity and study methodology variation to justify using this approach.

In examining the value of each of these treatments, some simplification is needed, as there are many named personality disorders and differences in choice of treatment. Most of the psychological treatments are time-consuming and need a considerable degree of motivation, but unfortunately for the therapeutic enthusiast only a minority of patients, mainly with borderline pathology, are strong treatment-seeking people (type S personalities). Apart from the avoidant anxious group, which still contains many patients who avoid treatment, people with other personality problems (75% of the total) are treatment-rejecting (type R) patients. It is therefore not surprising that most of the psychotherapies are competing with others for a small proportion of the total population with personality disorders (Table 43.5).

**Borderline personality disorder**

**Dynamic psychotherapies**

These therapies have been the mainstay of the management of borderline personality disorder ever since it was first identified as a clear disorder in the 1950s. Unfortunately, the evaluation of this has, until very recently, been confined to naturalistic studies; now that it has been shown that personality disorders have a tendency to improve irrespective of therapy (see above), such studies hardly constitute evidence of efficacy. Thus, the report by Michael Stone of nearly 550 patients followed up for 20 years showed that most had improved significantly, but it was impossible to tell whether this was a consequence of the psychological treatment they had received.

The first influential randomized trial was carried out by Bateman and Fonagy and was described as a combination of psychoanalytical psychotherapy combined with partial hospitalization (i.e. day hospital care). However, the authors have subsequently called this treatment ‘mentalization-based treatment’ (MBT). Mentalization is described as:

... making sense of the actions of oneself and others on the basis of intentional mental states, such as desires, feelings, and beliefs. It involves the recognition that what is in the mind is in the mind and reflects knowledge of one’s own and others’ mental states as mental states.

In short, mentalization involves awareness of complex mental functions in the self and others, and MBT aims to promote its development. The ability to mentalize is impaired in borderline personality disorder; the group and individual therapies focus on this facet but not exclusively, as a great deal of additional therapy goes into day hospital attendance and group therapy. In the original study of 38 patients, improvement in the MBT group was delayed until after 6 months, but its benefits have persisted up to 8 years.

There were many outcomes in the study – hospital admissions and their duration, frequency of suicide attempts and acts of self-harm, drug treatment use, and

CAT, cognitive analytical therapy; CBT, cognitive-behavioural therapy; DBT, dialectical behaviour therapy; MBT, mentalization-based treatment.
changes in clinical symptoms – all of which showed greater improvement in the MBT group compared with treatment as usual. The treatment has now been developed fully in a manualized form and has been adopted in many centres in the UK, particularly in day hospital settings. As yet, however, it has a very slim evidence base, with the results of a single small trial dominating many other, more substantial trials. What is needed is evidence that the effects of treatment can generalize to other centres.

Dialectical behaviour therapy (DBT) is an evidence-based multimodal treatment programme developed specially for women who self-harm but since applied to other populations. Five stages of treatment are outlined: pre-treatment, achieving behavioral control, emotionally processing the past, resolving ordinary problems in living, and capacity to experience sustained joy; most of the research evidence is concerned with the first two of these stages. Much of the treatment is concerned with reducing impulse acts such as substance misuse, binge eating and, particularly, suicidal behaviour. The treatment is a complex one and involves weekly individual therapy and group psychoeducational and skills training, usually for a contracted period of 1 year in the first instance. The central component of the dialectic is the combination of change and acceptance, the former involving behavioral change and the finding of solutions, and the latter encapsulated in the concepts of validation (acknowledgment of behaviour as logical and understandable) and mindfulness, a feature not completely separate from mentalization, in which thinking and feelings are allowed expression and put into a situational context without the need for immediate action.

Behavioral change also follows a complex pathway, with combinations of skills training, contingency management, exposure and cognitive modification. DBT also includes a structured team of therapists who have weekly supervision and consultation, and the option for patients to have telephone consultation, particularly in times of crisis.

**Psychodynamic and psychoanalytical psychotherapies**

These methods are generally less structured than MBT, CBT and cognitive analytical therapy (CAT) and have an emphasis on unconscious conflict that provokes disharmony in the relationships between people that create personality problems. Problems in relationships are classically seen to be repeated within the therapy relationship in the form of transference and counter-transference, which is interpreted by the therapist. In working with people with borderline personality disorder, this has changed in recent years, so that the therapist is now much more than a listener and interpreter. Transference-focused therapy is probably the best form of a structured and manualized form of psychoanalytical therapy that links dysfunctional patterns of current interpersonal relationships to the transference relationships within therapy, with promotion of stronger identity relationships and reflection.

**Therapeutic communities**

A therapeutic community is difficult to define but is primarily a social and group-based intervention that leads to change through its own impetus rather than one imposed from outside. It is permissive in its approach but democratic in principle (although in the USA it has also been used to describe a compulsory programme of care for drug dependence). There are no adequate evaluations of therapeutic communities, but a randomized trial has been mounted.

The proponents of the approach are dedicated to its values, and there is no doubt that some users of the service do very well, but this does not provide a justification in itself for the approach.

**Cognitive-behavioural therapy**

Cognitive-behavioural therapy adapted for borderline personality disorder has been shown to have some value in reducing suicidal behaviour, both in individual therapy over 15–30 sessions and also when combined with educational sessions in improving impulsive behaviour. It is a treatment that requires additional training to that given for CBT in general, and the approach shows promise. It has also been extended to antisocial personality disorder, where it has been shown to be a feasible intervention worthy of development.

Schema-focused therapy is a variant of CBT that also involves an element of reparenting. It is somewhat more intensive than standard CBT for borderline personality disorder. Social problem-solving is a related intervention that has good evidence of efficacy from a randomized trial.

**Cognitive analytical therapy**

This treatment, introduced by Anthony Ryle, is a well-constructed and theoretically sound treatment for borderline personality disorder that overlaps with CBT and psychodynamic approaches but that has some clear distinguishing features that make it quite separate. CAT has been subjected to a randomized evaluation where it performed at least as well as the best available alternative, but a low- or no-treatment comparison group was not tested – and needs to be.

**Nidotherapy**

This treatment (named after the Latin *nidus*, or ‘nest’), based on the systematic adjustment of the environment to fit the person rather than vice versa, is alleged to be particularly valuable in all forms of chronic mental illness that have failed to respond to treatment and for treatment-resistant (type R) personality disorders. It is very different from psychotherapeutic approaches, in that the emphasis is on making environmental, rather than person, changes. A randomized controlled trial in assertive outreach services, where type R personalities predominate, showed that it had a marked reduction in in-patient service provision.
SUMMARY OF THE CLINICAL VALUE AND IMPORTANCE OF PERSONALITY DISORDER IN PRACTICE

Assessment
Personality disorder is currently very badly assessed in clinical practice, and it is not assessed much better in research assessments. The main problem is the gross unreliability of individual personality disorders; the assessment of personality as a general concept is better. The diagnosis should always be considered when a psychiatric problem appears to be much more complex than expected and its outcome unpredictable. However, these should not be regarded as diagnostic features. When making an assessment, it is important to regard the personality disorder, if considered present, as a provisional diagnosis or as a disorder of current personality function\(^1\) that could be challenged if needed in the future.

Importance
Although assessment may be inaccurate, it is much better than not making an assessment at all. If there is any evidence of malfunction of personality, it should immediately give rise to the following questions:

- Is my mental state assessment of other problems presented an accurate one?
- Is the personality problem, even if not admitted or complained about, a major feature in the presentation?
- How should I accommodate the personality features in recommending treatment?

The answers to these questions lead to self-evident changes in the way that treatment is planned: an impulsive person with cluster B pathology should not be given an antidepressant that is dangerous in overdosage; an anxious person with clear dependent cluster C pathology should have clear instructions about the duration and ending of both psychological and drug treatment; and a meticulous person with obsessional personality features should have clear instructions about all treatments prescribed and, where possible, written material to help achieve the best results.

Treatment
Referral for formal treatment for personality disorder should be undertaken only when (i) it is part of a compulsory requirement (a court order) or (ii) it is specifically requested by the patient after a full discussion of the advantages and potential handicaps. In this context, it is worthwhile remembering the subtext of the formal recommendations from NICE for both borderline and antisocial personality disorders, which, although not referring to other groups, could almost certainly apply to them also:

When providing psychological treatment, especially for people with multiple comorbidities or severe impairment (or both), include:

- An explicit and integrated theoretical approach used by both the treatment team and the therapist, and shared with the service user
- Structured care in accordance with this guideline
- Provision for supervision by a therapist.

Although the frequency of psychotherapy sessions should be adapted to the person’s needs and context of living, consider twice weekly sessions. Do not use brief psychological interventions (of less than three months’ duration) specifically for borderline personality disorder or for its individual symptoms outside a service that has the characteristics outlined above.\(^5\)

The message here is that a specific intervention to change personality structure and functioning should not be taken lightly. In most cases, accommodation needs to be made to the personality characteristics rather than an attempt to change it, and in the case of nido-therapy this ‘accommodation’ in a systematic form becomes a treatment in itself. If personality treatment is required, it must be a planned, determined and well-resourced intervention.

KEY POINTS

- Personality may be reasonably stable, but personality disorder is not, as the problems created by an abnormal personality are very dependent on situation and setting. Any cross-sectional assessment of personality should be regarded as one of current personality functioning only.
- The current classification of personality disorders is grossly defective but can be partly rescued by grouping into clusters and using these to measure severity.
- The different clusters of personality disorder are manifest at different ages, with cluster B (antisocial, borderline, histrionic, impulsive, narcissistic) becoming manifest in childhood earlier than other disorders and ending during middle age.
- There is no good evidence that drug treatment is of significant benefit in the management of personality disorder, except as short-term management in a crisis.
- Psychological treatments are preferable to drug treatments but need to be given in a well-supervised structured format to be effective. DBT, MBT, CBT and CAT all show promise for people with borderline personality disorder, but only DBT has a sufficient database to suggest real evidence of value.
- Nido-therapy – the systematic adjustment of the environment to fit the patient – has some evidence of cost-effectiveness and may be more suitable for treatment-resisting (type R) personality disorders.
REFERENCES

INTRODUCTION

The psychiatry of childbearing (synonyms: mother-infant psychiatry, perinatal psychiatry) has advanced greatly in the past 20 years. The world literature on the subject has more than doubled. The nosological framework provided by the International Classification of Diseases, version 10 (ICD-10) and the Diagnostic and Statistical Manual, 4th edition (DSM-IV) no longer covers the wide variety of disorders closely or specifically related to pregnancy, parturition and the puerperium. Most of the research has been conducted in Europe and North America, but the pattern of disease in these places, where maternal mortality has fallen to less than 20 in 10^5 births, with a corresponding fall in morbidity, may not match that seen in countries whose maternal mortality is 100 times that figure. It is in the latter countries that most of the infants are born, and their morbidity may be similar to that seen in Europe in the nineteenth century.

PSEUDOCYESIS

When a woman incorrectly believes herself to be pregnant and develops symptoms and signs of pregnancy, this is called pseudocyesis.¹ The differential diagnosis includes delusions of pregnancy occurring in women (also men) with a variety of psychoses, but without the somatic changes of pregnancy. There is also pregnancy simulated for social, mercenary or legal purposes. Occasionally organic disease (such as tumours) can mimic pregnancy.

The clinical features include:

- a firm belief in the pregnancy, which may last until the onset of a false labour at 9 months;
- amenorrhoea;
- morning sickness and/or pica;
- enlargement of the breasts and nipples, and even a discharge of colostrum;
- abdominal enlargement, caused by muscular contraction, tympanites, fat, retained faeces or pathological lesions;
- an illusion of fetal movements;
- enlargement of the uterus to the size of a 6-week pregnancy.

Modern diagnostic tests have greatly reduced the frequency of pseudocyesis. Where radiology or ultrasound is unavailable, an examination under anaesthetic is recommended, in the presence of a family member in order to avoid accusation of abortion.

The psychological basis is usually an intense desire for children. In some cases, however, a guilty fear of pregnancy has been the background; this has occasionally led to dangerous attempts at abortion by non-pregnant women. Pseudocyesis is a demonstration of the influence of psyche over soma, mediated by hormonal secretion. It occurs in at least a dozen other mammals. Persistence of the corpus luteum would explain breast changes, moderate uterine enlargement and secretory endometrium, but it is not the only basis: hormonal measurements have been made in at least 30 patients, some of whom had chronic anovulatory states, hyperprolactinaemia or androgen excess.

These women require psychotherapy. Simply revealing the diagnosis is unsatisfactory because the patient may misinterpret the advice, consult another doctor or develop a recurrence. The underlying conflicts must be explored, helping the patient to accept that she is not pregnant.

THE PSYCHIATRY OF PREGNANCY

Pregnancy adjustment

The psychopathology of pregnancy needs to be understood in terms of the adjustment all women must make when they conceive. Pregnancy is not only a biological event but also an adaptive process. A pregnant woman must carry the baby safely and prepare for the birth. She must ensure the acceptance of the child by the family, and develop a somewhat different relationship with the child’s father and her inner circle of relatives and friends.

She must adjust to the sacrifices that motherhood demands; these include the loss of figure and facial bloom, weight gain and stretch marks. Some women take pride and
pleasure in these changes, but others are embarrassed by them; dysmorphephobia, with ideas of reference and social avoidance, can ensue. A pregnant woman ‘bonds’ or ‘affiliates’ to the unborn child in a way analogous to the formation of the mother–infant relationship after birth. The mother begins to have pleasure in these changes, but others are embarrassed by them; dysmorphephobia, with ideas of reference and social avoidance, can ensue. A pregnant woman ‘bonds’ or ‘affiliates’ to the unborn child in a way analogous to the formation of the mother–infant relationship after birth. The mother begins to have fantasies about the baby and talks affectionately to it. She may engage the husband and other children in ‘playing’ with the baby. At the same time, she prepares for the birth and motherhood (‘nesting behaviour’). In some mothers, however, there is minimal attachment even at term, and some who deeply resent their pregnancy try to harm the fetus by pounding and bruising their abdomen (fetal abuse). A poor mother–fetus relationship is one of the predictors of impaired mother–infant bonding 9,10 and, in clinical experience, fetal abuse predicts later child abuse.

Prepartum anxiety

For many mothers, pregnancy is a time of much anxiety. The first trimester may involve an anguished decision over whether to continue or terminate the pregnancy. Later, women who have experienced infertility, multiple miscarriages or fetal loss may be preoccupied by fears that they will lose this baby. In the third trimester, anxiety is focused on fetal abnormality and coping with motherhood. In addition, fear of parturition (tocophobia) may be a reason for elective Caesarean section. Prepartum anxiety is an independent predictor of postpartum depression.12

These anxieties will usually be managed by ventilation and support, but anxiolytic medication can be used cautiously. Benzodiazepines carry the risk of fetal intoxication (‘floppy infant syndrome’).13 Beta-adrenergic blocking agents risk neonatal hypoglycaemia.14

Denial of pregnancy

In women who do not realize they are pregnant, one must distinguish between three different phenomena:

- Unnoticed pregnancy in women who are obese or near the menopause
- Deliberate concealment
- Dissociative denial.

A German survey of 29 000 births found an incidence of 1 in 475 women who failed to recognize pregnancy until the twentieth week; 12 of 62 cases were not diagnosed until labour began.6 Welsh and American studies have obtained similar figures.7,8

The late discovery of an unwelcome pregnancy carries a small risk of suicide. The mother is also at risk of all those complications of delivery that, with modern antenatal care, have become rare. For the child, there are increased hazards, including prematurity and neonaticide.

Prenatal attachment

A pregnant woman ‘bonds’ or ‘affiliates’ to the unborn child in a way analogous to the formation of the mother–infant relationship after birth. The mother begins to have fantasies about the baby and talks affectionately to it. She may engage the husband and other children in ‘playing’ with the baby. At the same time, she prepares for the birth and motherhood (‘nesting behaviour’). In some mothers, however, there is minimal attachment even at term, and some who deeply resent their pregnancy try to harm the fetus by pounding and bruising their abdomen (fetal abuse). A poor mother–fetus relationship is one of the predictors of impaired mother–infant bonding 9,10 and, in clinical experience, fetal abuse predicts later child abuse.

Prepartum anxiety

For many mothers, pregnancy is a time of much anxiety. The first trimester may involve an anguished decision over whether to continue or terminate the pregnancy. Later, women who have experienced infertility, multiple miscarriages or fetal loss may be preoccupied by fears that they will lose this baby. In the third trimester, anxiety is focused on fetal abnormality and coping with motherhood. In addition, fear of parturition (tocophobia) may be a reason for elective Caesarean section. Prepartum anxiety is an independent predictor of postpartum depression.12

These anxieties will usually be managed by ventilation and support, but anxiolytic medication can be used cautiously. Benzodiazepines carry the risk of fetal intoxication (‘floppy infant syndrome’).13 Beta-adrenergic blocking agents risk neonatal hypoglycaemia.14

Depression

Prepartum depression is no less common than postpartum depression.15 It can be recurrent, and case studies show an association with puerperal mania.1 Some postpartum depression is a continuation of depression starting in pregnancy.

There are claims that prepartum anxiety and depression influence fetal outcome and child development, but there is a lack of consistency in the findings.16,17

The frequency of suicide is a vexed question. There are problems about the data since suicide and pregnancy are often concealed. Unwanted pregnancy is a factor in attempted and completed suicide. An increasing tolerance of single motherhood led to a decline of pregnancy-related suicide in Europe in the twentieth century, but this may not be true in countries that still stigmatize illegitimate pregnancy. Self-poisoning, usually in the first trimester, often results in fetal death19 but not fetal abnormality.19 Suicide is now (following the great reduction in fatalities from obstetric causes) the third most frequent cause of maternal death in the UK, after thromboembolism and heart disease,20 but the prepartum suicide rate is below that in the general population.21

Prepartum depression is sometimes left untreated because of fears about the effect of drugs on the fetus. There is evidence of a slightly increased risk of congenital cardiac lesions in infants exposed to paroxetine in the first trimester. Tricyclic antidepressants increase the risk of preterm birth, respiratory distress, neonatal convulsions
and other complications,\textsuperscript{23,24} toxic and withdrawal effects are seen occasionally, especially after clomipramine treatment. Selective serotonin reuptake inhibitors (SSRIs) have toxic effects on the newborn, including agitation, altered muscle tone, problems with breathing and sucking, neonatal pulmonary hypertension\textsuperscript{14} and other complications;\textsuperscript{23} there are slight effects on birth weight and gestational age.\textsuperscript{25} Withdrawal symptoms are often seen.\textsuperscript{26} These risks must be balanced against those of depression, but particular caution should be exercised in prescribing these drugs during the last trimester. Electroconvulsive therapy (ECT) has been given safely to pregnant women many times. Complications are rare, but occasional patients have developed premature uterine contractions, which can be treated with a tocolytic drug such as ritodrine. The mother must be well oxygenated during anaesthesia and should be screened for rare syndromes of pseudocholinesterase deficiency.

### Substance abuse

#### Ethanol

Heavy ethanol abuse has severe effects on the fetus. The main effect is retardation of intrauterine growth: although ethanol shortens gestation, the low birth weight is not explained by prematurity; rather, the infant is small for gestational age. The infant becomes addicted and may suffer neonatal withdrawal symptoms. Ethanol is also teratogenic, causing fetal alcohol syndrome (or ‘spectrum disorder’), which includes growth retardation, microcephaly and facial anomalies due to maxillary hypoplasia (short palpebral fissures, thin vermilion border and short philtrum).\textsuperscript{27} There is long-term cognitive and language impairment\textsuperscript{28} and an association with behavioural disorders such as attention deficit hyperactivity disorder (ADHD).\textsuperscript{29}

#### Narcotics

Narcotic addicts, like alcoholics, have multiple emotional and social problems. Many do not seek antenatal care. The infants may be affected by maternal malnutrition and infections such as venereal disease, hepatitis and acquired immunodeficiency syndrome (AIDS). Narcotics are not teratogenic, but a high proportion of the infants are of low birth weight, explained partly by prematurity and partly by intrauterine growth retardation. A withdrawal syndrome develops in most babies. Hair and meconium analysis improves the diagnosis of opiate (and also cocaine) abuse in mothers who present unexpectedly in labour. The perinatal mortality rate and frequency of sudden infant death are increased. There is an increased incidence of microcephaly, and there may be impaired mental development, although other factors in the maternal lifestyle may account for this. Methadone maintenance improves the birth weight, but it may depress respiration in the newborn and lead to a more severe and prolonged withdrawal syndrome, with a greater frequency of seizures. Buprenorphine may be a more suitable maintenance therapy, with milder withdrawal effects, but low birth weight and abstinence syndromes still occur.\textsuperscript{30}

If it is decided to withdraw heroin, this should be done in the second trimester, replacing it by methadone. Naloxone, which can be given by implant, has been used, although there are concerns about fetal abstinence syndromes. Newborn infants should be kept in hospital for at least 14 days. Respiratory depression can be treated by naloxone, and seizures and withdrawal symptoms by sedatives such as diazepam or by morphine itself. All these mothers should receive close psychiatric supervision and social casework.

### Cocaine and amphetamines

Some of cocaine’s effects are similar to those of narcotics – premature delivery, intrauterine growth reduction and an increased incidence of microcephaly. There is an association with rupture of membranes before 34 weeks. The withdrawal syndrome is less severe than with narcotics. The specific effects are cardiovascular: it causes uterine vasoconstriction, leading to placental abruption, and fetal cerebral infarcts. There is little evidence of toxic effects in the newborn,\textsuperscript{31} but 1-month-old infants show subtle neurobehavioural anomalies such as reduced arousal and increased excitability.\textsuperscript{32} Long-term effects on language development and behaviour are disputed and may be due to confounding factors such as low birth weight, maternal depression, poor parenting, abuse of other drugs, maternal education and poverty.\textsuperscript{33} An increased risk of sudden infant death is also sub judice.

The effects of amphetamine abuse in pregnancy are similar to those of cocaine, including placental abruption and fetal brain infarcts. Papers have only recently begun to appear on pregnancy abuse of 3,4-methylenedioxymethylamphetamine (‘ecstasy’).

### Other abused substances

Cannabis is the illicit drug most frequently abused by pregnant women: it may affect fetal growth and have long-term neurobehavioural and cognitive deficits, but it is difficult to exclude the effect of confounding factors. Lysergic acid diethylamide (LSD) may have teratogenic or mutagenic effects, but this is based on case reports in offspring from deviant subcultures, whose parents also abuse ‘street drugs’. Phencyclidine (‘angel dust’) addiction leads to neonatal withdrawal symptoms.

### Eating disorders

Most anorexic women recover and start to menstruate again when their weight reaches about 80 per cent of the standard weight. Their desire for motherhood is shown by the frequency of infertility treatment and planned pregnancy. Ovulation can be induced by clomiphene or gonadotropins in women who fail to menstruate. There are numerous case reports and several long-term studies
showing that many women with a history of anorexia nervosa give birth to children in the normal way. Several studies have found that anorexia and bulimia are associated with low birth weight\textsuperscript{34--37} but this is disputed.\textsuperscript{14,19} The only consistent finding is an increase in miscarriages, in common with women underweight for other reasons.\textsuperscript{40}

A minority of anorexic women become pregnant while in the throes of the disease. The diagnosis may be delayed by their amenorrhoea. If the mother continues to restrict her diet, the fetus may suffer from malnutrition, and occasionally it has been necessary to rescue the infant by elective Caesarean section.

Eating disorders tend to improve during pregnancy, but they often relapse in the puerperium,\textsuperscript{41} sometimes to a degree worse than before conception.\textsuperscript{52} When the mother is actively anorexic, there is often conflict at mealtimes; occasionally, children suffer from their mother’s asceticism, with stunted growth.\textsuperscript{43} Bulimic mothers may also show deviant mothering – ignoring or excluding their children while overeating or vomiting, restricting food supplies, or exerting too much control during play and mealtimes;\textsuperscript{42} video-feedback can be used to treat these disturbances.\textsuperscript{54}

### Obstetric factitious disorder

Self-induced illness behaviour can extend into the obstetric domain. Women may induce bleeding to simulate threatened miscarriage, placenta praevia or postpartum haemorrhage. They may stimulate rupture of the membranes or manipulate instruments such as an external tachodynamometer. In some cases this seems to be motivated by a desire for early delivery.

### Psychosis

Pregnancy has no effect on chronic delusional states but may have a beneficial effect on menstrual, bipolar\textsuperscript{45} and cycloid (acute polymorphic) psychoses. Nonetheless, acute manic and cycloid episodes occur during pregnancy, and some seem remarkably similar to puerperal psychosis. They would be regarded as sporadic or random, except that they have been observed in women with a history of puerperal psychosis (at least 13 in the literature). There is an association with multiparity, with the postpartum episode occurring first.

Many pregnant women with chronic psychoses require neuroleptic treatment. Butyrophenones are not teratogenic, but low-dose phenothiazines, used to treat hyperemesis in early pregnancy, are associated with a slightly increased risk of congenital abnormalities.\textsuperscript{46} The main (but infrequent) hazard found with phenothiazines, butyrophenones and risperidone is sedation and extrapyramidal symptoms in the newborn. The newer neuroleptics have been in use for only 10–15 years. Clozapine seems safe, although there have been some cases of gestational diabetes, and there is a theoretical risk of fetal agranulocytosis. One study reported low birth rate and more neonatal admissions after olanzapine exposure.\textsuperscript{47}

Lithium is relatively dangerous; at least 12 cases of the rare Ebstein’s anomaly have been reported. After cardiac development has been completed, lithium is probably safe until delivery. Stopping lithium during pregnancy has a relapse rate similar to withdrawing treatment in non-pregnant women.\textsuperscript{48} As delivery approaches, reduced renal clearance can result in toxicity with normal doses; eight cases of alarming blood levels (up to 5 mmol/L) have been reported, with coma and convulsions in the mother; even at normal blood levels, babies exposed to lithium have suffered lethargy, hypotonicity, nephrogenic diabetes insipidus and other effects. It is therefore advisable to withhold lithium for 1–2 days before delivery.\textsuperscript{49}

Anti-epileptic drugs are often used in the prophylaxis of bipolar disorders. Carbamazepine has been associated with increased rates of congenital abnormality, including orofacial clefts. Sodium valproate is the most teratogenic of the anti-epileptic drugs after primidone. It was first noticed to cause spina bifida, with a frequency of 1–2 per cent; this is a dose-dependent effect, the threshold being more than 1100 mg/day. Folic acid is prophylactic, and the advice to women on this treatment (after excluding undiagnosed vitamin B12 deficiency) is to take 5 mg folic acid/day.\textsuperscript{50} Valproate is now known to have wider effects. A fetal valproate syndrome has been described, with major malformations (especially congenital heart disease and limb defects), developmental delay and dysmorphic features, including a long upper lip with flat philtrum, and small nose, ears and jaw.\textsuperscript{51} Some studies have found low intelligence quotient (IQ)\textsuperscript{52} and early infantile autism,\textsuperscript{53} but it is too early to be sure that environmental confounding factors are not at least partly responsible.\textsuperscript{54} After the birth, infants may show withdrawal symptoms such as jitteriness and seizures. Lamotrigine clearance is 300 per cent greater in pregnancy, so blood levels are lower than expected; this is corrected rapidly after delivery. Given in normal doses in the first trimester, lamotrigine does not cause major congenital abnormalities.\textsuperscript{55}

### Obstetric liaison services

In view of the complexity of the psychological response to pregnancy, and the frequency of anxiety, depression and other psychiatric disorders, there should be a close liaison between obstetric and psychiatric services. In addition to the need to diagnose and treat prepartum psychiatric disorders, the high level of supervision in the antenatal clinics offers an opportunity for preventive psychiatry, by screening for vulnerabilities such as unwanted pregnancies, severe social problems and a history of psychosis, addictions and depression.
THE PSYCHOPATHOLOGY OF PARTURITION

Childbirth is among the severest of human ordeals, and, in spite of its brevity, carries a risk of various forms of psychopathology. In countries with advanced obstetric care, these complications are rare, but may still be common where delivery is unsupervised or pregnancy is denied. Acts of desperation, such as auto-Caesarean section, suicide and rage attacks endangering the fetus, are fully described. Delirium is well documented; in most cases, it lasts a few hours, starting shortly before delivery and disappearing after the birth, with amnesia for the event; it can also continue into the puerperium or start immediately after the birth. Unexplained stupor and coma have also been described during and immediately after delivery.

Neonaticide

The term ‘infanticide’ covers the killing of infants and children by their parents in a wide variety of circumstances, broadly divided into neonaticide (killing the newborn) and filicide (the later murder of a child). Neonates (especially females) have been suppressed at various times in history, and in various societies, as an official policy or grassroots custom to control population (‘customary neonaticide’). This is quite different from criminal neonaticide, in which a mother, who has concealed her pregnancy and given birth in secret, murders the newborn. A major public health problem in Europe during the nineteenth century, its frequency has dwindled as a result of contraception, legal termination and changed attitudes to single motherhood, but it does still occur. Neonaticide may be more common in countries that forbid abortion and stigmatize pregnancy, but data are lacking. The mental state of the mother can be deduced from the methods used: suffocation is the most common and testifies to the mother’s panic when faced with a crying baby. In a minority of cases, brutal head injuries, stabbing and decapitation testify to rage and hatred. There has been much debate over whether the defence of insanity can be invoked. Most of these babies die when the mother is in the grip of an emotional crisis. This is not generally acceptable in law as insanity. Delirium, however, which is rare in hospital practice, may be more common in clandestine deliveries and is hard to exclude. If the defence is burdened with the proof of insanity, then there can be no valid evidence in unwitnessed deliveries; but there is the possibility of a miscarriage of justice – that a mother who killed her baby when her consciousness was clouded is wrongly condemned.

INFANT LOSS

The child may be lost for a variety of reasons:

- Termination of pregnancy at the behest of the mother
- Miscarriage, ectopic pregnancy or late termination of a wanted child for medical reasons
- Fetal death in utero, stillbirth, neonatal death or sudden infant death
- Relinquishment to adoption.

Termination of pregnancy

The indications for abortion include the following:

- **Medical**: to preserve the health and life of the mother.
- **Humanitarian**: when pregnancy has resulted from rape or incest.
- **Eugenic**: where there is a risk of congenital abnormality.
- **Psychiatric**: where there is a perceived risk of suicide or severe mental illness.
- **Social**: because pregnancy is untimely and disruptive.
- **On demand**: where there is belief that women should be free to decide when to have children.

There has been a debate on the validity of the psychiatric indications; this turns on the psychiatric consequences of a refusal to terminate. Suicide threats are common but are rarely carried out. A history of puerperal psychosis is not an indication because it is equally likely to follow abortion. There are other, arguably more serious puerperal complications, such as mother–infant relationship disorders, which are more common and severe after unwanted pregnancy. These can be avoided by adoption, but the psychological effects of relinquishment are not negligible.

In the run-up to termination, shame, anxiety and emotional turmoil are common, but the abortion itself is often followed by relief. Most women who have made a personal choice suffer no adverse effects, either in the short or the long term. A minority experience regret and self-reproach over the ‘murder’ of the baby. Some feel like criminals and worry about punishment, a nemesis of sterility or congenital malformations. A few develop clinical depression, and a Finnish study showed that the suicide rate was raised.

Many of these women have to make this decision in isolation. They do not inform their parents, or they face censure and unwelcome pressure. The attitude of the child’s father is crucial but often unhelpful. It is essential that a woman makes her own decision – one of the most difficult she will ever take. It often has to be taken hastily, in an atmosphere of conflict and turmoil. The best outcomes are found when the woman makes a prudent decision in a context of respect and support from the child’s father, parents, friends and counsellor.

Various organic psychoses occur after abortion, including infective delirium after criminal abortion and Wernicke-Korsakoff syndrome after hyperemesis. Shame-related psychogenic psychosis has been reported. In addition, manic and acute polymorphic episodes are seen, especially in women who have suffered similar episodes after childbirth; several have requested termination in order to prevent a recurrence of puerperal psychosis.
Miscarriage

Spontaneous abortion and ectopic pregnancy have the same psychological effects. Their emotional consequences are far from trivial and can be compared to perinatal death – less severe, but still the loss of a greatly desired child. The event itself may be disturbing, and some of the psychological symptoms resemble post-traumatic stress disorder. The incidence of depression in these women is four times the rate found in the general population, and it is even higher in childless women. There may be depressive episodes at the time of the expected delivery, anniversary reactions, and increased anxiety during and after the next pregnancy.58 Another sequel is obsessional neurosis.59 Helping the woman who has suffered a miscarriage is a variant of grief therapy, in which her distress is shared and her sadness, guilt and anger ventilated.

Late termination for medical reasons, although a deliberate intervention, is psychologically similar to miscarriage and to fetal death in utero. Some women wish to continue the pregnancy in the full knowledge that the baby will be abnormal. Depression is common and grief long-lasting. All these women require counselling before and after the termination.

Fetal death in utero, stillbirth, neonatal death and sudden infant death

Reactions to these events are generally more severe than to miscarriage, and each has its special characteristics. When the baby dies in late pregnancy, the mother carries a corpse within her and must undergo a futile labour. If the baby dies during labour, the loss is sudden and the shock pronounced, with a strong sense of unreality. When the child dies in the first week, the parents have to endure great anxiety, with dwindling hope; they may be involved in the decision to switch off the respirator and witness the child dying. The later death of an infant, when the maternal emotional response is fully developed, especially sudden infant death, is at the very top of the catalogue of calamities; there is no warning or preparation, the cause of death is perplexing, and there is a forensic investigation.

The grief of these parents is similar to other grieving but has its own special character: there may be grief hallucinations related to the infant – of fetal movements, the baby’s face, or the infant crying or playing in the cot. There are the crises of disposing of the baby’s belongings and of meeting friends and relatives, some of whom, floundering in embarrassment, are unable to comfort or sympathize (‘wall of silence’). Especially after sudden infant death, there may be stigma, ostracism or malicious speculation. Envy of successful mothers is a problem; there may even be a temptation to steal another baby. Surviving children may be confused by their parents’ grief and upset by family turmoil; they are also grieving and searching for the meaning of death.

When helping the parents, the principles are as follows:

- **Honesty and openness**: the admission of errors is delicate, but the parents’ guilt should not be increased by the obstetric team’s refusal to accept responsibility. Recrimination, litigation and complaining reactions are common. Staff should accept this as normal and try not to be defensive. One or more interviews with the consultant obstetrician are indicated.

- **Continued support**: after a stillbirth, most women prefer to be segregated from other patients and discharged from hospital as soon as possible. The woman must be visited by a member of the primary care team. A lactating woman may need bromocriptine or to donate milk to a milk bank. Hypnotics may help the woman troubled by insomnia. The woman’s general practitioner (GP) should be alert for secondary psychiatric disorder.

- **Parents want to know why the baby died**: they should be warned that often no explanation is found. Necropsies in sudden infant death syndrome (SIDS) are specialized; the pathologist can play a vital psychological role and should be available for discussion.

- **Mementoes, including a photograph, should be kept**: the dignity of naming the baby and a burial ceremony is helpful. The value of seeing and holding the dead baby has been challenged: a controlled trial showed that these women had more anxiety, depression and post-traumatic stress disorder than women who had minimal contact with the stillborn infant.60 However, what is wrong for some parents may be right for others.

- **The bereaved mother needs to share her distress**: a sensitive and sympathetic listener can help the woman to grieve and accept her loss. This may be her husband or partner (who is also grieving), a family member or a friend. If not, professionals, especially chaplains and nurses, should step in. Self-help groups and voluntary agencies are invaluable for some bereaved mothers.

- **The next pregnancy**: no dogmatic advice can be given about the timing of the next pregnancy. Bereaved parents will be very anxious during pregnancy and in the puerperium and generally more anxious about their other children.

- **The grieving sibling**: the routine and rhythm of family life should be disturbed as little as possible. The parents should not be afraid to acknowledge their sadness. They should give a factual account of what happened, avoiding euphemisms. They should reassure their other children that they are not responsible and will not lose their parents’ love; they should understand that neither they nor their parents are in imminent danger of death. The child can be helped to grieve by looking at pictures of the dead sibling, attending the funeral and visiting the graveyard.
Relinquishment

Adoption used to be the main way to handle accidental pregnancy and satisfy the longing to rear children. In the past 30 years, the number of children born to single mothers has climbed steeply, but European and North American society has developed a new tolerance, and the number of adoptions has fallen. International adoption has developed in response.

Although adoption is on the wane, attention has been focused on the psychological effects of relinquishment. For some adolescent mothers, giving up the child is a painful, loving and selfless action. In others, it is the enforced loss of a wanted child, with a charade of informed consent. As with termination, there is often loneliness and ostracism instead of understanding and support. Time is no healer; the child exists and can be seen again, and there is often a fantasy of restitution. After a decade, there is a new component: the adolescent child may seek its biological mother – an event the mother cannot influence. There are organizations to help relinquishing parents to find their offspring, and it has been necessary to legislate for reunions. In order to avoid adverse effects, a relinquishing mother needs counselling during the pregnancy and for at least 6 months after delivery. She may wish to see the newborn infant, and photographs should be filed. Information on the child’s progress should be available, and some birth-mothers wish to reciprocate. ‘Open adoption’, where both sets of parents remain in contact, is under consideration. The aim is that a relinquishing mother emerges from the experience with self-respect and dignity.

The coercive removal of a child from abusive parents is a different situation. Where maternal mental illness is the reason, relinquishment is among the most unfortunate events that mothers can experience; it may also be traumatic for the child.

THE PSYCHIATRY OF THE POSTPARTUM PERIOD

The normal puerperium

For many mothers, giving birth is a supreme moment. Feelings of elation, peace and fulfilment help to sustain the mother during the weeks of strain that follow; but prolonged euphoric reactions, lasting a week or more, raise the possibility of puerperal hypomania and often switch to depression.62

Newly delivered mothers have to face a number of challenges, including the following:

- **Exhaustion and perineal trauma.**
- **Breastfeeding:** although this has many advantages, it is often difficult to establish. Breast abscesses (and uterine sepsis) can cause delirium.
- **Insomnia:** Sleep deprivation and disruption, especially during the first month, are common.
- **Recovery of normal figure and attractiveness:** bodily changes, especially weight gain, disturb some women, occasionally to the point of dysmorphophobia.2
- **Loss of libido:** episiotomy and vaginal trauma often cause dyspareunia, and fatigue may depress sexual activity. Sexual relations are usually resumed within 1–3 months, although reduced in frequency and with a delayed return of orgasm.
- **Loss of employment and leisure, and relative social privation.**

Against this background of rapid biological, social and emotional transition, a variety of psychiatric disorders occur. The psychiatric complications of childbirth are more numerous and complex than those of any other life event.

The maternity ‘blues’

Often, between the third and fifth days postpartum, mothers experience a sudden, fleeting and unexpected period of sensitivity and uncharacteristic weeping. In the majority of women, this passes within a few hours or a day or two.

Reactions to severe labour

Post-traumatic stress

After an excessively painful labour, a labour with a disturbing loss of control,63,64 fear of infant loss65 or complications requiring emergency Caesarean section,66 some mothers suffer nightmares and intrusive images and memories (‘flashbacks’), similar to those occurring after other harrowing experiences. These flashbacks can last for months.67 Some women avoid further pregnancy (secondary tocophobia), while those who become pregnant again may experience a return of symptoms, especially in the last trimester. Rates of up to 5.9 per cent of deliveries have been reported.64 There is some evidence that early counselling reduces these symptoms.68 Enduring symptoms require specific psychological treatment.

Querulant reactions

Another reaction to a severe labour experience is pathological complaining. These women complain bitterly about perceived mismanagement, and angry rumination and vengeful fantasies may continue for weeks or months, interfering with infant care. This disorder can be treated by a psychotherapeutic approach that distracts the mother from her grievances and reinforces productive child-centred activity.

Postpartum anxiety disorders

The frequency of postpartum anxiety disorders is comparable to that of postpartum depression.69 A review of eight
studies of panic disorder showed that 44 per cent of anxious women had an exacerbation and 10 per cent a new onset in the puerperium.\textsuperscript{70}

Benzodiazepines should be used with caution in lactating mothers. The drugs are well absorbed from the gut and are metabolized more slowly in the neonatal liver; the neonatal blood–brain barrier is not fully developed. Sedation, poor suckling and weight loss have been described with diazepam; oxazepam is preferred.\textsuperscript{71}

It is important to identify the focus as well as the form of anxiety, because there are several themes that require specific psychological therapies.

**Infant-centred anxiety**

Some mothers, especially primiparae in isolated nuclear families, are overwhelmed by the responsibility of caring for the newborn. In severe cases, this can result in panic, agitation and phobic avoidance of the infant; without intervention, these mothers risk losing their mothering role. This anxiety can often be handled by the wider family, without invoking professional help: contact with the baby should be encouraged, but always with the support of a competent adult. In severe cases, treatment is by systematic desensitization. While the infant is cared for by family or staff, the mother gradually takes over, at her own pace, undertaking the easiest tasks first, and involved in all decisions. With correct diagnosis and management, the prognosis is excellent.

**Anxieties about infant health and survival**

In women prone to anxiety and excessive worrying, and in those who have suffered years of infertility, recurrent miscarriage or infant loss, motherhood can lead to excessive solicitude about banal tasks such as bathing, and sensitivity to the slightest indication of childhood illness. In some women, the anxiety is focused on the possibility of sudden infant death.\textsuperscript{71} These mothers lie awake listening to the baby’s breathing, sleep with their hand on the infant’s chest, check the infant many times each night, or even wake the baby to ensure that it is still alive. This results in excruciating tension, insomnia and exhaustion. Clinical experience suggests that day-hospital attendance, with anxiety management therapy and group support, is helpful, as are devices to monitor the infant’s breathing. The vicious cycle of insomnia and hypervigilance can be interrupted by involving relatives and friends so that the mother can sleep under sedation. The support of other mothers who have recovered from similar problems is helpful.

**Puerperal obsessional disorders**

The puerperium is one of the main precipitants of obsessive–compulsive disorders.\textsuperscript{71–75} In addition to rituals, there is a specific puerperal symptom – obsessions of infanticide. These mothers are gentle and devoted, but they experience extravagant thoughts, images or impulses of destroying their babies by fantastic methods, such as decapitation or throwing them in the fire. They are afraid to be left alone with their infants and may take extraordinary precautions.\textsuperscript{76} It is important to distinguish these impulses from the pathological anger felt by irritable mothers with impaired bonding, which is a harbinger of child abuse. Ventilation, explanation and psychotropic medication are part of the treatment but are rarely sufficient. It is important to discourage avoidance of the child and to encourage cuddling and play, thus strengthening positive maternal feelings. Cognitive-behavioural treatment can help to achieve mastery over irrational impulses.

**Depression**

Over 1800 works have been published on postpartum depression, including more than 1600 in the past 12 years. But ‘postpartum depression’ is a term with two levels of meaning. For laypeople it covers all mental illness appearing after childbirth. As a household term, ‘postnatal depression’ has been valuable in drawing attention to the plight of mothers in poor mental health, providing a valid explanation for role failure, diminishing stigma, enabling mothers to accept that they are ill and to come forward for treatment, and persuading authorities to fund the necessary services. Some practitioners also use the term in this sense: much research is based on self-rating scores from which a diagnosis of ‘postnatal depression’ is made, without the confirmation of an interview.

In the strict sense, the postpartum illness must meet widely accepted criteria for depression. Focusing on confirmed diagnoses, the following facts have emerged:

- There is no clinical picture characteristic of postpartum depression.\textsuperscript{77}
- Taking an overview of many studies, the incidence of depression is not raised in the puerperium.\textsuperscript{78,79} Depression is common in women during the reproductive years, whether they are infertile, pregnant, puerperal, menopausal or involved in childrearing.
- The suicide rate is below the female rate in the general population.\textsuperscript{80}
- Postpartum depression is not a homogeneous disorder. It includes the depressive pole of a bipolar illness as well as stress-induced depression and chronic dysthymia.
- Patients presenting with ‘postpartum depression’ often have co-morbid disorders, which also require diagnosis and their own specific treatment. Many mothers with anxiety, obsessional, post-traumatic or substance abuse disorders,\textsuperscript{81,82} or with a disturbed infant relationship, are depressed.

Studies of the aetiology have found the same causal associations as for depression occurring in other circumstances: heredity, a history of previous attacks of depression, adverse events or social conditions, difficult relationships especially marital dysharmony, and social
isolation. If depression were associated strongly with childbirth, then one would expect to find specific pregnancy-related factors, and there is some evidence for these:

- Depression during pregnancy is a predictor of postpartum depression.
- There is some evidence of genetic factors: an Australian twin study found genetic factors distinct from lifetime major depression. Other studies have found a familial tendency, but only if onset is within the first 6–8 weeks after delivery.
- Two studies have implicated sex steroid hormones: in one, hypogonadism was induced in euthymic volunteers; oestrogen and progesterone were added back and then abruptly withdrawn: women with a history of postpartum depression became depressed. An extension of this experiment, using corticotrophin releasing factor, showed that the pituitary–adrenal axis of women with a history of postpartum depression was more sensitive to gonadal steroids.
- Unwanted pregnancy predicts both antepartum and postpartum depression.
- In some cultures, having a female child and in others polygamy increases the risk.

Whatever the epidemiological evidence, the effects of depression on family life and the emotional climate in which children are reared is of great concern. A growing child needs emotional support, attention, approbation and stimulation. The mother is the child's primary environment, and the mother's state of mind dominates the child's world. Even very young infants are disturbed by deviant maternal behaviour. Although deficits are not universal, the mother's depression can lead to anergia, brooding, reduced quantity, quality and variety of interaction, and loss of reinforcement of the mother's gaiety and tenderness. The mother's anger may be misdirected at her children. Frequent irritability, impatience and criticism induce social withdrawal, anxiety and resentment. Moreover, depression may affect persistence in breastfeeding, the requirement for acute paediatric care and, especially in developing countries, nutritional status.

There have been attempts to study the long-term effects of maternal depression on the child's cognitive development. The results are inconsistent: at one extreme the timing and duration of depression had no effect, and at the other extreme deficits in language or full-scale IQ were detectable at 5 and 11 years. These investigations are bedevilled by many confounding factors, including social class, parental IQ, chronicity and severity of depression, life events, parental conflict and the quality of the mother–infant relationship. This latter factor has been examined by only one study and then only by a 5-min videotaped study of play at 2 months: the conclusion was that early postpartum depression, and associated disturbances in the mother–infant relationship, posed a risk to the development of the child; in one analysis, infant engagement with the mother at 2 months was the only variable predicting cognitive functioning at 5 years.

In extreme cases, maternal depression can lead to the tragedy of combined suicide and filicide. Filicide has other rare causes, including delusions or command hallucinations involving the child, the late murder of an unwanted child, euthanasia, epileptic automatism and somnambulism, but only child abuse and depression are relatively common (in combination, 2–3/105 children under 5 years of age per year). In child abuse, death results from ill-tempered assaults or overzealous punishment, without homicidal intent. In depression, filicide is committed in the belief that the child's best interests are being served (delusional mercy-killing). These mothers, if they survive, usually make no attempt to conceal the crime; they confess and seek punishment. Mothers may kill more than one child, but family murder seems more common in men.

Many more mothers are depressed than ever make their way to the surgery. The reasons for the failure to seek help are not fully understood: some recover early, some do not realize they are ill, and some are ashamed of confessing their symptoms, suffering in silence because of ignorance, stigma or fears of losing their baby. Screening procedures help the primary care services to identify cases. Patients identified by screening or self-referral require a detailed interview to identify vulnerability factors and all the components of the postpartum illness. The interview should explore the symptoms and course of the illness, and its context in the mother's life history, personality, circumstances and relationships with spouse, baby, other children and family of origin. It should systematically review this pregnancy, starting with conception and reactions to it, and exploring physical health and events trimester by trimester, paying particular attention to the experience of parturition. It is essential to probe the mother's developing relationship with the fetus and the infant. There are advantages in conducting this initial interview at home, because clinic attendance is an obstacle for mothers fettered with the care of young children, and because domiciliary assessment has a quality that cannot be achieved in the surgery.

Treatment is focused on depression and any underlying vulnerability. It will always involve psychotherapy, if only in the form of a single interview; it will usually include medication or other specific treatments; a few women require ECT. Working with the baby's father, potentially the main supporter, is important; fathers can come under strain, either because their partner's intimacy with the baby disturbs conjugal dynamics or because her depression has a domino effect on him. Home visits by community nurses are an ideal way of delivering continuing care and psychotherapy. An extensive literature has accumulated on the efficacy of psychological treatments. A wide variety of treatments have been tried, including psychodynamic and interpersonal psychotherapy, cognitive-behavioural therapy, peer and partner support, non-directive counselling, group therapy, midwife-led debriefing, psychoeducational
groups, relaxation and massage therapy, exercise and light therapy. As for drug treatment, there is no evidence that any drug is superior to others. There are at least 50 reviews of drug treatment in lactating mothers. The suckling infant has little body fat, less plasma protein-binding, an immature liver and kidney, and an undeveloped blood–brain barrier, but the risks are minor. Occasional babies have developed adverse effects such as sedation, respiratory depression and colic (with doxepin, nefazodone and fluoxetine). With most antidepressants, only a minute dose is delivered to the infant. Tricyclic antidepressants have the advantage of long usage, with no reports of adverse outcomes. Among the SSRIs, fluoxetine and citalopram deliver relatively high doses to the infant, and occasional infants develop significant serum levels and a decline in platelet 5-hydroxytryptamine (5-HT) concentrations. Sertraline treatment, in contrast to treatment with paroxetine or fluvoxamine, leads to detectable levels in some breastfed infants but does not affect infant serotonin levels. The serotonin–noradrenaline reuptake inhibitor venlafaxine produces a higher drug level in breast milk than in maternal serum. Bearing these reports in mind, it is not recommended that antidepressant agents be withheld, or that breastfeeding be stopped, but it is wise to use these drugs cautiously, and it may be helpful to administer the drug after breastfeeding. Among the hormonal treatments, progestogens given after delivery increase the risk of depression. There is some evidence that oestrogens are antidepressive and may be efficacious in postpartum depression, but only one or two trials have been published.

Postpartum depression has a recurrence rate of about 40 per cent. Pregnant women often request advice or prophylaxis. If they are already symptomatic, or have risk factors such as marital friction or social isolation, they need support from community psychiatric nurses, voluntary agencies or other groups. If they are well, it is necessary only to establish contact, so that a recurrence is diagnosed and treated promptly. Prophylactic antidepressant medication can be considered: although a prophylactic trial of nortriptyline failed to affect the recurrence rate, sertraline had a beneficial effect.

**MOTHER–INFANT RELATIONSHIP DISORDERS**

The growth of the mother–infant relationship is the key psychological process in the puerperium. ‘Bonding’ is a popular term; professionals prefer the term ‘attachment’. One must not confuse mother–infant with infant–mother attachment, which develops much more slowly. The mother–infant relationship consists essentially of ideas and emotions aroused by the infant, which find their expression in affectionate and protective behaviour. Its inner presence is betrayed by external signs, such as touching and fondling, kissing, cuddling and comforting, prolonged gazring and smiling, baby talk and cooing, recognizing signals, tolerating demands and resisting separation. No single activity defines it: particular behaviours wax and wane, but the relationship endures. Its power is revealed in self-sacrifice and the pains of separation. This emotional response enables the mother to withstand the never-ending vigilance and exhausting toil of the nurture of the newborn.

There is no critical period in the development of the maternal response. Close proximity from the start (‘rooming-in’) helps the mother to gain confidence, and breastfeeding may help. The infant plays an important part. The infant reacts preferentially to the human face and voice. Eye-to-eye contact mediates the interaction, and mutual gazing becomes an absorbing activity. The baby’s smile and laughter are catalysts. Videotape studies have shown the infant contributing to a dialogue with its caregiver. Sometimes the maternal response is immediate, primed by affiliation to the fetus, but sometimes there is a worrying delay. For the first 3–4 weeks many mothers feel bruised, tired and insecure, and their babies seem strange and distanced. Some mothers are distressed by a temporary absence of affection for their babies. As the baby begins to respond socially, a normal relationship develops rapidly.

The term ‘mother–infant relationship (or bonding, attachment) disorder’ is appropriate for severe and persistent states in which the maternal emotional response is dominated by either or both of the following:

- **A negative emotional response:** the mother regrets the pregnancy and expresses dislike or hatred of her baby. She may try to persuade a relative to take over, and may demand that the infant be fostered or adopted. The most poignant manifestation is a secret wish that the baby ‘disappear’ – be stolen or die. Rejection of the infant is threatened when the mother seeks its temporary removal, and established when she persistently demands permanent placement.

- **Pathological anger:** the infant’s demands anger the mother and provoke aggressive impulses, which may lead to shouting, cursing, screaming or assaults.

The frequency of these disorders in the general community can be estimated at about 1 per cent of children born. It is much higher in mothers who seek help for ‘postnatal depression’ – about 10 per cent at the level of established rejection and another 15 per cent for threatened rejection.

There is a close relationship between these disorders and postpartum depression. Both are often present in mothers who present to services. Treatment of depression (e.g. by ECT) sometimes simultaneously cures an aversion to the infant. The onset of a late postpartum depression can be accompanied by the loss of a bond, even to the extent of rejection of the infant. But it is not appropriate, clinically or scientifically, to subsume this disorder under ‘postnatal depression’. Some of these mothers are not depressed, and in other mothers the severity, course and treatment...
response differ. In the clinic, the relationship disorder must be diagnosed because it often requires specific psychological treatment. Without treatment, many cases become chronic. The children are insecurely attached and develop behavioural problems. Scientifically, the mother’s relationship to her infant, and especially its severe malfunction, deserves close study. Unwanted pregnancy, impaired affiliation to the fetus and rejection of the infant are risk factors for child neglect and abuse and can contribute to their prevention.

The diagnosis can be facilitated by self-rating questionnaires. The main resource is an interview probing the mother’s emotional response and behaviour. In severe cases and in research, the gold standard is direct observation, preferably over a substantial length of time – a 5-min videotape may not be sufficient to distinguish between impaired interaction due to aversion and that due to anxiety, obsessional impulses or depression. In the day hospital or in-patient unit, 24 h/day, 7 days/week nursing observations are invaluable. In the future, functional magnetic resonance imaging (MRI) may provide objective correlates of the mother’s emotional response.

The treatment proceeds in stages:

- Where there is merely an absence of maternal emotional response, explanation and reassurance are appropriate.
- When hostility, rejection and anger are prominent, the primary decision is whether or not to attempt treatment. The infant’s safety and wellbeing are the first consideration. The mother must not be trapped in unwelcome motherhood. The father also has his rights. The option of relinquishing the infant must be openly acknowledged and discussed fully with both parents.
- If it is decided to embark on treatment (as in most cases), depression should be treated with psychotherapy, drugs or ECT.
- The specific therapy is working on the dyadic relationship. This relationship, like others, grows through mutual pleasure, and the aim is to create circumstances in which mother and child can enjoy each other. They must therefore be treated together. Completely separating them (e.g. by hospitalizing the mother on her own) compounds the problem by adding an element of avoidance. But, if there is any hint of pathological anger, she must never be left alone with her infant and must be spared the irksome burdens of infant care. When mother and baby are calm, the mother is encouraged and helped to interact with the baby – to cuddle, talk, play and bring out the baby’s smile and laughter. Participant play therapy and baby massage may assist.

Treatment can take place at home, provided there is enough competent adult support to relieve the mother of night care and stressful duties. Day-hospital treatment is ideal for disorders of moderate severity. In severe and refractory cases, it may be necessary to admit the mother and infant to a psychiatric mother-and-baby unit, where an experienced team of psychiatric and nursery nurses can bring their skills to maximum effect. Even in the most severe cases, one can feel optimistic about a successful outcome.

Research on the prevention of these disorders is in its infancy. A controlled study showed that a videotape advising mothers how to interact affectionately with their infants had a significant positive effect on mother–infant interaction.

### POSTPARTUM PSYCHOSES

Postpartum psychoses fall into two main groups – organic psychoses and bipolar disorders; a third group – reactive or psychogenic psychosis – is most convincingly seen in adoptive mothers and fathers.

Among the organic psychoses, two prepartum disorders – Wernicke–Korsakoff syndrome and chorea psychoses – can also present after childbirth. The most important causes of postpartum delirium are eclampsia and infection. The rarer causes are arterial occlusion, postpartum cerebral angiopathy, subdural and subarachnoid haemorrhage, cerebral venous thrombosis (common in India), epilepsy, ethanol withdrawal, Sheehan’s syndrome, water intoxication and urea cycle disorders causing hyperammonaemia. Before 1925, a considerable proportion of postpartum psychoses were organic, but they are now hardly ever diagnosed in Europe or North America. They may still be important in Africa, India, South-East Asia and Latin America, where most of the world’s children are born.

The form of psychosis still seen in Europe and North America is related to the bipolar spectrum and to acute polymorphic (cycloid) psychosis. These psychoses are acute, rapidly reaching a climax of severity. The onset is usually between 2 and 14 days after delivery. Mania is severe, often with schizoaffective symptoms or extreme excitement. Almost every psychotic symptom is seen – the whole gamut of delusions, verbal hallucinations, disorders of the will and self, and catatonic features. There is often an apparent confusion or perplexity. Since the advent of ECT and neuroleptic medication, the duration has fallen to a few weeks. A minority of patients show a tendency to relapse in rhythm with menstruation. Puerperal recurrences occur after 20–80 per cent of subsequent pregnancies, or 100 per cent of subsequent pregnancies if depressive episodes are included. Non-puerperal recurrences are also common.

These are biological brain disorders, with high heritability and an inborn tendency to develop episodes throughout life. The problem of causation can be broken down into three subsidiary questions: the nature of the diathesis, the determinants of clinical polarity (mania, depression or cycloid), and the trigger that provokes the episode. The first two questions belong to the wider study of bipolar and
acute polymorphic disorders. The third is specific to puerperal psychosis. Clinical observations suggest not one, but several, triggers related to the female reproductive process – abortion, pregnancy itself (especially the last trimester), the early puerperium (especially the first 10 days), postpartum mensturation, mensturation in general, and possibly weaning. These triggers can be added to other biological events that trigger bipolar episodes, including surgery, steroid treatment and seasonal climatic changes. The incidence is less than one in 1000 pregnancies.\textsuperscript{130,131} There is no association with twin pregnancies, breastfeeding, single parenthood or stillbirth, but higher rates are found in first-time mothers.\textsuperscript{132} This psychosis has high heritability – not only for bipolar disorder but also for the puerperal trigger.\textsuperscript{133} Molecular genetic studies are proceeding, and there is evidence of linkage with chromosomes 16p13 and 8q24.\textsuperscript{134}

For treatment, the first resource is sedation by neuroleptic agents, but haloperidol should be used with caution because of the risk of severe extrapyramidal side effects, which include neuroleptic malignant syndrome. There have been few studies of breastfeeding mothers, but occasional infants have had haloperidol levels in the adult range.\textsuperscript{135} Clozapine may accumulate in breast milk. Lithium has been used increasingly since the link with manic-depressive psychosis was recognized, and there is some evidence for its prophylactic value in women at high risk. Given to lactating mothers, it has rarely had adverse effects on the infant,\textsuperscript{136} and is not absolutely contraindicated. Carbamazepine and valproate produce low serum levels in breastfed infants.\textsuperscript{137} Electroconvulsive therapy is effective.\textsuperscript{138} The location of treatment is an issue. Hospitalization is disruptive to the family, and it is possible to treat moderately severe cases at home, where the patient can maintain her role as partner, homemaker and mother, and her relationship with the newborn. If hospital admission is necessary, there are advantages in conjoint mother and baby admission.

**SERVICES FOR MOTHERS WITH MENTAL ILLNESS**

An outline of the services required for this area of psychiatry is slowly emerging. Its aims are prevention in those who are vulnerable, early and accurate diagnosis, and rapid effective intervention, with minimal disruption of family life. These aims require the following:

- **A multidisciplinary specialist team:** this team is of universal value – a key resource whatever the cultural background. It should include psychiatrists, nursing staff of various kinds, psychologists and social workers. It can serve a population of several million inhabitants, handling severe and intractable illness, training staff, developing services and conducting research.

- **A community service:** domiciliary assessment and home treatment are appropriate for mothers.

- **Day care:** a day hospital can provide a full range of interventions, including groups, play therapy, motherhood classes, anxiety management and occupational therapy, with minimal family disruption. The presence of mothers with similar disorders is an additional support. The children are cared for in a crèche.

- **In-patient facilities:** clinical experience suggests that conjoint admission of mother and infant is superior to the admission of the mother alone, and wards dedicated to conjoint admission also have advantages over admissions to general psychiatric wards. But there have been no objective comparisons of these state-of-the-art, expensive units with other forms of care.\textsuperscript{139}

- **An obstetric liaison service:** apart from treating preparum mental illness, this provides an opportunity for preventive psychiatry, by detecting vulnerability during pregnancy.

- **Links with other agencies providing services for mothers:** the social services have a key role. They can relieve the burden on the mother and safeguard the child by providing emergency foster care, and their family centres fulfil a similar function to mother-and-baby day hospitals. Other agencies that care for mothers and their infants include the National Society for the Prevention of Cruelty to Children (NSPCC), midwifery services, primary care teams and child psychiatry services.

- **A network of voluntary organizations:** these lay organizations can have close cordial ties with the professional service. Support from another mother who has suffered a similar problem and is now well is particularly appropriate – she knows the stratagems or words of comfort that were helpful, and she is proof of the possibility of recovery. For each disorder, a panel of recovered mothers is an important resource.

- **Medicolegal expertise:** expert advice is often required in cases of child abuse or infanticide, and where a mother with mental illness is seeking custody or access to her children.

**KEY POINTS**

- Knowledge of the psychiatry of pregnancy, parturition and the puerperium has advanced greatly during the past 20 years, with the publication of thousands of papers. Most have emerged from Europe and North America, where the birth rate and complications are low. The disease picture in the developing world may be very different.

- The most serious consequences of maternal mental illness are adverse effects on the child. Unwanted pregnancy and maladaptation to motherhood can have disastrous outcomes, including neglect (emotional and physical), abuse and infanticide.

- Depression, during pregnancy and after delivery, is not specific and is often accompanied by other disorders that require diagnosis and their own treatment.
Anxiety disorders are common and often have themes specific to childbearing, such as tocophobia, infant-centred anxiety and the pathological fear of cot death.

Obsessional disorders are common, and obsessions of infanticide are important, partly because of the differential diagnosis from anger-based abusive impulses.

Pregnancy in women with eating disorders or substance abuse presents particular challenges.

Traumatic delivery and infant loss have lasting consequences that require skilled psychological handling.

There are many forms of prepartum and postpartum psychosis, most of which are rare complications of organic brain disease. The non-organic psychoses are linked to bipolar and acute polymorphic psychosis.

Drug treatment has an extra dimension of unwanted effects on the developing fetus and the breastfed infant.

The complexity of this field of psychiatry demands the deployment of specialist teams. Their resources (community services, day hospitals, joint admission) vary from one country to another, but their expertise is of universal value.

REFERENCES

There are approximately 10,000 published works on the psychiatry of childbearing. Works published up to 1995 were reviewed and referenced in my monograph Motherhood and Mental Health. Limited to about 150 references, I have therefore cited only more recent publications.

Sex and the mind–body split

For better and for worse, we live in a post-Cartesian world. When René Descartes philosophically divided mind from body, or res cogitans from res externa, in 1641, he gave the Western world a powerful tool for thinking clearly about physical and mental health and illness as separate entities.1 This divide has often served us well; but wherever mind and body illnesses are most deeply interconnected, this split in our thinking is apt to confuse rather than clarify. Sex, not uniquely, but par excellence, is almost impossible to think about usefully within separate categories of mind and body. Although a whole panoply of experts, including religious leaders, politicians, anthropologists, psychologists, psychotherapists, psychiatrists, gynaecologists, urologists, sexual health doctors and epidemiologists, each with differing languages and agendas, all consider sex their legitimate business, none has a real monopoly on relevant knowledge. There are, therefore, no true ‘experts’ on sex. Patients with sexual troubles are often at a loss as to where to turn, caught between sometimes contradictory-seeming agencies and approaches. And although for many patients the doctor will be a first port of call, it is unsurprising that doctors often feel out of their depth.

Sex and the medicine–psychotherapy split

Sometimes a simple, treatable, single cause can be found for a sexual difficulty, but more often the picture is complex, entangled and unamenable to a straightforward disease-based approach on the one hand, or a purely psychological approach on the other. While medicine adopts a disease-based view of illness, with specific aetiologies, epidemiologies and treatments attaching to the disease, in which the doctor is the expert and the relevant data are drawn from outside the consulting room, psychotherapy takes an individually centred view, in which symptoms are no more than pointers to an underlying illness, whose causes and solutions are personal, and in which the patient, with privileged access to the full data, is the expert and the doctor a facilitator of the self-investigatory process. Sexual distress, biopsychosocial in its very nature, calls for a crossing of this intellectual and clinical divide.

Bridge-building in doctor and patient

Hence, in encountering patients’ psychosexual difficulties, we cannot stick either purely to the disease-based categorization of organic medicine and psychiatry, or purely to the narrative-based language of psychotherapy. We are forced out into an uncomfortable no-man’s land between scientific discourses, because this is the place where our patients find themselves. Just as the psychosexual patient needs to open his or her mind to possible mind–body connections that could not hitherto be made, so the psychosomatic doctor needs to build intellectual and cultural bridges that join those objective and subjective, medical and psychotherapeutic, empirical and narrative-based, quantitative and qualitative approaches that have become disconnected and at times held artificially apart by factionalism and mutual suspicion. Psychosomatic work is therefore, to an extent, a process of post-Cartesian academic and clinical peace and reconciliation.

HISTORY

Sex research has traditionally been conducted in a political and moral battle zone. All early research into sex met with fierce political, moral or religious opposition, and, of the seven key contributors outlined in Box 45.1, all suffered strong political criticism, two had their works banned, one was imprisoned, and one felt obliged to change nationality. Whatever scientific criticisms we may legitimately make with the benefit of hindsight, modern psychosexual medicine owes each of these pioneers a debt.2–14

BIOLOGY

Anatomy

Normality in genital anatomy (Figures 45.1 and 45.2) is wide-ranging. Markedly differing lengths and diameters of
Box 45.1 Key figures from the history of sex research

VON KRAFFT EBING (1840–1902), SEXOLOGIST AND PSYCHIATRIST
- **Methodology:** Theoretician.
- **Key scientific criticisms:** Lacks an underlying theoretical framework to his classifications. Concept of ‘degeneracy’ – sexual activity not leading to procreation – later criticised by Havelock Ellis and Freud.
- **Principal works:** Textbook of Insanity (1879), Psychopathia Sexualis (1886, transl. 1902).

HENRY HAVELOCK ELLIS (1859–1939) SEXOLOGIST, PHYSICIAN AND SOCIAL REFORMER
- **Methodology:** Theoretician.
- **Key theoretical contributions:** Co-authored the first English-language textbook on homosexuality. Regarded homosexuality as neither a disease nor a crime. Championed women’s rights and sexual education. Tolerant of childhood and adolescent sexuality. Sought the demystification of sex. Suggested psychological origin for most ‘frigidity’ and ‘impotence’. Coined the terms ‘narcissistic’ and ‘autoerotic’.
- **Key scientific criticisms:** Observations were purely theoretically based.
- **Principal works:** Studies in the Psychology of Sex (7 vols, 1897–1928), Sexual Inversion (1896).

SIGMUND FREUD (1856–1939), NEUROLOGIST, SEXOLOGIST AND FOUNDER OF PSYCHOANALYSIS
- **Methodology:** Theory based on clinical case studies.
- **Key theoretical contributions:** Postulated blocked libido as a cause of neurotic/hysterical/psychosomatic symptoms. Developed a theory of childhood sexuality, including a stage model of psychosexual development.
- **Key criticisms:** At times, makes sweeping theoretical and therapeutic claims on the basis of small numbers of cases.
- **Principal psychosexual text:** Three Essays on the Theory of Sexuality (1905).

WILHELM REICH (1897–1957)
- **Methodology:** Observation of clinical case material and that of colleagues.
- **Key theoretical contributions:** Elaboration of the psychosomatic mechanisms connecting blocked sexual energy and neurosis. Development of a theory of character based on these blocks. His work gave rise to the tradition of body psychotherapies.
- **Key criticisms:** Mental breakdown in later life and political discreditation cast a shadow retrospectively on his earlier, more cogent work.
- **Principal works:** The Function of the Orgasm (1927).

ALFRED KINSEY (1894–1956) PHYSICIAN AND SEXOLOGIST
- **Methodology:** Personal interview and filming of sexual acts.
- **Key theoretical contributions:** Two first large-scale surveys of sexual behavior: the *Kinsey Reports*. First statistical reports of childhood masturbation. Elucidated the high prevalence of extra- and premarital sex, the ubiquity and harmlessness of masturbation, and the high level of homosexual encounters.
- **Key scientific criticisms:** The use of personal interview rather than observation, and a focus on counting the frequency of sexual events rather than focusing on the whole experience. Ethically, the presentation of data that could probably not have been obtained without observation of child sexual abuse or through collaborations with child molesters.
- **Principal works:** Sexual Behaviour in the Human Male (1948), Sexual Behaviour in the Human Female (1953).

WILLIAM MASTERS (1915–2001), OBSTETRICIAN AND GYNAECOLOGIST, AND VIRGINIA JOHNSON (b. 1925), PSYCHOLOGIST
- **Methodology:** Direct observation of sexual acts in the laboratory, sometimes using ‘assigned partners’.
penis and sizes of labia majora and minora are all capable of being functionally normal in both sexual and reproductive terms, as well as attractive and pleasurable to the individual and their partner. Abnormalities certainly exist, such as marked Peyronie’s disease, hypogonadism and vaginal stenosis, and are dealt with in detail in the gynaecological, urological and paediatric literature. On these, the doctor and patient usually agree, although even here the agreement on anatomical difference is not so much the end as the beginning of the exploration of what this means to the patient, how it affects him or her, and what treatment is appropriate. Far more common than frank anatomical abnormality is the fear of abnormality. As psychosexual doctors, we frequently encounter people who are worried that their genitalia might be abnormal when, on examination, we do not find them so. In the extreme case of body dysmorphia, the patient may be passionately convinced that his or her genitalia are abnormal or grotesque and strongly request treatment such as labial reduction surgery or penile enlargement, while the doctor, perplexed, can find no abnormality at all.\(^\text{15}\) The pressure to endorse the patient’s negative self-image and comply with requests for ‘treatment’ can be strong, and the fear of seeming unsympathetic or arrogant if we do not act looms large; but it is particularly important for psychological as well as physical reasons that the doctor is able to trust his or her clinical and medical judgement and remain truthful and congruent. Reporting our findings of normality in a way that does not dismiss the patient’s concern, but instead invites curiosity and conversation about the discrepancy between the doctor’s and the patient’s judgement, can help the patient to reflect on the origins of his or her own dissatisfactions.

**Physiology**

Our understanding of the physiology of sexual response has travelled in just over a century from theory and speculation (see Box 45.1), via empirical and qualitative methods of data-gathering, to direct imaging via magnetic resonance imaging (MRI) scans made during sexual intercourse. Masters and Johnson were the first to characterize the human sexual response, in four stages of arousal, plateau, orgasm and resolution, which are summarized in Boxes 45.2 and 45.3.\(^\text{9,16}\)

---

**Figure 45.1** Normal female genital anatomy

**Figure 45.2** Normal male genital anatomy, showing mechanism of penile erection

---

**Key scientific criticisms:** Unrepresentative research participants. Uncritical acceptance of cultural assumptions such as that it is ‘normal’ for a woman to orgasm through penile thrusting.

**SHERE HITE (b. 1942), SEX EDUCATOR AND FEMINIST**

- **Methodology:** Individualistic, large-scale, questionnaire-based research. Development of a discourse on human responses to gender and sexuality.
- **Key theoretical contributions:** Focus on individual subjective sexual experience of sex. Incorporation of key feminist theoretical perspectives.
- **Key criticisms:** Low response rates and possible response bias.

---

Part 4: Mental health problems and mental illness
Box 45.2 Masters and Johnson’s four stages of sexual arousal

1. Excitement phase (in initial arousal)
2. Plateau phase (at full arousal, but not yet at orgasm)
3. Orgasm
4. Resolution phase (after orgasm).

Box 45.3 Physical aspects of the sexual response in women and men

IN WOMEN

The excitement phase draws on physical and psychological stimuli and involves vasocongestion of the external genitalia, clitoral erection, colour changes in the genital skin, and flattening and opening of the labia majora. Increased vaginal transudate reduces friction during intercourse. A turgid cuff of engorged tissue forms in the lower third of the vagina, the nipples and areolae become erect, and there is often a pink flush over the breasts, abdomen and limbs, known as the ‘sex flush’.

The plateau phase draws more strongly on physical stimulus, which must continue if orgasm is to be achieved. The vagina lengthens and distends, with ballooning or tenting at the proximal end, the turgid cuff at its distal end increases, the uterus elevates, and the clitoris retracts.

Orgasm is characterized by brief myotonic contractions of the pelvic floor muscles of about 1 in every 0.8 s, and the release of genital vasocongestion. It varies markedly in intensity within and between women, has no definite endpoint, and is followed by the resolution phase, during which some women are able to return rapidly to orgasm (‘multiple orgasm’).

IN MEN

The excitement phase draws on physical or psychological stimuli, or both, and leads to vasocongestion of the penile corpora cavernosa, causing erection of the penis. Erection is dependent on the integrated action of psychological, endocrine, neural vascular and anatomical elements, and damage in any of these pathways can result in erectile dysfunction. In general terms, the ability to have spontaneous nocturnal or early morning erections, or erections during masturbation, precludes serious neurovascular causes of erectile dysfunction. At full penetration, the penis appears boomerang-shaped, with an average length of 22 cm from root to tip, reaching mid-sacrum or the sacral promontory, and filling the whole anterior or posterior fornix of the vagina. The plateau phase draws more strongly on physical stimulus and leads to orgasm, which is characterized by brief myotonic contractions of the pelvic floor muscles every 0.8 s, the release of genital vasocongestion, and ejaculation. Orgasm is followed by a refractory period, during which a return to orgasm is physiologically impossible. Orgasm and ejaculation are neurologically distinct, and it is possible for a man to ejaculate without experiencing satisfactory orgasm.

Non-biological influences on sexual response

A number of cultural and life-stage factors can affect sexual response and practice. The age of first sexual activity, the willingness to have sex during menstruation or before marriage, the use of contraception, attitudes to pregnancy, infidelity and divorce, and sexual activity in later life are all highly culture-bound. For example, the age of first adult sexual experience has moved steadily downwards across the Western world, with figures from the USA suggesting that one in five under-15s, and from the UK one in five under-16s, are sexually active,17 with teenage pregnancy rates rising steadily in parallel.18–20 Cultural attitudes within and between societies vary widely, from the extremely liberal, as exemplified by the ‘free love’ movement in the 1960s, which promoted unrestricted sex, to the extremely conservative, such as countries and subgroups that punish homosexuality with the death penalty or ostracize unmarried mothers. Sex is heavily mythologized in all ages and cultures, and some sexual myths can get in the way of sexual health and functioning (Box 45.4). Similarly, large-scale societal changes, such as the introduction of the contraceptive pill, the legalization of first homosexuality and then abortion, and the advent of human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), have revolutionized sexual attitudes and practices (Box 45.5).

At a more personal level, there is considerable variation in sexual activity through the menstrual cycle, with some questionnaire-based evidence suggesting an increase in sexual activity pre- and post-menstrually and little evidence for an increase at ovulation, which one might expect based on the analogy with other mammals.21 There appears to be widespread cultural avoidance of sex during menstruation, although this is less marked in white middle-class women. A minority of women use menstruation as a ‘safe’ period of presumed reduced fertility. Where menstruation is heavy, painful or irregular, this can affect sexual relating.
Box 45.4 Myths and taboos can interfere with sexual health and function:

- ‘Sex during pregnancy might damage the baby’
- ‘You can’t get pregnant from first ever sexual intercourse’
- ‘Orgasm is normally or should be mutual and simultaneous’
- ‘Women should orgasm from penile thrusting only’
- ‘Sex during menstruation or postpartum bleeding is impermissible/undesirable/dirty’
- ‘Men should always feel like sex’
- ‘“Nice” women are not too interested in sex’
- ‘Gay men are more promiscuous than straight men’
- ‘Masturbation makes you blind’

Box 45.5 Key historical influences on sexual behaviour and attitudes

- 1844: mass production of vulcanized rubber condom. Latex introduced in 1880s but widely available from 1930s.
- 1861: legislation (Offences Against the Person Act) abolishes death penalty for buggery.
- 1885: legislation (Criminal law Amendment Act) to completely criminalize male homosexuality.
- Early 1900s: vibrators available to public (previously restricted to doctor’s consulting rooms) – fifth available household electrical appliance pre-dating iron and vacuum cleaner.
- 1921: publication of Wise Parenthood by Marie Stopes – a brief guide to contraception. First Marie Stopes clinic opened.
- 1960: publication in UK of Lady Chatterley’s Lover by DH Lawrence (written in 1928). Publisher prosecuted unsuccessfully under the 1959 Obscene Publications Act.
- 1963: publication of The Feminine Mystique by Gloria Friedan (early feminist challenge to the idea that women could derive satisfaction only through devotion to home, husband and children).
- 1964: first use of the term ‘women’s liberation’ (Women’s Liberation Movement coined 1968).
- 1967: legislation (Abortion Act) to allow limited abortion in UK.
- 1984: approval of morning-after pill in UK (over-the-counter availability since 2001).
- 1981: first cases of AIDS in the USA (term coined in 1982).
- 2001: equalization of homosexual and heterosexual age of consent (at 16 years, except in Northern Ireland, where it is currently 17 years but in the process of being equalized).

AIDS, acquired immunodeficiency syndrome; DSM-II, Diagnostic and Statistical Manual of Mental Disorders, 2nd edn.

The influence of contraception on sexual activity can range from positive effects of liberation from the fear of pregnancy, through hormonal side effects such as decreased libido or breast tenderness, to psychological unease about the loss of ‘naturalness’ associated with exogenous hormones or ‘foreign bodies,’ or even an unconscious desire for the very pregnancy that is consciously being prevented. Reliable data are difficult to gather in this area, since the attitudes, desires and cultural backgrounds of two partners both simultaneously influence the nature and timing of sexual activity.

Pregnancy can affect sexual desire and function in both partners, in both positive and negative ways. A couple’s general feelings about the pregnancy, specific fears and fantasies about miscarriage or preterm labour, changes in the woman’s body such as increased breast size and tenderness, increased genital congestion and lubrication, exhaustion, physical discomfort, uterine irritability, and milk spurting from the breasts during orgasm can all influence sex. On average, sexual activity appears to reduce in the first and third trimesters, when exhaustion, sickness and fear of miscarriage are greatest, but to increase, even in relation to the non-pregnant state, in the second trimester, but with wide variations between women.21 Sex postpartum will depend on the pre-pregnancy state of the sexual relationship and on factors such as both partners’ experience of the labour, the degree of exhaustion due to sleep deprivation or breastfeeding, physical discomfort relating to aspects of the delivery, and any postnatal depression or low mood. Breastfeeding, described by some women as sexually pleasurable, is experienced by others as neutral or even uncomfortable. Sexual desire often returns before the
Menopause, with its associated symptoms of vaginal dryness, hot flushes and reduced libido, can represent a challenge or crisis in many women’s sexual lives, although some suffer only minimally. In general, the motto ‘use it or lose it’ appears to apply to a degree, in that regular sexual activity appears to preserve the ability to lubricate and to tolerate and enjoy intercourse and orgasm. Uterovaginal prolapse and age-related urological symptoms can inhibit sexual activity, as can relationship factors such as sexual boredom, erectile dysfunction, illness in oneself or one’s partner, and the inhibitory effects of perceived societal attitudes to sexual activity in older people. However, recent evidence confirms that sexual activity can continue in a satisfying, albeit modified, form beyond the menopause and into late life, and suggests that older people nowadays are enjoying more frequent and satisfying sex than that reported in previous generations.\(^{22}\)

**SEX AND EVIDENCE**

### Cultural challenges

Because sex is biopsychosocial, its study is spread across disciplines, no one of which can claim full expertise. This makes it challenging to research, at the level of both the individual study and the institution. Each discipline has evolved its own scientific culture, from the nuanced case-reporting and supervisory self-reflection of psychotherapy, through the qualitative research methodologies of the social sciences, to the numerical, population-level objectivity of randomized controlled trials and systematic reviews. Each approach contributes a different perspective on sexual dysfunction, and each has its own passionately defended ethic of rigour. It can be hard for differing disciplines to agree on the important research questions, never mind the correct methodologies for addressing them and the outcomes of interest. Both in the consulting room and in the university department, the resolution of sexual problems requires individuals who are willing to bridge the gap between biological and psychological approaches by learning each other’s languages and research methodologies.\(^{23,24}\)

### Bias

Sex research is particularly bias-prone. Aside from subcultural biases based on the researcher’s scientific background, researchers and clinicians are inevitably prone to personal biases based on their own sexual beliefs, feelings, experiences and preferences, however liberal or conservative, conscious or unconscious these may be.

Since direct observation of sexual activity is practically difficult, ethically questionable and almost by definition non-representative, research relies heavily on self-reporting, which is prone to the usual biases that this entails: the relationship between what people do and what they say they do is known to be unreliable, and the more socially unacceptable or controversial the behaviour, the more likely underreporting bias is to play a role. This complicates the investigation of anything from homosexual sex, anal sex or extramarital affairs to minority sexual practices such as paedophilia or fetishes. As well as underreporting bias, generally poor response rates common to all questionnaire surveys often limit the external validity, or generalizability, of research findings.

In addition, it is helpful to remember that most sex research is born of experience with individuals with sexual problems who present to doctors, which many, but not all, do, leading to possible selection bias. By definition, we know nothing about the number of people who do not present to doctors, and how and with what success they address their sexual problems. All of these biases place limits on the internal validity of sex research – that is, its accuracy in reflecting the research population – and its external validity – that is, its generalizability to a wider population. This means that caution in interpreting individual studies is particularly important, and the use of ‘triangulation’ whereby a picture is assembled using data from a variety of different sources and methodologies, much like the piecing together of a mosaic from fragments, is particularly helpful.

As sexual dysfunction has become more widely recognized, in part due to pharmaceutical company research interest, a number of validated and reliable measures of sexual function/dysfunction have been developed, usually brief, self-report questionnaires taking 10–20 min to complete.

In summary, just like work with an individual patient’s psychosexual difficulty, scientific work around psychosexual distress is a multilayered reconstructive process, closer to the reassembling of fragments of data from different disciplines, using different methodologies and a variety of outcome measures, whether of biological function, self-reported physical experience, self-reported emotional experience, or broader factors such as quality of life.

### What is known?

Although a wealth of rich, narrative-based and qualitative information exists on sexual function and dysfunction, there is a dearth of high-quality quantitative data, such as randomized controlled trials and systematic reviews with patient-centred outcomes. A critical review of the evidence relating to the efficacy of psychological interventions for sexual dysfunction carried out in 2004 by a body of international experts concluded that:\(^{25}\)

- the best available evidence (levels 3, 4 and 5) supports the use of a multidisciplinary and/or biopsychosocial approach;
- more high-quality research into the efficacy of psychosexual treatments, and in particular combined biopsychosocial approaches, is needed;
outcome studies are notoriously difficult to design and conduct in ways that meet high evidence standards while respecting the complexity of sexual life;

- many studies have a narrow view on genital function/dysfunction or performance, and an overemphasis on frequency counts of various sexual acts, as opposed to more subtle measures of satisfaction or health-related quality of life;
- even function-oriented studies disagree as to what constitutes a good treatment outcome (does the achievement of a single orgasm count as success in treating anorgasmia in women? Or should one count orgasm on some specified percentage of occasions – and from manual or oral stimulation or from coitus? Similarly, is frequency of heterosexual coitus a satisfactory measure of treatment for erectile dysfunction?);
- love, widely regarded as important especially in Western counties in fostering relational and sexual intimacy, is not typically discussed in scientific discourse or evidence-based research.

THE PSYCHOSOMATIC TRADITION AND PSYCHOSEXUAL MEDICINE

Psychosexual medicine: deep penetration on a narrow front

Psychosexual medicine arose in response to the needs of British doctors and patients struggling to understand and treat sexual difficulties. It is based on the work of two doctor-psychoanalysts, Michael Balint and Tom Main, who founded the Institute of Psychosexual Medicine in 1974, which offers training to somatic doctors and psychiatrists (Box 45.6).26 Psychosexual medicine is an integrated approach that presupposes competence in taking a medical history and identifying underlying or coexisting organic disease, and treating or referring appropriately, but adds to these the skills and methods of psychodynamic psychotherapy. It is therefore intercultural, and firmly rooted in a wider academic tradition of psychosomatic medicine.27

Psychosomatic medicine in the UK and elsewhere

Although psychosomatic medicine exists as an independent clinical and academic specialty in many countries, such as the USA and parts of mainland Europe, the treatment of psychosomatic illness in the UK is spread across medical specialties. Individual pools of expertise have grown piecemeal in subspecialist areas such as liaison psychiatry, psychosexual medicine, pain management and general practice. The management of psychosomatic illness in the UK therefore depends on strong interdisciplinary liaison and is at particular risk from each specialty’s pressures to deliver on ‘core’ targets and of being treated in inappropriate ways.

Psychosexual medicine differs both from other forms of sex therapy usually practised by non-doctors, where cognitive-behavioural methods, often involving the use of exercises, are used to modify unhelpful sexual attitudes and behaviours,28 and from general psychotherapy, with its broader scope and often longer-term work. Each of these has a useful place, and in general the evidence is good that a skilled psychotherapist trained in a theoretically grounded model delivers effective results irrespective of primary orientation,29 and that the differences between approaches are less sharply delineated in the clinical practice of experienced practitioners than in theory.30 However, the Institute of Psychosexual Medicine’s (IPM) brief, psychodynamic, sex-focused, medically grounded work is particularly suited for the time- and resource-constrained environment of the medical consultation and was described by IPM founder Dr Tom Main, with the wartime analogy: ‘deep penetration on a narrow front’.

Box 45.6 Real-time questions in the psychosexual doctor’s mind

- What, in detail, is the sexual problem? When does it occur and whom does it distress? For example, the answer ‘I love my boyfriend and get aroused, but when I get close to orgasm I burst into tears, and he gets upset, and this puts me off having sex at all’ is more informative than ‘I don’t feel like having sex’.
- When did it all start, and was anything else emotionally significant happening at the time, such as a death, an operation, an affair or a traumatic birth?
- Why is the patient presenting now (e.g. desire for a baby or fear for the relationship), especially when the problem has been long-term?
- How has the patient managed the problem so far, and what can you learn about the patient from this?
- How does the patient behave with you and make you feel (e.g. protective, warm, irritated, frustrated)? How might this relate to the patient’s sexual life?
- How might the feelings or behaviours in the room reflect the patient’s sexual life?
- What might the patient’s body be ‘saying’ or ‘thinking’ that they have struggled to say or think?
- How is the patient responding to the examination or to your interpretive comments?
The psychosomatic tradition and medicine

When the psychic system fails, the organism begins to think – Sandor Ferenczi

Psychosomatic medicine is the study of genuine physical illness caused by mental or emotional rather than biological processes. Wherever the mind is not able to contain or metabolize distress, according to psychoanalytical theory the body takes over and, in Ferenczi’s words, ‘begins to think.’ The more ‘unthinkable’ the thought – be it too painful, shameful or frightening, or simply embarrassing – whether past abuse, ambivalence in relation to one’s spouse or guilt about an affair, the more likely it is to be pushed beneath the surface of conscious awareness, only to burst out in unconscious, somatic ways that present to a doctor and not a psychotherapist. It is helpful if the doctor is alert to this possibility, so that he or she can offer an integrated medical and psychological approach to diagnosis and treatment.

The key idea behind analytical psychotherapy is that restoring hidden distress to awareness, however painful, delivers the patient from the need for his or her neurotic symptom and restores a kind of psychological homeostasis – the psychosomatic equivalent of lancing an abscess or debriding a wound of necrotic tissue, which superficially protects but actually impedes healing. In other words, much like some of the simpler surgical interventions, analysis is symptom and restores a kind of psychological homeostasis.

So, although psychosomatic illness is also treated widely by psychotherapists, some of whom are specialized in a body-centred approach, and to whose academic tradition we owe much of the useful literature on the mind–body connection, it remains a medical concern. This is recognized by the inclusion of these syndromes in the World Health Organization’s International Statistical Classification of Diseases and Related Health Problems as ‘neurotic, stress related and somatoform disorders.’

How do psychosexual problems present to doctors?

Because sex is an intensely private activity, which many people find hard to speak about openly, sexual problems may present directly or indirectly, via an associated physical or psychological symptom, referred to by psychosexual doctors as a ‘calling card,’ such as pelvic pain, recurrent vaginal discharge, difficulty with having a smear test, depression or anxiety. The ritual of excluding organic pathology, while useful in itself, can also be an opportunity for the patient to test the doctor’s perceived suitability to being entrusted with the full story.

Making an assessment can be complicated by the patient’s or the doctor’s feelings of embarrassment in discussing the problem, resistance to considering psychologi-
patient flinch or shrink, become impassive or ‘absent’, or stretch out in an elaborate display of confidence? How does the patient describe his or her experience during and after the examination, and in response to the doctor’s finding? Was the patient less fearful than expected? Is the patient relieved or anxious?

To the general consulting and counselling skills used in good medical and psychiatric history-taking, psychosexual medicine adds some specific skills, learned experientially over a 2- to 4-year period of reflective practice and derived from psychodynamic theory (see below).

The psychodynamic approach is most straightforwardly summarized in Malan’s image of the ‘triangle of person’ (Figure 45.3) in which the patient’s current relationship difficulties both mirror their past relationships (e.g. with parents in childhood) and are echoed in their relationship with the doctor in the consulting room. For example, a patient who has been violently penetrated during sexual abuse by a parent may quite involuntarily resist all penetration, however much needed or desired, by both her partner who wants to make love with her and her doctor who wants to take a swab or a smear test or perform a vaginal examination. The patient may dearly want the intimacy of lovemaking or the reassurance of the examination, and fear the consequences of not being able to tolerate these, but she may find herself unable to allow a penis or a speculum anywhere near her vagina. The ‘echo’ might be detectable in the doctor–patient relationship both in physical ways, involving resistance of examination, and in more symbolic or psychological ways, such as a tendency to shut down or become distressed in response to probing questions. These responses can be noticed.

![Figure 45.3 The psychodynamic triad](image)

In short, the most important clinical tools of psychosexual medicine are those learned from reflected-on experience, rather than those acquired from reading books, even those based on high-quality evidence. Psychodynamic work requires a capacity for symbolization – the decoding of symbolic connections between emotional and physical worlds – and is not suitable for work with people suffering from psychotic illness, in which the capacity for symbolization – with the ‘stepping back’ that this implies – is impaired, and who are likely to experience attempts at analytical work as unhelpful at best and distressing at worst.

Psychosexual medicine uses general communication skills, such as:
- active listening;
- observation;
- letting the patient tell the story in their own way;
- the ability to tolerate silence;
- a non-judgemental attitude;
- an ability to discuss sexual events and body parts in a straightforward and relaxed way.

It also uses specialized psychodynamic skills, such as:
- observation and reflective use of the doctor–patient relationship: noticing how the patient behaves in relation to the doctor, and how the doctor finds him- or herself feeling or behaving in relation to the patient (known in wider analytical psychotherapy as analysis of the transference and countertransference);
- observation and reflective use of body language;
- psychodynamic, interpretive use of the physical, genital examination;
- retaining an awareness of the main thrust of the work: conversation about the sexual difficulty and physical examination and noticing where this is not adhered to, and attempting to understand why not (when is a digression helping to make important connections and when it is acting as a distraction?);
- awareness of the doctor’s defences (e.g. recourse to overly medicalized language or unnecessary investigation or prescription) and interpretation of their relation to the sexual problem;
- awareness of the patient’s defences (e.g. bringing a third party – a mother, baby or partner) to the consultation, or unwillingness to stay with the subject.

(See Table 45.1 overleaf and Box 45.6 on page 749 for a summary.)

## NORMAL AND ABNORMAL

### Normal variants

Variants of sexual expression now accepted as normal include homosexuality (sexual attraction to people of the same sex), bisexuality (sexual attraction to both the opposite and the same sex) and asexuality (no sexual desire at all). The word ‘lesbian’ is widely used to denote female homosexuality, ‘gay’ to denote male homosexuality or sometimes homosexuality in general, and ‘straight’ to denote heterosexuality. There is a worldwide prevalence of between 1.5 per cent and 10 per cent for homosexuality and around 0.1 per cent for bisexuality, with studies con-
ducted by gay rights groups showing higher figures and those conducted by anti-gay campaigners lower figures. In general, homosexuality and heterosexuality appear to exist on a spectrum, with only a large minority of people falling within a totally heterosexual category.7,8

Homosexuality has historically been the focus of widespread prejudice and persecution, ranging from criminalization and the death penalty at one extreme, through widespread legal and social discrimination, to pathologization with a variety of aetiological theories and largely ineffective and humiliating ‘treatments’ applied.

Homosexuality was finally decriminalized in the UK in 1967 and removed from the American Medical Association’s list of mental disorders in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) in 1974, following decriminalization campaigning in the 1960s and the gay rights movement in the 1970s. There is no evidence that homosexuality either predisposes to or protects against psychosexual distress, although its presentation and assessment can be complicated by fear of prejudice. There is some evidence that homosexuality is associated with higher rates of mental illness, suicidality and psychosocial stressors, but as these data are cross-sectional no conclusions as to direction of causality can be drawn.37

Common psychosexual problems

A psychosexual problem by definition involves a level of distress to the individual or within his or her relationship, since there is and can be no legitimate scientific consensus about the ‘normal’ or ‘correct’ nature and frequency of sexual activity between consenting adults. Needs, desires and expectations vary widely. Even an objectively discernible biological problem such as erectile dysfunction or vaginismus becomes a psychosexual problem only when it is causing actual unhappiness. Hence the most useful focus in psychosexual work is a pragmatic one, based on what works and what does not, and what is satisfactory and what is distressing, for the individual or couple concerned.

The prevalence of sexual dysfunction is high – as high as 31 per cent according to population-based data from the USA.38 Against a background of high prevalence and a lack of outcome data on the majority of sexual dysfunction, an evidence-based expert review of the psychological and interpersonal dimensions of sexual function came to the following general conclusions:25

- A variety of biopsychosocial factors may play a role in the development of sexual dysfunctions, including patient variables such as performance anxiety or depression; partner variables such as poor mental or physical health or disinterest; interpersonal non-sexual variables such as the quality of the relationship overall; interpersonal sexual variables such as the interval of abstinence, and specific sexual ‘scripts’ or presuppositions; and contextual variables such as current life stresses, for example involving money or children.
- Despite this recognition, there are few well-designed randomized trials on integrated approaches to the treatment of sexual dysfunctions. The greatest good-quality evidence exists in relation to erectile dysfunction. There is little good-quality research conducted on sexual dysfunction in women.

Because sexual pathology is seldom purely biological, a preformed disorder-based focus is seldom helpful in clinical practice, whatever the presenting complaint. One person’s anorgasmia or erectile dysfunction will have a very different biopsychosocial signature from the next person’s, and hence the most useful stance is one of ‘interested ignorance’. In fact, a central element of psychosexual work is helping the patient to move beyond the collusive reductionism whereby sexual symptoms are assumed to arise from a physical disease that the doctor can ‘fix’, and towards a position where

the patient can understand and begin to modify his or her own problem. However, symptom-based classifications are traditional, have wide currency especially in a research context, and are therefore useful to be aware of.

Sexual difficulties have traditionally been divided into disorders of sexual function, disorders of sexual preference and paraphilias, and disorders of gender identity, each appearing in a different section of the tenth revision of the World Health Organization’s International Classification of Diseases (ICD-10). Functional sexual disorders currently appear in ICD-10 category F5, ‘behavioural difficulties and physical disorders and factors’, while disorders of sexual identity and preference belong to Chapter 6, ‘personality disorders and factors’.

The following list of common sexual disorders is not exhaustive but reflects those seen most commonly in the psychosexual medical clinic: for men, erectile dysfunction, ejaculatory problems and loss of libido; and for women, loss of libido and sexual aversion, dyspareunia. Among men, erectile dysfunction, ejaculatory problems and loss of libido are the most common sexual disorders, while disorders of sexual identity and preference belong to Chapter 6, ‘personality and behavioural disorders’. The following list of common sexual disorders is not exhaustive but reflects those seen most commonly in the psychosexual medical clinic: for men, erectile dysfunction, ejaculatory problems and loss of libido; and for women, loss of libido and sexual aversion, pain during sex, and anorgasmia. Painful sex occurs rarely in men, usually in the forms of ejaculatory pain or anal pain experienced during anal-receptive gay sex, known as anodyspareunia.

**Common disorders of sexual function**

**Erectile dysfunction**

Erectile dysfunction is the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual intercourse. Its aetiology can be biological or psychological but is usually mixed. Its worldwide prevalence is high, with the Massachusetts Male Aging Study quoting a combined prevalence of 52 per cent (17.2%, 25.2% and 9.6%, respectively, for mild, moderate and complete erectile dysfunction), while a more recent Cologne-based study quotes an overall prevalence of 19.2 per cent, rising to 53.4 per cent in older men. It can be acquired or lifelong.

Although benign in a narrow, biological sense, erectile dysfunction is often malign in its effects on quality of life, as well as increasingly recognized as a possible early warning sign of vascular disease, with which it shares common risk factors such as lack of exercise, smoking, obesity, hypercholesterolaemia and the metabolic syndrome. Of all psychosexual disorders, erectile dysfunction is the most intensively researched, and it is the only psychosexual disorder for which effective pharmacological therapy is available.

Erection is a neurovascular function under hormonal control and is susceptible to neurological, vascular, endocrine and psychological interruption (Figure 45.4). Part of the physiological process of erection involves the release of nitric oxide (NO) in vasculature of the corpus cavernosum as a result of sexual stimulation. NO activates the enzyme guanylate cyclase, which results in increased levels of cyclic guanosine monophosphate (cGMP), leading to smooth-muscle relaxation in blood vessels supplying the corpus cavernosum, and resulting in increased blood flow and an erection. Phosphodiesterase type 5 (PDE5) inhibitors inhibit the degradation of cGMP by PDE5, increasing blood flow to the penis during sexual stimulation. This mode of action means that PDE5 inhibitors are ineffective without sexual stimulation.
Both the urological and the psychosexual communities agree on the biopsychosocial nature of most erectile dysfunction and the need for a joint psychological, biological and interpersonal approach to management. This should include addressing modifiable lifestyle factors, optimizing the treatment of any underlying medical or psychological illnesses such as diabetes, obesity or depression, and considering the use of PDE5 inhibitors for symptom relief and psychosexual therapy to address underlying psychological causes.

Pharmacological treatment should not be used without proper investigation and, where possible, treatment of underlying psychological or neurovascular causes, but it can play a helpful role in both short- and longer-term treatment. The three available PDE5 inhibitors work by increasing blood flow to the penis and promoting smooth muscle relaxation (Figure 45.5). The biological efficacy of the PDE5 inhibitors is extremely good, with efficacies of 50–90 per cent measured on validated objective scales such as the International Index of Erectile Function (IIEF). Despite this, 50 per cent of men fail to continue treatment, in part due to failure to address relevant psychological and interpersonal issues.

In general, men with both acquired and lifelong erectile dysfunction benefit from psychosexual interventions, but with greater benefit on average for those who have acquired erectile dysfunction. Masters and Johnson quote significant improvement in around three-quarters of men with acquired dysfunction and around half of men with lifelong erectile dysfunction, with these gains sustained in 2- to 5-year follow-up.

Intracavernosal (injected) or urethral alprostadil is an effective second-line treatment where PDE5 inhibitors are contraindicated or ineffective, but it can be associated with penile pain and, occasionally, prolonged erection. Numerous other prescribed and non-prescribed treatments have been used, but with weak evidence of efficacy, including the α2-adrenergic antagonist yohimbine, a centrally acting aphrodisiac used for more than a century, specific serotonin reuptake inhibitors (trazodone) and red-Korea ginseng. Vascular reconstructive surgery has been shown to have poor long-term outcomes as a treatment for erectile dysfunction of vascular origin.

The role of erectile dysfunction as a possible early warning sign of cardiovascular disease is increasingly clear. With a high prevalence of cardiovascular co-morbidity among men seeking treatment for erectile dysfunction, the opportunity for cardiovascular secondary prevention should not be missed, and caution should be observed in treating those at highest cardiac risk, such as men with recent myocardial infarction or unstable angina, because of the potential risks of sexual activity on the one hand and the effects of PDE5 inhibitors on cardiac smooth muscle on the other hand.

**Ejaculatory problems**

Ejaculatory problems, of which premature ejaculation is by far the most common, are predominantly psychogenic, with only a minority caused by organic disease. Premature ejaculation, or ejaculation that occurs immediately after or even before penetration, is one of the most common forms of male sexual dysfunction, affecting 20–25 per cent of surveyed men in industrialized countries, although prevalence data are fraught with methodological difficulties related to the subjective nature of the definition of ‘prematurity’. Masters and Johnson’s definition was ejaculation that occurred too soon for the partner to reach orgasm, while other definitions have been based on a given length of time in the vagina before ejaculation. For practical, clinical purposes, it is the relationship between speed of ejaculation and the satisfaction of both partners that is deemed important. Although ejaculation is often thought of as the visible manifestation of orgasm, the two are neurologically distinct, and men who ejaculate very rapidly often describe a lack of orgasmic satisfaction.

The problem of premature ejaculation can be compounded by the partner’s frustration and sometimes anger, with secret resentment in both partners.

Premature ejaculation can be a transient problem in adolescence or an occasional event throughout a man’s sexual life course, but for many men who present to psychosexual clinics it is a primary and persistent problem, experienced
continuously since the onset of sexual activity. The causes are individual, and treatment involves their careful exploration, which may include sexual shame acquired in childhood or early sexual relationships, current relationship discord, life stresses, more generalized anxiety, physical or mental illness in the patient or his partner, or unconscious hostility towards the opposite sex.

A number of behavioural techniques help some men to delay orgasm, including the ‘squeeze’ technique, where firm squeezing of the glans penis can delay orgasm, the ‘stop-start’ technique used to introduce space into the process of arousal, and local anaesthetic gels and creams. Delayed ejaculation can be partial or, rarely, complete and associated with anorgasmia. Although it is natural for sexual arousability in men to decline with increasing age, with more stimulation required over a longer period of time, and a decreased volume and forcefulness of ejaculate, and it is unhelpful to ‘pathologize’ this normal trend, a small minority of men have difficulty in ejaculating at all. There is no shorthand checklist of psychosexual causes, men who struggle to ejaculate may also seem highly controlled and lacking in spontaneity in the consultation, and these clues can often point towards difficulty in letting go of other emotions, or having access to their own liveliness in the presence of an intimate partner. They often come from families where the showing of emotion of any sort was not encouraged. Rarely, an inability to ejaculate is accompanied by pain, which is often investigated in a urology or genitourinary medicine clinic to exclude prostatic or seminal vesicle pathology. Even here, the pain often proves to be related to an emotional pain.

**Vaginismus**

Vaginismus describes an involuntary spasm of the muscles surrounding the outer third of the vagina that occurs in response to any attempt to penetrate. When severe, it can also involve the thigh adductors, preventing anyone from approaching the external genitalia. The woman may be seen retreating up the examination couch, clamping her knees together, or she may perch nervously on the edge of the couch, unwilling to adopt a reclining position to allow examination. A woman may or may not describe pain in association with penetration, but often an overriding terror of being touched is sufficiently powerful to preclude any meaningful examination or penetration. She may be well aware that her own muscular contraction is ‘causing the problem’ but nevertheless is unable to prevent this by means of any conscious effort. Her body and her mind are at odds in ways that defeat her, her partner and often her doctors.

Vaginismus is not a disease but a symptom, with a variety of possible physical or, more commonly, psychological causes. These are variable, individual and cannot be summarized in a simple checklist. Sometimes a woman will report an inability to use tampons, indicating an absolute aversion to penetration, whereas sometimes the problem occurs only during sex, suggesting that it is penetration outside of her own control that is the problem. A woman may present with vaginismus directly or, often, in a hidden form referred to by psychosexual doctors as a ‘calling card’, such as recurrent thrush, inability to have a smear test taken, or non-consummation discovered as part of infertility treatment. It is a symptom often laden with fear or shame, or both. It is not uncommon for a woman to speak of feeling guilty towards her partner, and trapped between the terror of penetration and the terror of losing him. High anxiety and a sense of ‘block’ are often palpable in the consulting room.

A woman’s resistance to penetration may express itself in the doctor–patient relationship not only literally, in an inability to allow physical examination, but also metaphorically, in terms of an emotional recoiling or ‘shutting down’ in response to ‘penetrative’ questioning. The gentle analysis of these symbolic behaviours in the consulting room often leads to disclosure of just what or who it is that needs to be kept out, or would once have needed to be kept out but could not be. There may turn out to be connections with current feelings such as anger against the current partner, or past-traumatic experience, such as sexual abuse in childhood; but it is essential to make no assumptions and instead to stick rigorously to the narrative and behavioural evidence presented and observed in the room.

The management of vaginismus usually involves a kind of gentle persistence, in which the doctor neither colludes with the ‘impossibility’ of getting to the heart of things nor attempts to railroad a path through sensitive territory in pursuit of a therapeutic goal. During the course of this, the doctor may experience therapeutic frustration that mirrors the patient’s sexual frustration, and perhaps the patient’s frustration with herself, and may feel inclined either to bully or to give up. The doctor’s capacity to observe his or her own feelings and sometimes to use this observation to make connections with the patient’s or the partner’s experience is an essential part of maintaining the therapeutic connection and staying on course with the diagnostic work. Discovering the mind–body connection, where possible, often affords considerable emotional relief to a woman who has seen her behaviour as ‘senseless’ and can allow her to take over from the doctor and attitude of gentle persistence with herself, to own her own problem, and to find her own way to symptom resolution.

Behavioural methods such as inviting a woman to attempt putting a finger or fingers in her own vagina, either alone or during the examination, can be a helpful addition or alternative to psychodynamic work, by creating a sense of possibility and ‘ownership’. Similarly, graded dilators of increasing sizes can sometimes offer an opportunity to experiment with the possibility of penetration away from the complexity of sexual relating. A 2001 Cochrane review of vaginismus found only three studies, none placebo-controlled, and concluded that evidence from uncontrolled studies suggests that sex therapy may be helpful.
Dyspareunia

Dyspareunia, or painful sex, is reported almost exclusively by women. It may be deep, felt high in the vagina or in the abdomen on deep penetration, or superficial, felt at the introitus at the onset of penetration. It can be momentary or last for hours or even days. Its primary causes can be physical or psychosomatic, but even in the minority of women in whom a biological diagnosis with a straightforward treatment is found it usually has both somatic and emotional consequences. It may present directly or more indirectly as generalized pelvic pain, dysmenorrhoea, inability to have a smear test, or recurrent complaints of vaginal discharge or vulval soreness.

Before psychosexual referral, these women will often have had multiple investigations in a gynaecology or sexual health setting. Because pain is a symptom that strongly invites a medical explanation, it can be challenging to make a psychosomatic diagnosis. The individual doctor may feel considerable pressure to find a physical diagnosis and treatment and, as a profession, we conceal our collective medical impotence in the coining of so-called functional disorders, such as vulvovestibulitis, with multiple aetiological theories, and very limited evidence for the efficacy of biological treatments such as local anaesthetic creams. Although it is important, faced with pain, to remain a physical doctor and consider possible physical pathology such as ovarian or vulval disease or endometriosis, it is also important not to hide behind biological investigations and hypotheses and miss relevant emotional ‘sore spots’.

Psychosomatic dyspareunia does not necessarily need long-term intervention, but it does need a careful physical and emotional history-taking, clarifying the nature and location of the pain, any signs of possible organic pathology, and the meaning and consequences of this pain for this woman. It is important to acknowledge that the pain is real and physical, whatever its aetiology, but also to suggest that feelings might be involved and to ask after these explicitly rather than to make assumptions.

Psychosomatic pain is always individual in origin. It might be a way of holding her partner at bay or expressing anger; it might express grief, loss or fear. Timing of onset can be a clue and perhaps point to pain, anger, grief or fear connected with a life event such as the traumatic delivery of a baby, an abortion, a death, an affair, sterilization, infertility or hysterectomy. In short, pelvic or vaginal pain can symbolize hurt sensitivity arising elsewhere in a woman’s past or present life. At best, brief psychodynamic intervention can spare her years of fruitless and ineffective treatments.

Even dyspareunia of purely physical origin such as infection or cancer may become complicated by emotional distress, such as self-disgust, anger or terror.

Anorgasmia

Anorgasmia presents almost exclusively in women, can be lifelong or acquired, and has no single aetiology. Physical causes, which include hypopituitarism, late-stage diabetic neuropathy and extensive pelvic surgery for cancer, are relatively rare, although anorgasmia can arise more commonly as a side effect of antidepressant treatment with specific serotonin reuptake inhibitors or some antipsychotic medications. Even in these cases, biological and psychological causes are often both present, and there are usually psychological sequelae.

Acquired or secondary anorgasmia may sometime relate to situational stresses such as the presence of children or parents, or relationship difficulties such as loss of trust following an affair. These often respond well to relationship counselling. Lifelong anorgasmia is likely to have a more deep-seated cause and may benefit from a psychosomatic approach, aimed at making connections with wider personality issues or experiences in early life, such as sexual abuse.

Research into adults with sexual difficulties who had been sexually abused as children showed that almost a quarter complained of inability to achieve orgasm. Sexually abused individuals often develop strategies for suppressing sexual feelings that have become fused with painful feelings. The avoidance of the painful memories blocks access to sexual arousal and orgasm. Psychosexual counselling can provide a safe space in which to confront painful feelings with which sexual arousal have become linked, allowing the patient to reclaim her sexuality for her own pleasure.

However, questionnaire surveys also show that, in general, women with orgasmic difficulties tend to have more sex-related guilt, to be less sexually assertive, to endorse more negative attitudes around sexual activity and masturbation, and to be less aware of physiological signs of arousal and orgasm and fear loss of control. Some of these factors are suited to cognitive-behavioural intervention, such as directed masturbation for lifelong anorgasmia, or couples therapy for acquired anorgasmia, or the coital alignment technique used to maximize penile-clitoral contact during male-on-top sex. Research in this area is impeded by misclassification of anorgasmia as arousal disorder.

Loss of libido

Loss of libido, also known as hypoactive sexual disorder, is perhaps the most maddeningly, medically defeating of all sexual ‘symptoms’. With barely an agreed working definition for libido, whether we think of it narrowly as sexual desire or more widely as life-force or creative energy, there is little hope of neatly categorized aetiologies or symptom-specific treatments for its absence. Unlike flaccid penises and tense vaginas, the libido has no bodily locus on which doctor and patient can focus medical attention. True, there are a number of potential physical causes for loss of libido, including drugs, depression and endocrine dysfunction (Table 45.2), but sometimes even treating these causes, such as switching or reducing antidepressant medication, or

*The symptoms of altered sex drive, decreased secondary hair and reduced shaving without changes to the voice, body proportions or penis size would alert the doctor to the possibility of secondary hypogonadism. A single measurement of the morning basal total testosterone, luteinizing hormone, follicle-stimulating hormone (FSH) and prolactin could confirm it.

**Headaches, impaired visual fields, polydipsia and an elevated serum prolactin would indicate a hypothalamic or pituitary tumour.
offering testosterone where levels are low, can leave the loss of libido unchanged.

Loss of libido has a high prevalence of around 30–35 per cent.58 Sometimes, for example where sexual boredom or loss of creativity in lovemaking has become a problem, behavioural approaches can be helpful, such as setting aside child-free time or using sensate focus exercises in which a focus on sexual pleasure without intercourse or orgasm is designed to reawaken a sense of intimacy and pleasure for its own sake. However, evidence for these interventions is mixed and is often based on uncontrolled studies, and they carry a high relapse rate.56–58

Sometimes, intractable loss of libido, ossified into a kind of institutionalized ‘not caring’ about sex, has become the ultimate defence against intimacy in the sexual relationship, and often in the doctor–patient relationship too. Small wonder that psychosexual doctors report high non-attendance rates even in those referred,19 and that those patients who do attend sometimes claim to be there for their ‘partner’s sake’: loss of libido can be ‘not caring’, elaborated into a whole way of life, with ‘heartsink’ potential for both partner and doctor. On the positive side, this symptom leaves us no medical place to hide from the difficult emotional questions. Faced with a patient who is apparently ‘not bothered’ but nevertheless present asking for help in the consulting room, it is often possible to use our perplexity at the mismatch to discover what has made the patient’s heart sink.

There are currently no evidence-based biological treatments for loss of libido in women. Although there is increasing interest from pharmaceutical companies and some clinicians in the use of testosterone, evidence to date for its efficacy, even in women with low testosterone levels, is weak.25

**Rare disorders of sexual function**

**Disorders of sexual preference**

There are no reliable prevalence data on disorders of sexual preference. Clear definition is in any case difficult, because the broad spectrum of ‘normal’ human sexual behaviours and those considered or experienced as problematic or distressing are on a continuous spectrum. There is therefore both a degree of arbitrariness and a widespread consensus about the following categories and definitions.

ICD-10 defines disorders of sexual preference, or paraphilias, as follows:

- The individual experiences recurrent intense sexual urges and fantasies involving unusual objects or activities.
- The individual either acts on the urges or is markedly distressed by them.
- The preference has been present for at least 6 months.33

**Fetishism**

Fetishism is on a spectrum ranging from common and unintrusive sexual preferences such as the desire to see a partner wear a particular item of clothing, through more minority sexual preoccupations such as with leather, rubber or metal, to more extreme fetishes that cause distress to the individual or their partner, either because they involve repulsive objects such as faeces or because they involve illegal activity such as stealing objects.

Fetishes may arise in infancy or around puberty, often in an accidental, circumstantial way, and reinforced by masturbatory conditioning. Sociobiologists emphasize the analogy with ‘imprinting’, such as that seen in animals, whereas psychoanalysts emphasize symbolic meaning of the fetish objects.

Culturally acceptable and essentially harmless fetishes call for reassurance rather than treatment and help in integrating the particular preference into the relationship with a partner. Fetishes serious enough to disrupt wellbeing, relationships and normal functioning may benefit from help from a specially trained psychologist, which often involves masturbatory reconditioning and response prevention. Inhumane treatments used in the past, such as presenting the stimulus along with electric shocks or emetic drugs, are no longer acceptable.

**Paedophilia**

DSM-IV defines paedophilia as a period of at least 6 months of recurrent, intense sexually arousing fantasies, sexual urges or behaviours involving sexual behaviour with a prepubescent child or children (generally aged 13 or younger).

The formal definition also specifies that this must cause clinically significant distress or functional impairment in work or social life. However, for practical purposes, anyone with such urges may be considered a paedophile, since sexual contact with children is illegal and therefore this form of sexual preference is by definition problematic. The definition also specifies that the individual must be over 16 years and 5 years older than the child or children, a measure intended to exclude innocent exploratory behaviour common in prepubescent children, but that does not integrate research showing that sexual abusers of children can often begin early in life.

Aetiological factors include a history of sexual abuse, dysfunctional relationships in the family or origin, neglect, and emotional and physical abuse. Triggering factors often include alcohol use and life stress.

Therapists working with paedophiles report ‘cognitive distortions’ used to justify the behaviour, such as the belief that the activity has not harmed the child, that it was mutually enjoyable, that the child invited sexual contact by seductive behaviour, and that the child was capable of giving consent. There may be a false claim that there was an isolated incident in situations where a clear pattern of ‘grooming’ can be identified.

**Sadomasochism**

Sadomasochism describes sexual arousal or activity where
The infliction of pain or humiliation or bondage plays a key role. Sadism is arousal in association with inflicting pain, while masochism is arousal in association with having pain or humiliation inflicted. Affected individuals often feel arousal in both situations.

**Voyeurism and exhibitionism**
Voyeurism describes a consistent sexual drive towards watching others engaged in sexual activity, or in other intimate activities, such as undressing. Exhibitionism describes the continual or repetitive desire to expose one’s genitals to strangers, usually of the opposite sex, without seeking or desiring any further contact.

**Other disorders of sexual preference**
Other disorders of sexual preference include frotteurism (pressing or rubbing oneself against the bodies of strangers in pursuit of sexual arousal), bestiality (sexual activity with animals) and erotophonia (sexualized telephone calls to strangers).

**Disorders of gender identity**
DSM-IV describes gender identity disorder as:

- a strong and persistent cross gender identification (not merely a desire for any perceived cultural advantages of being the other sex);
- persistent discomfort with his or her sex, or a sense of inappropriateness in the gender role of that sex;
- the disturbance is not concurrent with a physical intersex condition;
- the disturbance causes clinically significant distress or impairment in social, occupational or other important areas of functioning.60

This is almost interchangeable with the ICD-10 classification (Box 45.7). It is a rare disorder with a prevalence of 1 in 40 000–50 000. It is three to six times more common in men wishing to be women than in women wishing to men.61 Its aetiology remains the subject of scientific speculation, but it has a high psychiatric morbidity and mortality, both treated and untreated, with 60 per cent of untreated individuals giving a history of intermittent depression and up to 20 per cent suicide attempts.61 Its management should be undertaken by specialists in this area, but it is important that other clinicians are able to encounter it with awareness and sensitivity. It is helpful to bear in mind the following:

- True gender identity disorder is by definition persistent and associated with profound distress and high psychiatric morbidity and mortality. It is important not to diminish or dismiss it.
- It must be distinguished from homosexuality, transsexuality and transient psychosis, in connection with personality disorder, and simple non-conformism with gender expectations without a disorder of gender identity.
- It is often associated with a strong wish for hormonal or surgical gender reassignment treatment, the achievement of which is often associated with a strong self-reported improvement in wellbeing. However, reliable long-term outcome data on such procedures are lacking.
- Treatment involves careful assessment by a psychiatrist with special expertise and involves specialist psychotherapy, a 1-year observation period to establish the constancy of the transgender wish, a trial period of a

Sex and illness

Sexual function can affect and be affected by mental or physical illnesses and their treatments, either in direct physical ways or in psychologically mediated ways. It is important therefore to consider past medical and psychiatric history and drug history in a psychosexual medical consultation, even if these are subsumed in a psychotherapeutic approach to history-taking. Occasionally, optimizing or adjusting the treatment of a coexisting condition such as depression, diabetes or endometriosis will be the primary or sole treatment for sexual dysfunction. More commonly, these factors will form a part of a more complex picture, in which the clinician’s role is not so much to identify a single problem to treat as to find the most promising starting point in untangling a knot of problems. It may be a question of deciding whether a woman presenting with dyspareunia following traumatic childbirth has vaginal scarring, psychological scarring amenable to psychosexual treatment, or severe enough psychological disturbance to warrant a diagnosis of post-traumatic stress disorder and/or psychiatric intervention.

A particular example is depression, which is very commonly associated with sexual dysfunction, in ways that can be complex. Depression can cause sexual dysfunction, such as loss of libido; but chronic sexual dysfunction and relationship strain can also cause or worsen depression. In addition, antidepressant and antipsychotic medications can cause sexual dysfunction such as anorgasmia secondary to treatment with specific serotonin reuptake inhibitors, which may in turn worsen depression or undermine adherence to treatment. A holistic view of the patient’s global situation is essential for all concerned.

Finally, although our concern as doctors is traditionally not so much with the meaning as with the elimination of disease, we cannot escape the meanings diseases have for our patients, their families, their sexual partners, ourselves as their doctors, and society at large. Experiences such as cancer, AIDS, sexually transmitted infection, menopause, hysterectomy and sterilization can impact on lives, biologically and emotionally, non-sexually and sexually.

SUMMARY

Recognition that sexual problems usually include biological, psychological and social aspects and are best addressed in a holistic or a multidisciplinary way is now widespread. Appropriate treatment may be medical and/or psychological and may include urological, gynaecological or sexual health assessment, the treatment of any coexisting physical or mental illness such as diabetes, cancer or depression, behaviourally based sexual therapies, wider psychotherapy or counselling, and psychosexual medicine, which is a British manifestation of a psychosomatic approach. The right route of referral is not always immediately obvious because it is not dictated solely by the presenting complaint; rather, it may suggest itself from more detailed sexual and psychological history-taking. Where clear relationship difficulties or unhelpful attitudes or behaviours are revealed as a likely primary problem, behaviourally based sex therapies are often helpful. Where sexual problems are part of wider, long-term psychological distress, psychotherapy, if available in a National Health Service (NHS) setting or affordable privately, may be the most useful. Where both medical and psychological assessment are needed in parallel, or where the medical and the psychological aspects cannot readily be distinguished, psychosexual medicine, with its integrative approach, can play an important part.

KEY POINTS

- Sexuality involves both mind and body, and understanding it requires an integrated approach, both clinically and academically.
- Most sexual problems have either emotional or mixed emotional and physical causes; all have both physical and emotional consequences.
- Rarely, a sexual problem is attributable solely to organic pathology. More commonly, it may be an early warning sign of physical disease (erectile dysfunction and cardiovascular disease). Although psychosexual medical work is often psychologically focused, physical pathology must always be considered.
- Physical and psychiatric co-morbidity are common, and sexual dysfunction and other illadies and their treatments can exacerbate each other. Maintaining a holistic overview is important.
- There is a dearth of high-quality outcomes research on sexual dysfunction, particularly in women.
- Psychosexual medicine offers a psychosomatic approach to the diagnosis and treatment of sexual dysfunction and draws on both medicine and analytical psychotherapy. It addresses the mind–body connection within an individual, predominantly, although couples work can be offered. It is particularly helpful where there is a strong physical or potentially medical element to the presenting problem. Training and registration are overseen by the Institute of Psychosexual Medicine.
REFERENCES

INTRODUCTION

Throughout this chapter the terms ‘male’ and ‘female’ refer to sex assigned at birth.

Disorders of gender identity require a more multidisciplinary input than any other disorder in psychiatry. Endocrinologists, speech and language therapists and surgeons (ENT, plastic, urological) are routinely involved. Further, the field is highly politicized, attracting much public fascination and arousing strong opinions.

Disorders of gender identity have probably always existed, inside and outside Europe. The incidence of transsexualism is very roughly one in 60,000 males and one in 100,000 females, and it seems to have remained constant. There is the suggestion that there may be a raised rate in Polynesian people, possibly related to a greater incidence of partial androgen insensitivity syndromes (Dr Herbert Bower, personal communication, 2000).

CLASSIFICATION

Currently, in the International Classification of Diseases, version 10 (ICD-10), disorders of gender identity are classified as disorders of adult personality and behaviour, and comprise the following:

- 64.0 Transsexualism
- F64.1 Dual-role transvestism
- F64.2 Gender identity disorder of childhood
- F64.8 Other gender identity disorders
- F64.9 Gender identity disorder, unspecified.

DIFFERENTIAL DIAGNOSIS

Important differential diagnoses include fetishistic transvestism, dysmorphophobia, autogynaeophilia and some of the other disorders of personality or sexual function. Occasionally, psychoses may present in such a way as to resemble a gender identity disorder and, increasingly rarely, male homosexual or lesbian people may present as transsexual.

AETIOLOGY

It is not clear what causes disorders of gender identity. Originally, hypotheses about causation addressed psychological factors and came mostly from a psychoanalytical perspective. Over the decades, though, what evidence there is has suggested a multifactorial aetiology, with biological factors rising in importance.

It is known that there is a raised rate of disorders of gender identity in people with Kleinfelter’s syndrome. It is also known that males with disorders of gender identity are more likely than chance would allow to be left-handed and to have particular aptitude with computers (Dr Stephen Whittle, personal communication, 2002). Their family trees show a relative lack of maternal uncles, and they are more likely to come from lower down a male birth order. One hypothesis arising from these findings supposes that, in these families, women mount an immune response to a Y chromosome in pregnancy, the titre rising with each successive male pregnancy.

A single, small, postmortem brain study showed a female-sized bed nucleus of the stria terminalis in males with transsexualism. Although interesting, this study had
no control group of homosexual males without gender identity disorder, and the finding might have been caused by earlier treatment with hormones.9

It should be noted that nearly all these curious findings do nothing to address the genesis of gender identity disorders in females. In their case, there is the clinical suspicion that polycystic ovarian syndrome rates may be raised, but this remains statistically unproven.9

There is still no overarching hypothesis drawing these disparate findings together. This might, of course, simply reflect a multifactorial aetiology.

**PSYCHOPATHOLOGICAL ASPECTS**

There is a public and to some extent a general psychiatric perception that transsexualism is the only or at least the main disorder of gender identity. This is probably illusory,10 but the illusion persists in part because most dual-role transvestites do not come to the attention of psychiatric services. Certainly, transsexualism is the diagnosis for which most treatment evidence is available. There is little research into dual-role transvestism, nor much into dysmorphophobia or autogynaephilia presenting as or relating to a gender identity disorder,11–15 even though these are important differential diagnoses and there is the suggestion that non-transsexual disorders of gender identity are more associated with psychopathology.16 These differential diagnoses may require different management from transsexualism.17

Originally, problems with gender identity were thought to represent severe mental illness. Most of the abnormalities detected were character disorders, but a significant proportion of patients were thought to have schizophrenia.6,18

Larger, more recent studies show that fewer than 10 per cent have problems associated with mental illness, genital mutilation or suicide attempts.19 Studies now generally support the view that transsexualism is usually an isolated diagnosis and not part of any general psychopathological disorder.20 Similar results are found in adolescents, supporting the idea that major psychopathology is not required for the development of transsexualism.21,22 It seems that the earlier findings might have represented a sampling bias.

On the other hand, though, the inference in the current diagnostic classification that other psychiatric disorders be excluded may mean that the populations actually referred to gender identity clinics have been filtered, so that there is an artificially lower rate of psychopathology in these clinic populations, falsely suggesting a low rate of psychiatric co-morbidity.

Transsexualism has important differential diagnoses, all of which may cause gender dysphoric feelings.

Some homosexual men and lesbians may present with claims of transsexualism15,23 and have, of course, no psychiatric diagnosis. The most frequent formal differential diagnosis is of transvestism (dual-role or fetishistic), but the others include psychoses and mood disorders.21 Autogynaephilia may also present. This is the state of being sexually aroused by the idea of having both male and female sexual attributes (usually breasts and a penis). Autogynaephilic males usually seek oestrogen treatment to elicit this effect. Such treatment diminishes the libido that gives rise to the very desire itself, and autogynaephilia may wane over time, only to be replaced by another unusual sexual drive. For these reasons, autogynaephilia is not usually an indication for oestrogen treatment.23

Rarely, partial androgen insensitivity syndromes may cause cross-sex identification, and males with these syndromes would qualify for a diagnosis of gender identity disorder (not otherwise specified) because there is an abnormality of endocrine function. These syndromes can be detected only with the endocrine expertise and complex pathological testing offered by a gender identity clinic. They cannot be detected if hormone treatment has already started. The presence of a partial androgen insensitivity syndrome does not greatly alter the subsequent management of the affected patient, but it is important because, as inherited conditions, they may affect the sons of the patient’s sisters. Genetic counselling may be indicated.9

**MANAGEMENT**

The treatment of disorders of gender identity may be drastic and irreversible, and so treatment should be undertaken only in a setting of diagnostic certainty.

The least certain diagnosis is that made by the patient, made as it is without any training or objectivity. This uncertainty is not lessened by the patient’s high degree of conviction. Neither does the support of others with gender dysphoria help, since conviction leads people to associate with like-minded others and to discount or fail to seek out incongruent views.

Local psychiatric services are only slightly better placed to make a diagnosis, having objectivity but not experience or much training. Accordingly, diagnoses should properly be made by gender identity clinics. Internationally accepted guidelines stipulate that at least two experienced diagnostic opinions are required before any patient undergoes gender reassignment surgery. It seems sensible to have the same degree of safety in the earlier stages of treatment because an initial diagnosis leading to a change of social gender role has serious social implications, and hormone treatments (particularly in females) have many irreversible effects.

People who present at a gender identity clinic usually state that they have transsexualism and seek immediate treatment with hormones or surgery, or both. They may arrive at this point from any of a number of rather distinct earlier trajectories.

Considering male patients in whom differential diagnoses have been excluded, the most common history is that of...
earlier dual-role transvestism, often preceded by fetishistic transvestism. Such sexual interest as there is (it is usually slight) is directed towards females. As time passes the patient begins to feel fake and unreal in a male rather than a female role.21

A smaller proportion of male patients would earlier have been seen by others and themselves as feminine homosexual men, again with a low libido, with a liking for wearing female clothes. As time passes their femininity grows, and they begin to feel more female than feminine, and to be regarded as such in homosexual male circles.22

Female patients often give a history of having earlier been viewed by others, and less often themselves, as masculine lesbians. Their sense of masculinity becomes so overwhelming that they come to identify as male. A change of social gender role may denude such patients of much of their social circle.24

A small number of female patients show a sexual preference for males, but they are interested in homosexual men and identify themselves as such.24

A small proportion of patients seem to have displayed a sense of cross-gender identification from their earliest years and either attracted or could have attracted a diagnosis of gender identity disorder of childhood. Many patients make this claim, only for documentary evidence or the testimony of relations to refute it, or alter it to a history of childhood tomboyism or unmasculinity, which is a very different matter.24

Children and adolescents with gender identity disorders pose particular problems. Instinctive caution has led to surgery and hormones being delayed, although all the evidence is that with carefully selected patients early surgical intervention carries a good outcome.25 There is a trend towards postponing puberty by means of gonadotropin-releasing hormone (GnRH) analogues and introducing cross-sex hormone treatment when the child is able to give valid consent. There is the suggestion that, for males, earlier age of onset of transsexualism was associated with better outcome,17 which may reflect ‘core’ transsexualism. The question is rendered more problematic by a study that followed up ten ‘feminine’ boys, of whom only one became transsexual and four heterosexual. Childhood gender dysphoria appears to be a necessary but not sufficient factor in a transsexual outcome. The strength, rigidity and persistence of cross-gender behaviour through latency were thought perhaps to predict transsexual outcome.26

It is a cardinal principle in a gender identity clinic that reversible changes should precede irreversible changes and that no step should be undertaken unless the preceding steps have been accompanied by psychological and social improvement.

It follows from this that the first step should be a change of social gender role. This involves the patient changing their name to one clearly appropriate to their preferred gender role, and altering all their associated civil and legal documentation. They should make it clear to everyone that they have changed their social gender role. People doing this are protected from discrimination in the workplace and elsewhere by UK legislation (Sex Discrimination Act, amended 1999).

There is no evidence that providing hormone treatment before a change of social gender role makes such a transition easier or more likely. Rather, it may give rise to a seemingly endless drive for ever higher doses of hormones, each increase failing to diminish the patient’s anxieties about changing role. If the change of role does not occur, or the desire to change role dissipates (as it may, despite the patient’s earlier certainty that this will not be the case), the patient may be left with unwanted, irreversible bodily alteration.27 Consequently, it is reasonable to undertake treatment with cross-sex hormones only if both a proper diagnosis has been made by an appropriately trained and experienced clinic, and a change of social gender role has been achieved satisfactorily. Clearly, such treatment varies with the birth sex of the patient.

The mainstay of treatment in male patients is high-dose oestrogen therapy. This treatment is acceptably safe provided the patient is a non-smoker and has no history of thromboembolic disease, since the major risk is that of thromboembolic problems.9,28 In younger patients, treatment may need to be augmented by a GnRH analogue to suppress native androgen production. This is preferred to cyproterone acetate, because cyproterone acetate may cause deranged liver function tests, depression, lethargy and fatigue – seemingly more commonly in the context of gender identity disorders than that of prostate cancer.29

The oestrogen dose should be increased progressively over about a year to maximize eventual breast size. The use of high doses from the outset is associated with rapid onset of breast growth but the eventual development of small, hard, conical breasts whose size cannot be increased by any further hormonal manipulation.30

This treatment requires 6-monthly monitoring of serum lipids, prolactin and liver function tests, since, rarely, these may be deranged.

There is no role for progesterone because it seems not to have any feminizing effect, and it probably serves to slightly raise the risk of breast cancer.9

Oestrogen treatment causes modest breast development and even more modest reduction in facial hair growth. Androgen levels almost always fall, and the already small libido further diminishes (usually a welcome effect). Appetite is increased, and so weight gain is a common problem. There is no change in vocal quality, so speech and language therapy may be indicated.25 If this is not fully successful, it may be augmented with a cricothyroid approximation to alter vocal quality.30 This procedure is effective only if followed up with further speech and language therapy.

Born-male patients display feminization on top of an earlier masculinization caused by puberty. Consequently, most end up looking sufficiently female that, if they present
in a clearly female role, others feel inclined to treat them as women. Nearly all would be detectable as having been born male.

Female patients require treatment with androgens, either by imprint or by intramuscular injection. Oral treatment is anecdotally associated with a raised rate of hepatocellular carcinoma. It is thus ethically and legally challenging to use oral agents.³

Androgen treatment causes marked virilization. The first effect is an increase in libido, followed by cliteromegaly and facial and body hair growth. Vocal pitch steadily decreases to that of a male. Menstruation almost always gets less, and menopause is usually achieved within the first 6 months of treatment. Androgens also increase appetite, and so weight gain may be a problem. Muscle mass increases only if there is considerable exercise.³

Androgen treatment is very effective, and most born-female patients end up so masculinized that others would not suspect that they were born female save, perhaps, for unusual shortness of stature.

Although it is inappropriate for hormone treatment to start without the assessment and approval of a properly established gender identity clinic, it is best for prescription and administration to occur in a primary care setting because such treatment is likely to be lifelong and is not challenging or unduly hazardous.

Surgical procedures are not contemplated unless the patient has lived and prospered in their assumed gender role, showing psychological and social function that is at least as good as in their former role, and preferably better. A useful means of determining this is noting whether the patient can undertake an occupational role (consistent with their abilities) for at least a year. This can be verified and gives a good measure of social acceptance in the new gender role. It is sometimes termed ‘the real life experience’.³¹

Born-female patients may sometimes be considered for bilateral mastectomy after having lived in a male role for a year, whether or not they have been occupied, because large breasts are a significant impediment to passing successfully as male. This procedure is not ‘cosmetic’ in the sense that most breast surgery for non-malignant conditions is. Rather, it is more akin to surgery for severe and intractable gynaecomastia in a young male. The psychological and social benefits of bilateral mastectomy in this setting are considerable.³²

Genital surgery varies with the birth sex of the patient. It is not contemplated until there has been a successful life in the assumed gender role for at least 2 years.

Genital surgery for born males always includes the following:

- Penectomy
- Bilateral orchiectomy
- Cliteroplasty
- Vulvoplasty.

Vaginoplasty is usually included, but patients who have no desire for penetrative sexual relations, or no desire to form any sort of sexual relationship at all (particularly if older or in less good health), may be better served by this procedure being omitted. The absence of a vagina could be detected only by the most detailed of genital inspections.³³

These procedures are usually completed in one stage, with the occasional need for very minor revisional procedures. Hospital in-patient stay is typically 10 days, with a convalescence of 2 months.³⁴ The results are very effective. At least one patient has been undetected by her general practitioner (GP) and boyfriend of 9 years. Another was undetected in the course of several lesbian relationships.³⁵

Genital surgery for born-female patients (phalloplasty) is much more complex and usually comprises multiple stages. The new phallus must be constructed with material harvested from another part of the same patient. Usually the abdominal or forearm skin is used. Placing a urinary conduit in the phallus is challenging. Erectile capacity can be bestowed only by means of implanted hydraulic devices, and this, too, is challenging.³⁶

The results of phalloplasty are improving all the time but would still be detected as an artificial construction by any but the most brief of glimpses. Only about a third of born-female patients opt for phalloplasty, the remainder choosing to wait until techniques improve or until their life circumstances will allow the time off work that such surgery inevitably entails.

The results of genital surgery have been subject to investigation since, as patient numbers have grown, it has become possible to properly assess the psychological and social outcomes and to relate these to features of the patients’ presenting histories.

The effects of a social gender role change and the timing of surgery were addressed by fully controlled studies, which established that a change of role improved psychological function, and that, once patients had been approved for surgery, those fast-tracked showed better psychological function than those who joined a standard waiting list.³⁷,³⁸

The functional results of gender reassignment surgery have been assessed in sexual and cosmetic terms. There was general satisfaction expressed over the quality of cosmetic and functional aspects, despite orgasmic capacity after gender reassignment surgery declining in male patients and increasing in female patients.³⁹-⁴¹ Despite the decrease in orgasm in males, satisfaction with sex and general satisfaction with the results of surgery were high in both.³²

There have been good outcomes in very disparate settings,³³,³⁴ and the strong suggestion from several studies that the technical success of surgery and a subsequent legal recognition of a change of sex relate strongly to good psychological and social outcome.³⁵,³⁶ Indeed, in one study, technical surgical outcome accounted for nearly all the variation in postoperative psychopathology.³⁷,³⁸

It seems increasingly clear that psychological support is needed after surgery in order to optimize outcomes, since
social stressors may persist despite treatment, particularly if the patient has children. There is no evidence that a change of parental gender role has any effect on the sexual development of children. Despite this, many patients have experienced impaired access to their children on the grounds of their change of gender role.

PROGNOSIS

Analysis suggests that female patients tend generally to fare better than do male patients. Regrets about gender-reassignment surgery are associated with poor family and friend support, a lack of an earlier history of childhood gender identity disorder, a lack of attraction to the same biological sex, personality disorder and axis II diagnoses. Completed military service, a history of typically ‘masculine’, hard jobs, and a comparatively late (older than 30 years of age) first request for surgery were also found to be negative prognostic factors in sex-reassignment evaluations. It was thought that both too much and too little ambivalence may suggest a poor prognosis.

LEGAL ASPECTS

The Gender Recognition Act allows people who have changed their gender role to acquire a gender recognition certificate and, if they have a UK birth certificate, a birth certificate in their assumed gender. Applicants must have the support of a recognized specialist and another registered medical practitioner (usually their GP) and need to have lived in their assumed gender role for at least 2 years. They are not absolutely required to have undergone hormone treatment or gender reassignment surgery, but there seems to be a need for a good reason for not having done so. Applications are made to the Gender Recognition Panel (PO Box 6987, Leicester LE1 6ZX; tel: 0845 355 5155; www grp.gov.uk).

Anyone with a gender recognition certificate is legally of their new sex, just as if they had been born so. If they have children they will remain a parent in the original sex. Adoptions would be in the new sex, so it would be possible for the person to be both a father and a mother.

INTRODUCTION

The term 'paraphilia' is from the Ancient Greek for 'irregular love' – that is, an attraction or love (philia) of the irregular (para). It implies being outside the normal range in the sphere of sex. This is an emotive area; before its discussion, it is standard to issue the formal disclaimer, if not in the words of English actor Patricia Campbell in the first half of the twentieth century that 'It doesn't matter what you do in the bedroom as long as you don't do it in the street and frighten the horses', then at least that any particular sexual behaviour done in private, and not causing harm to self or others, does not necessarily constitute a psychiatric disorder and a need for psychiatric treatment. What has constituted a paraphilia has varied through history. For instance, sexual orientation towards members of one's own sex is not considered a paraphilia nowadays, but homosexuality was listed as a psychiatric disorder in the eighth revision of the International Classification of Diseases (ICD-8). A further consideration in this area is the difference between psychological theories of sexual development, such as those of Freud – who, of course, did have theories about, for instance, homosexuality, including that it was not appropriate for a psychoanalyst to be either homosexual or bisexual – and political arguments – for example, about non-discrimination towards individuals not causing harm to others.

NORMAL SEXUALITY

This can be defined as that approved by society, but it varies from country to country, through history and between social levels. For instance, 300 years ago it was common in the UK for 12- to 13-year-olds to become pregnant. An alternative definition is that which is statistically common. In fact, there is a far greater width of sexual activity than is usually recognized.

Alfred Kinsey, Professor of Biology at Indiana University in the USA, amazed the general public of the USA with the results of his studies commenced in 1938. In 1948 he published Sexual Behaviour in the Human Male after interviewing 5300 males, and in 1953 Sexual Behaviour in the Human Female after interviewing approximately 6000 females. It was these studies, although now criticized for selection bias, that highlighted high rates of premarital sexual intercourse before the age of 20 years (73% in males, 20% in females) and the high rates of infidelity within marriage (50% of males). It also highlighted that males reached a sexual peak during late adolescence while for females it was in their thirties.

Differences in sexual behaviour between cultures have been well described by anthropologists. Homosexuality was accepted in Ancient Greek and Roman times, was repressed in Elizabethan times, and is still a criminal offence in some parts of the world, but, although never the norm, it has been expected of young boys with their elders before marrying in cultures such as in New Guinea, apparently not resulting in any post-traumatic stress disorder, perhaps because of its cultural acceptability. In the past, in some specific cultures, such as in Tahiti as described by Robert Louis Stevenson, and in the Arctic, it was considered hospitable for visitors to be offered the host’s wife or daughter as a sleeping companion for the night.

An important milestone in the clinical literature of paraphilias was Richard von Krafft-Ebing’s 1887 book Psychopathia Sexualis, which was translated into English from the German. Krafft-Ebing, a neuropsychiatrist, provided detailed case histories of paraphilias comparable to those described in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), but also including flagellation, lust murder, necrophilia, bestiality and incest.

The terms ‘sexual deviance’ and ‘deviant (perverse) sexual behaviour’ now have rather pejorative and moralistic implications, akin to the terms ‘imbecile’ and ‘idiot’, which previously were legal terms for a person with learning disability. Paraphilias are also termed ‘sexual minority practices’, which highlights the associated psychology of being in a minority. The characteristic features include:

- deviation from a primary adult sexual drive;
- tendency to avoid procreation;
- characterized by its persistence and preference over normal adult sexual behaviour. It is not uncommon that some normal adult sexual behaviour occurs in people...
with a paraphilia. On the other hand, elements such as voyeurism and exhibitionism, and even fleeing sadism, may be present to a lesser degree in normal sexuality;
- often unable to relate adequately to adults;
- often has a cathartic (emotional releasing) function such as that seen in self-harm.

It is important to distinguish paraphilias from facultative deviation due to unavailability, usually transiently, of normal sexual contacts, such as in institutions such as prisons.

Another useful clinical concept is that of a latent perversion, which is generally well compensated for and becomes apparent only under stress, for example in marital conflict, certain circumstances or disinhibition by alcohol or drugs, or is released by mental illness, such as depression. Indeed, perverse behaviours can sometimes be seen as acting as self-esteem or mood regulators. Latent perversion represents regressed, as opposed to a fixed, deviation.

Sexual behaviour is motivated by a desire for affection and a need to belong, and not merely for orgasm. A useful analogy is that of a barrier or wall due to anxiety in forming adult relationships. If the wall is too big, then the individual may:
- turn away (paedophilia, fetishism);
- peek over (voyeurism) or stand on the wall (exhibitionism);
- reach over and touch (frotteurism, indecent assault);
- crash through by force (rape).

Paraphilias or disorders of sexual preference should be distinguished from gender dysphoria, which is varying degrees of dissatisfaction with the current sex gender, including transsexualism. The strength of sexual drive is determined by biological factors and follows androgen levels in males and females, but gender role, identity and direction of sexual interest are determined largely by psychological factors. Before 1 year of age, it is simple to reassign sex correctly, such as in cases of hypogonadism, but this is almost impossible after 5 years of age – that is, between 1 year and 5 years, gender role is established by cultural expectation, whatever the actual genetic sex.

Androgen-insensitivity syndrome (which occurs in 1 : 30 000) results in a male appearing female, while congenital adrenal hypoplasia (which occurs in 1 : 6000) leads to increased levels of testosterone, resulting in a female appearing male.

Sexual orientation, for example homosexuality or bisexuality, is not now regarded as a disorder in the tenth revision of the International Classification of Diseases (ICD-10) or DSM-IV, unless it is egodystonic (ICD-10 F.66.1).

Non-paraphilic sexual addictions

These are culturally acceptable sexual interests and behaviours but so intense or frequent that they interfere with sustained intimate relationships, for example:
- compulsive masturbation;
- repetitive promiscuity (using people as sex objects, use of prostitutes);
- dependence upon anonymous sexual outlets, e.g. pornography, including on the Internet, or telephone sex.

They have been conceptualized as:
- addictions;
- compulsions;
- hypersexuality;
- disorders of impulse control;
- depressive equivalent, especially in the presence of (i) an affective disorder, which itself causes a disorder of sexual regulation, leading to an increase in non-conventional sexual interests and an increase in desire equivalent to bulimia nervosa, which also shares comorbidity with depression and responds to antidepressants; or (ii) an obsessive–compulsive disorder (OCD) variant. Treatment with fluoxetine (20–60 mg/day), a selective serotonin reuptake inhibitor (SSRI) antidepressant, which is also anti-obessional, anti-impulsive and anti-aggressive, has been recommended as effective. This would theoretically be beneficial for (i) or (ii) above.

Obsessive–compulsive disorder

In contrast to paraphilias, in OCD, as defined in ICD-10, the thought of carrying out the act must not in itself be pleasurable, even if it brings temporary relief of tension and anxiety.

PARAPHILIAS

The DSM-IV defines paraphilias as recurrent, intense, sexually arousing fantasies, sexual urges or behaviours generally involving (i) non-human objects, (ii) the suffering or humiliation of oneself or one’s partner or (iii) children or other non-consenting people that occur over a period of at least 6 months (criterion A) and cause clinically significant distress or impairment in social, occupational or other important areas of functioning (criterion B) – that is, not part of normative sexual arousal patterns and interfering with capacity for reciprocal affectionate activity.

Paraphilias are often experienced by the individual as insistent, demanded and fixated. The person may say they will never behave sexually in that way again but then do so in spite of law involvement and the potential risk to the self or others. They often describe an inability to stop paraphilic behaviour, unless someone externally intervenes, and also a feeling of altered consciousness at the time, which perhaps reflects high sexual arousal or dissociation.

In ICD-10, ‘disorders of sexual preference’ is the term used in preference to ‘paraphilias.’ Table 47.1 describes and contrasts the types identified in ICD-10 with the paraphilias described in DSM-IV.
Aetiology of human sexuality

ICD-10 points out that more than one disorder of sexual preference may occur in one individual, fetishism, transvestism and sadomasochism being the most common combination.

**AETIOLOGY OF HUMAN SEXUALITY**

Exact aetiologies of human sexuality are unknown. Most authorities speak of a combination of constitutional and acquired characteristics, and all schools have contributed observations and theories that help our understanding. In spite of psychodynamic interest, sex is one of the most biological of human functions. As with other branches of medicine and biology, the importance attached to nature and nurture has varied over time.

**Constitutional factors**

**Genetic factors**

It appears that genetic factors do have a bearing on the development of human sexuality, as shown by work on sexual orientation. Kallman originally reported 100 per cent concordance for homosexuality in monozygotes. However, as he noted, his population comprised mentally ill institutionalized men and he later considered these figures to have been statistical artefacts. Numerous discordant monozygotic pairs have been reported.

Eckert and colleagues, after studying monozygotic twins reared apart, found some concordance for male homosexuality but none for females. Bailey and Pillard have found concordance rates for homosexuality of 52 per cent in monozygotes and 22 per cent for dizygotes compared with a rate of less than 10 per cent for non-twin biological brothers. Such work has also been replicated on female homosexuals. Other authors have found lower concordance rates. Family studies have suggested that sexual orientation is inherited through the maternal side – that is, possibly X-chromosome-linked, expressed in men but carried by women. Hamer and colleagues found that 33 of 40 pairs of homosexual male siblings had five shared markers on the distal arm of the X-chromosome (Xq 28 locus for sexual orientation, \( P = 0.00001 \)). It is unlikely that there is one ‘gay gene’. There are probably many and none absolute. Also, twin studies have shown that half or more of variability on sexual orientation is not inherited. Overall, large discordant rates for paraphilias have been found in spite of the same genes and environment.

Kleinfelter’s syndrome, due to the chromosomal abnormality XXY, has been associated with not only psychosexual infantilism but also increased rates of paedophilia.

**Hormonal influence on the prenatal brain**

Harris and Levine have shown that androgens in very young animals given at critical periods affect their normal rough-and-tumble play and their adult sexual behaviour, which leads to a similar theory for the case of humans. It has been theorized that the basic human brain is female; exposure to androgens, due to the Y-chromosome, leads to the differentiation to a male brain. However, there is no clear evidence for this leading to paraphilias in humans, even for those exposed to large doses of exogenous hormones prenatally.

**Hormone levels**

There is no evidence for differing levels of testosterone in paraphilias or homosexuals in spite of previous claims. Hormones have more complex effects. High testosterone levels are, however, associated with aggression, which is linked to limbic pleasure centres, perhaps accounting for the association of sex and violence.
Neuroanatomical basis
Brain damage has been suggested as a possible biological basis for paraphilias, perhaps by affecting perception of erogenous zones, although these themselves vary in importance across cultures. People with temporal lobe epilepsy have an excess of sexual dysfunctions, including paraphilias.

A biological basis is also suggested by the great resistance of paraphilias to change.

Environmental factors
Although often cited as aetiological factors in paraphilias, the evidence base is weak. Factors cited include the following:

- Unsatisfactory or absent father
- Overprotective or close-binding intimate mother
- Child’s temperament and health leading to the mother being overprotective
- Analytical theory: paraphilias are seen as resulting from desires, real or fantasy experiences or conflicts at particular stages of psychosexual development at which the individual becomes fixed. Ego defence mechanisms are regarded as important. Paraphilias may also be seen as a solution to castration fear during the development of infantile sexuality. Although society views sexuality as a phenomenon that follows the onset of puberty in adolescence, sexuality is not only present through the so-called Freudian latent period but also is evident in the womb, where the fetuses can be seen to be masturbating
- A solution to the problem of relating normally and forming adult social relationships: in monkey colonies, low-dominance monkeys adopt a passive sexual position in relation to high-dominance monkeys. In humans, dominance is affected by mood and environmental stress. Maternally deprived monkeys not only develop into sexually incompetent adults but also exhibit sexual minority practices akin to paraphilias
- Behaviour theory: paraphilias can be understood in terms of learning theory, e.g.
  - training by family;
  - conjunction of a neutral object with sexual arousal or reinforcement.

First sexual experiences can be important. Childhood sexual abuse is associated with paedophilia. US students were conditioned to develop a foot fetish by pairing slides of boots with those of nude women. However, clinically, learning theory seems an insufficient total explanation for paraphilias. Cultural factors, symbolism of objects, deficiencies in normal sexual arousal, and deficits in social skills and social anxiety may all be relevant.

Paraphilias or disorders of sexual preference are more common in males. Theories why this may be so include the following:

- Male children have to separate from the mother and move to identify with the father.
- The basic template of the brain is female, from which the male brains may be unsuccessfully modified.
- Visual aspects may be more important for males compared with the overall relationship for females. Males also self-evidently have an external visual feedback organ – the penis – of sexual arousal.
- Different gender roles: males are more likely to make advances; females are more submissive. This may merely be cultural.
- Male perverse acts are aimed at external part objects. Equivalent female perverse acts are aimed at themselves, e.g. self-mutilation, anorexia nervosa, or objects of own creation (babies). Male external genitalia symbolically reflect externalizing of aggression and alcohol abuse. Female genitalia symbolically reflect the turning-in of the equivalent of female perverse acts.

Interactional model
An interactional model (Figure 47.1) provides a theory to account for the multiple factors above. Genes and hormones give rise to certain temperamental and personality traits. Genes may also lead to different environmental experiences, for example through certain personality traits such as sensation-seeking. These interact with the environment and are shaped and reshaped by experience and give rise to adult sexuality, including paraphilias. Paraphilias are clearly phenotypic, not genotypic. As such, this is a biopsychosociocultural-political model of human sexuality. An example to illustrate this is given in Figure 47.2.
ASSESSMENT OF HUMAN SEXUALITY

In assessing human sexuality, it is necessary to consider the following:

- **Sexual fantasies:** these are most important and cannot be measured in animal studies.
- **Sexual activity:** human sexual activity is not predominantly a cyclical reproductive activity, as in non-humans. This is a further limitation of animal studies.
- **Sense of identity.**
- **Social role.**

TRANSVESTISM

Transvestism is the desire to wear clothing appropriate to the opposite sex (cross-dressing), often associated with sexually arousing fantasies, urges and behaviour and sexual gratification, in which case it may be regarded as a form of fetishism, referred to in ICD-10 as ‘fetishistic transvestism’, which is the wearing of the clothes of the opposite sex in order to obtain sexual excitement. DSM-IV confines this paraphilia to heterosexual males. Transvestism is a paraphilia or disorder of sexual preference, in contrast to transsexualism (Table 47.2).

Transsexualism is a gender disorder. It is a wish to be able to function as a member of the opposite sex associated with a compulsive conviction that the person is assigned to the wrong gender. The person may wish to function as a member of the opposite sex anatomically and physiologically. Such individuals may be referred to as ‘trans’.

Dual-role transvestism involves the wearing of clothes of the opposite sex in order to enjoy temporary membership of the opposite sex without the desire for permanent change of sex. Unlike transvestism, it is not associated with sexual excitement.

The term ‘transgenderism’ includes transvestism and transsexualism.

Table 47.2 Differentiating transsexualism from transvestism

Dysfunctional relationships with parents
e.g. physical/sexual/emotional abuse, neglect, rejection, suppression of sexuality

Feel neither loved nor lovable

Low self-confidence
Poor social skills
Poor peer relationships

Loner, isolated, confused
Miss out on interpersonal learning
Misattributes early sexual feelings

Puberty – activating hormones

More aggressive and antagonistic
Aggression and abnormal stimuli used in masturbation fantasies
Pair orgasm with deviant fantasies

Figure 47.2 Example of interactional model of human sexuality

Incidence

The prevalence is unknown, but it is estimated that there are around 30,000 transvestites in the British Isles, most never coming to the attention of the medical or legal professions. Transvestism may be the most common paraphilia. It is not uncommon as a transient developmental phenomenon around 10 years of age in boys.
Aetiology

- **Analytical theory:** transvestism is seen as a solution to castration fears or an attempt to identify with the individual’s mother through wearing female clothes to recapture the primitive sexuality of having her skin against his. Physical or emotional distance from the father is also cited.

- **Particular personality characteristics:** transvestism is seen sometimes with obsessional personalities, where the paraphilia has an obsessive characteristic. However, other personalities are clinically apparent. Some studies suggest that 50–70 per cent of transvestites can be diagnosed as having a personality disorder.

- **Abnormal conditioning.**

- **Family background:** a pattern of a rigid, uncongenial or absent father and a dominant or overprotective mother has been described.

Behaviour patterns

Most information on the clinical features is derived from surveys, for example of 504 cases in American and Australian clubs. In transvestites, the impulse arises during early childhood. Cross-dressing is practised at all convenient opportunities. The condition appears to be very persistent and becomes associated with sexual arousal after puberty. Subjects are generally but not necessarily heterosexual in orientation.

Transvestism may be:

- **Compulsive:** in such cases, tension relief is apparent when the individual gives into the compulsion. There is no wish to change sex, but satisfaction from passing off the self as a member of the opposite sex may be apparent.

- **Symptomatic:** this is seen in homosexuality, lesbianism and transsexualism.

Treatment

The majority of transvestites do not request treatment or wish to be ‘cured.’ Some are brought for treatment by relatives or their partner. Others are referred because of brushes with the law due to personality difficulties rather than (except for the stealing of clothes) their specific paraphilia, for example soliciting or importuning in a public place for immoral purposes, or insulting behaviour likely to cause a breach of the peace. Historically, ‘success’ was claimed with aversion therapy, although follow-up indicates that many transvestites relapse after attempts at treatment.

Indecent exposure

This is the corresponding offence in England and Wales resulting from exhibitionism of ‘openly, lewdly and obscenely exposing his person with intent to insult any female’ (1824 Vagrancy Act). The comparable behaviour in females, for example female streakers, is dealt with by the offence of ‘behaviour likely to cause a breach of the peace’. It is a summary, non-indictable offence – that is, the individual can be tried without a jury by a magistrate’s court and, as such, is not recorded in the England and Wales criminal statistics as a notifiable offence.

Incidence

There are over 3000 convictions in England and Wales for indecent exposure each year. This is the most common type of sexual offence committed by adults. The rate for adults has remained steady, but the rate for individuals under 21 years has increased since 1948. It is more common in summer. Cultural factors may be important. It is said to be rare in non-psychotic Afro-Caribbean people.

Classification (after Rooth)

- **Type 1 (80%):** characteristically this involves an inhibited young man of relatively normal personality and good character, who struggles against his impulse but finds it irresistible. He feels anxious, guilty and humiliated because of it. He exposes with a flaccid penis, does not masturbate, and derives little if any pleasure from the act. The behaviour is probably related to assertiveness. Such individuals value being in control, however briefly, of the transaction, whether it induces fear, annoyance or even amusement. They want a response but not the female to initiate sex. This type is said to be not physically dangerous.

- **Type 2 (20%):** these individuals are less inhibited and more psychopathic. They expose in a state of great excitement, with an erect penis and masturbation. These individuals obtain great pleasure and show little guilt. In this group, the act may be associated with a marked sadistic element, other sexual disorders and other types of offence. These individuals can be seen as trying to break a barrier to their forming a relationship and, as such, may escalate their behaviour to include accompanying indecent suggestions such as ‘Kop a load of this!’ touching, thoughts, and acts of indecent assault or rape.

This classification is only a guide, and many individuals show features of both categories. Exhibitionists are more likely to show two or more paraphilias, such as voyeurism and making obscene telephone calls.

Aetiology

- **Family background:** a greater relationship with the mother and a poor relationship with the father has often been described.

EXHIBITIONISM

This is the exposing of the genitals to an unsuspecting stranger, usually a member of the opposite sex.
• *Psychoanalytical viewpoint*: the deviation is said to stand against the fear of impotence and castration.
• *Excessive inhibitions due to family attitudes*: the caricature of exhibitionists wearing dirty raincoats may be seen as hiding something viewed as dirty.
• *Behavioural theories*: these include various explanations of learning and reinforcement by perverse masturbation fantasies.

**Clinical presentation**

Individuals with exhibitionism have a normal distribution of intelligence and are seen in all social classes. Common personality traits described include immaturity, passivity and obsessionality. The most common age of onset is the late teens; a late onset suggests major psychiatric disorder, including depression, alcoholism and even general paralysis of the insane (GPI). Only about 5 per cent of individuals with exhibitionism are psychotic or have a learning disability. Early sexual development is usually unremarkable. A normal sexual appetite is present at puberty but, with the onset of adolescence, there is mounting anxiety about forming heterosexual relationships; indeed, such individuals tend to be less successful in establishing heterosexual relationships. Premature ejaculation and impotence are common. However, stable relationships and marriages are often subsequently made by individuals in the type 1 group.

The act is frequently on favourite ‘hunting grounds’. The individual may claim that he was simply urinating because he could not wait any longer. On the other hand, the not uncommon observed behaviour of individuals urinating in public, for example not going behind a hedge, may also reflect latent exhibitionist behaviour. Discretion is often absent, with very high risk-taking. Activity may be higher in depressive moods. The witness chosen is generally a stranger. There is a desire to engage the woman’s attention in a situation in which the individual, normally a passive person, is in control. The reaction most unwanted is that of indifference. This brief encounter is associated with feelings of excitement, exhilaration and achievement. Victims are commonly girls around the age of puberty or women. A preference for children is said to occur in the more immature and timid individuals, who are frightened of women. However, crime surveys show that perhaps the majority of females in the UK are exposed to at some time during their lifetime.

**Prognosis**

Eighty per cent of exposers do not re-offend once convicted; however, they may do so frequently before conviction. There is a small recidivist group who persist, but in this group the behaviour falls off in the forties. Generally, exhibitionists are physically harmless, non-violent people. A few may escalate to become paedophiles, and some may commit violent offences, either sexual or otherwise. The more offences committed, the worse the prognosis. A good prognosis is associated with mature sexual experiences, including sustained sexual relationships and marriage, and otherwise good social relationships and work record.

**Management**

Management has been eclectic. Anti-libidinal drugs have been used as a temporary expedient. Supportive psychotherapy may be useful by increasing the self-esteem of the often timid, anxious type 1 offenders; such therapy may offer these individuals their only emotional release. Group therapy is also used; the probation service may run groups for convicted indecent exposers, which has the advantage that all such members of the group know why they are there and are subsequently less deceiving. Cognitive-behavioural therapy (CBT) is the specific psychological treatment of choice. In the past, aversion techniques were used; there was even a recommendation for exposers to wear their trousers back-to-front.

**PAEDOPHILIA**

This is the sexual preference for prepubertal children or children under 13 years of age. The term ‘hebephilia’ refers to a sexual preference for young people of adolescent age. To meet the DSM-IV diagnostic criteria for paedophilia, the person must be at least 16 years of age and at least 5 years older than the child or children. The majority of paedophiles are male, but female paedophiles do exist. Paedophiles are subject to public outrage and viewed as monsters, and their behaviour is seen as unexplainable in spite of the way such individuals might be seen as having difficulty distinguishing affection to children and its sexualization.

**Underage sex**

It was not uncommon 300 years ago for females to become pregnant at the age of 12–13 years. Even in Victorian times, in England and Wales it was legal to have sexual intercourse with girls under 13 years of age. Now sex with a female under 16 years of age is always illegal, as consent at that age is considered invalid. Sex with a female under 13 years of age is equivalent to rape in seriousness; it is, however, a valid defence if the male is under 24 years of age and believes the female to be older than 16 years, provided there are no previous similar offences. If the sex is by force or against the female’s will, then the offence is equivalent to rape. The age cut-off of 16 years may be seen as rather arbitrary compared with the psychologically more important stage of emotional development. In addition, individuals of the age of 10 years are criminally responsible and may receive a custodial sentence if convicted. One can
legally buy a pet at 12 years of age, have sexual intercourse at 16 years of age, drive a car at 17 years of age and vote at 18 years of age in England and Wales.

**Classification**

Clinically, it is useful to distinguish those individuals with a fixed disorder of the sexual preference of paedophilia, estimated in numbers to be about 300–400 in the UK, compared with larger groups of people whose paedophilic behaviour represents regression, such as under stress, as a result of mental illness or following substance abuse. The evidence base regarding paedophilia is limited.²² Other classifications include the following:

- **By the characteristics of the offender:**
  - Adolescent – such behaviour usually represents an emotionally and sexually immature investigation. Rarely but tragically, sometimes the offender kills the victim in panic after the victim screams or in order to conceal the offence. This contributes to the average four sex murders per year of children in the UK.
  - Elderly – this group includes lonely, isolated individuals with a fear of impotence.

- **By relationship to children:**
  - The sexuality arises out of a relationship to the child. This is the most common type of paedophilia – the group represents about 80 per cent of paedophiles. The offender has an affection for the child or children and no particular wish to harm them, although clearly the act is illegal. In effect, the offender may be ‘in love’ with the child. Deprived children may more often be victims, as they may be more open to strangers and seeking affection. Freud pointed out that children do have sexuality and seek adult affection; however, it is an adult’s responsibility not to sexualize their relationships with children.
  - The child is merely a source of sexual gratification. Here, the victim is generally a stranger and the relationship a casual one. Two groups are seen, characterized by (i) non-aggressive seduction with money or sweets (this is the group parents warn their children against) and (ii) an aggressive seduction or rape associated with violence.

- **By the sex of the victim:**
  - Heterosexual group – individuals in this group are often married, have lower reconviction rates and are less criminal.
  - Homosexual group – individuals tend to be single and more likely to re-offend. This group carries a worse prognosis.
  - Indiscriminate group – where the victims are of either sex. This group includes up to 20 per cent of paedophiles. The victims are more likely to be younger (6–11 years), perhaps because both sexes at that age are physically similar and asexual.

‘Child molesters’

Research on adults who sexually abuse children (‘child molesters’, i.e. not simply primary paedophiles) has found that they are more indiscriminate than previously thought, often choosing victims of either sex and of a broad age range and choosing both intra- and extrafamilial victims. Up to 90 per cent of child molesting is intrafamilial. Taking offenders convicted of sexual offences against children in general, criminal statistics for England and Wales suggest that around 80 per cent of offenders know the child, of whom 13 per cent are relatives. Few such sexual offences are life-threatening, certainly compared with the average of 80 children killed in England and Wales each year by their parents or a stranger. Sexual killing of a child and abduction of a child by a paedophile occur in fewer than ten cases a year.

**Aetiology**

Paedophile offences are often committed for reasons of power to counter low self-esteem as much as for sex.²³ Paedophiles often abuse a child of the sex and age when they were abused themselves, which was often their first significant sexual experience. Most paedophiles do not have impulsive personalities and may ‘groom’ and seduce a victim over a lengthy period. One in ten abused girls and one in four abused boys are abused by women, either alone or as coerced accomplices or co-offenders with men.²⁴,²⁵ Such involvement of women in offences does not necessarily reflect passivity in the face of a dominant male co-offender but may reflect the woman’s own primary sexual deviance.

There is no definite evidence of an increase in sexual assaults on children by paedophiles in the UK, but their visibility and conviction rates have increased due to the greater ease of detecting the illegal use of the Internet to view indecent paedophilic images, compared with the previous pattern of viewing such images in private in magazines.

**Clinical features**

Paedophiles have a normal intelligence quotient (IQ), education and occupational range. They often have a poor ability to relate to adults, while being proud of their ability to relate to children, although in reality this does not differ from others. Full coitus is rare, and behaviour may be fondling or exhibiting and sometimes orgiastic. Two-thirds of the victims participate, for example by kissing and cuddling. Offending often follows alcohol abuse.

**Management**

Acceptance of responsibility for the sexual abuse is usually essential. However, paedophiles often admit only to those offences for which they have been caught. Success has been
claimed for all forms of treatment, including psychotherapy, CBT and anti-libidinal medication. The homosexual form of paedophilia has the worst prognosis and is generally regarded as extremely difficult to treat. Most success has occurred with anti-androgen hormone therapies. Castration has never been used in the UK, but it was reported to be successful in selected cases of repetitive paedophile rape offenders who were then subject to indefinite detention at Herstedvester Prison in Denmark.29 However, a relationship with a child may be so important that, even after an individual has been made sexually impotent, the adult may still seek out children.

Prognosis
Untreated, such individuals may abuse large numbers of victims. Recidivism rates are high, even with treatment, and do not decrease over time. Fifteen per cent are reconvicted in law in England and Wales, while up to 35–45 per cent may re-offend on the basis of self-reports. Recidivism is associated with early onset, length of history, variety of sexual offending, offending against both sexes, and deviant arousal to paedophile images on penile plethysmography. Paedophiles on sex offender registers, which are available to social services departments, are excluded from adoption and fostering by such agencies.

Studies on paedophilia include cases where there appear to have been trivial incidents, or activities involving an otherwise sexually active adolescent.31 Parental reactions may partly determine the long-term effects of being a victim as a child, and isolated minor abuse may have minimal long-term effects. However, Mullen has shown that childhood sexual abuse can adversely affect adult functioning, resulting in intergenerational problems, including uncaring or overcontrolling parents, sexual adjustment difficulties, decrease in socioeconomic status due to disruption of a sense of effective agency and low self-esteem, and increased substance abuse, personality problems, anxiety and depression.28

RAPE

Definition
This is an offence, not a paraphilia, but it is covered here for convenience. Rape is anal or vaginal penetration by a penis – that is, sexual intercourse with a man or woman without his or her consent, by fear or force or fraud. Full penetration need not occur. The very rare female equivalent behaviour results in a charge of indecent assault, although females assisting males in rape may be convicted of rape themselves. An offender under the age of 14 years cannot be convicted of rape or attempted rape in the UK but can be convicted of indecent assault.

In England and Wales, a law in 1736 stated that it was not illegal to be raped by one’s husband. This clearly reflected attitudes of the time, including the so-called ‘rule of thumb’, where it was legal for a man to hit his wife with an implement no wider than his thumb. It was not until 1990 that the Court of Appeal ruled that if a husband raped his wife and they were separated, this did constitute rape in law. In 1994, the Public Order and Criminal Justice Act included males for the first time in the definition of victims of rape.

Incidence
The true incidence is unknown because, in spite of increased reporting in recent years, only a fraction of cases are reported. Home Office estimates for England and Wales in 2000 suggested that only 10–25 per cent of victims tell the police; of these reports, only two-thirds were recorded as offences of rape. However, there has been a three-fold increase in convictions since the 1980s. The nature of the offence means that it is often one person’s word against another; in England and Wales, only 6 per cent of individuals charged with rape are convicted. Most cases reported are ‘date rape’.

Psychopathology
Although by definition a sexual offence, rape often represents displaced aggression,29 possibly from a rejecting mother or a rejecting society. It may at times be a defence against homosexuality. Evolutionary theory suggests rape is a way for low-status individuals to pass on their genes.

Clinically, offenders often perceive the passivity of the victim – often induced through fear – as consent and that they enjoy the domination and denigration.30 Rape is not confined to humans, with examples in nature including ducks (especially in artificial ponds), gorillas, scorpions and bees.

Classification
Various classifications have been attempted, such as that of Gibbens and colleagues.31 The following is clinically practical:

- ‘Normal’ rape: this is described as occurring when normal social sanctions are removed and new group pressures and stresses are substituted, e.g. invading armies such as during the Second World War and in Bosnia, and by Hell’s Angels. It may be that the combination in wartime of tension, arousal and of having already been violent makes it easier, especially in groups, to commit rape. It may bond troops together and be used to induce fear and alter the ethnicity of opposing communities. It may also lead to men not wishing to leave their families and fight.
- Aggressive personality: in this group, rape is one aspect of generalized aggressive behaviour. Victims are seen by the rapist as objects to be used or defiled.
• **Inhibited, frustrated men:** these men are isolated and unable, through their particular psychological difficulties, to relate normally to women. Such individuals are often aware of, and dislike, the increasing drive to attack and rape. The act may be preceded by indecent exposure. This group is less common than that of aggressive personalities.

• **Sadistic men:** these men are often isolated socially, and the behaviour is egosyntonic and enjoyed. Such individuals are often from a very disturbed background with a rejecting mother.

• **Paedophilic rapists.**

• **Mental illness or learning disability:** the association of rape with mental illness is due largely to the resulting general disinhibition of behaviour. Mania may also lead to rape through increased sex drive. For deluded rapists, one should note the sexual content of their delusions. However, most psychotic patients who rape do not do so directly due to their delusions, which contrasts with violence associated with psychosis. Rarely, organic factors, such as a seminoma secreting androgens, may be important.

**Epidemiology**

Most male rapists are under 25 years of age, single and not mentally ill and often have convictions for non-sexual offences, often for violence. Thirty per cent of victims are neighbours or acquaintances. Twenty per cent of victims have a criminal record, often of soliciting. Prostitutes are the group most at risk of being victims. Half of rapes are committed by someone known by the victim for less than 24 h. Twelve per cent of rapes are by total strangers. The incidence is higher in the USA than in the UK, in cities, during the summer, at weekends, and in the first half of the night.

**Assessment of the alleged rapist**

This should include a full history from the alleged rapist, including sexual fantasies and impulses, combined with an objective account of the offence (e.g. from statements or Crown Court depositions), a list of all past offences, and details of any previous psychiatric assessments and management.

**Management**

This must reflect the underlying cause. Psychological treatment to improve social functioning, such as social skills training, may be necessary but is likely to be insufficient to prevent re-offending. Anti-libidinal treatment can be used where the patient feels that his sexual drive is a factor in the motivation. However, most offenders do not consider themselves in need of psychiatric help, and 80 per cent are sentenced to prison following conviction, where they are paradoxically more highly regarded than child molesters, who tend to be scapegoated. Some specialized prison regimes offering sex offender treatment programmes are available in England and Wales for serious sex offenders.

If psychiatric in-patient treatment is offered, this will usually have to be under conditions of security, such as in a medium secure unit or a maximum secure or special hospital, and will be on the basis that the individual is detained on grounds of mental disorder, on the basis of underlying mental illness or severe personality disorder, and since, but not before, the Mental Health Act 2007 of England and Wales, sexual deviancy.

Management of the victim requires specialized counselling. Victims may have problems of guilt, pregnancy, venereal disease and fear of being shunned by friends and partners, and may have to deal with the stress of court appearance. Overall, the more the victim struggles during rape, the more he or she is likely to sustain injuries, unlike the situation for other, non-sexual, violent offences. However, the less the victim struggles, the more guilt and depression he or she may experience.

**Prognosis**

Follow-up of men charged with rape show that 90 per cent will not commit a second rape. However, 15–20 per cent will commit a sexual assault of some sort, and 17 per cent commit violent offences. The risk of similarly dangerously re-offending, however, is apparent only over a long follow-up period (e.g. 15 years) and not in the short term (e.g. 2 years). A comparison of exhibitionists and rapists is shown in Table 47.3.

**OTHER PARAPHILIAS**

Not all sexually deviant behaviour is against the law, but some, such as paedophilia, always is. However, a combination of paraphilic behaviour and crime creates a high newsworthiness.

**Fetishism**

This is sexual arousal and gratification arising primarily and preferentially from inanimate articles. It can lead to recurrent convictions for theft, for example of used underwear from clothes lines, referred to as ‘snowdropping’ among prisoners. It is the thought of such articles having belonged to others that is important, in contrast to the theft of unused items from stores. Fetishism may be compulsive or symptomatic. In the latter, male individuals may be impotent unless fetish objects such as black stockings, leather gear or whips are present. Fetishistic objects can be classified into three main groups: articles that are often pink, red, furry, shiny and spherical; articles representing threat, such as black leather and whips; and symbols of femininity, such as female lingerie and shoes. The term
**Other paraphilias**

Part 4: Mental health problems and mental illness

**Mysophilia** reflects the preference for smelly soiled clothes. Unusual fetishisms described have included car exhaust pipes. If the desire is focused on a part of the body, such as the feet, then DSM-IV regards this as partialism rather than fetishism. Ethologically, fetishism has been viewed as possibly arising from imprinting, as seen in ducklings, reflecting a child crawling and following a mother at shoe level.

**Bestiality/zoophilia**

This represents a sexual desire and preference for sexual or anal intercourse with animals. The term ‘formicophilia’ refers to the preference for small animals such as ants touching the erogenous zones. Of note, the offence of buggery refers to anal intercourse by a man with a man or woman, or anal or vaginal intercourse by a man or a woman with an animal, and still carries a maximum sentence of life imprisonment in England and Wales. The term ‘buggery’ originates from reference to the Christian group Bogomils of Bosnia.

**Scotophilia/voyeurism**

As defined in DSM-IV, this is sexual arousal derived from observing an unsuspecting person who is naked or in the process of disrobing or engaging in sexual activity. There may be masturbation during the act. It appears exclusive to men. It is epitomized by ‘Peeping Tom’, a tailor who peeped at the naked Lady Godiva as she rode through Coventry in protest against her husband Leofric, Earl of Mercia, imposing a heavy tax in the first millennium AD.

**Telephone scatalogia or scataphilia**

This refers to the making of obscene or lewd telephone calls. Usually it is by an individual with an inadequate personality and represents a form of voyeurism. It is usually chance who the individual phones, hence the importance of not giving out one’s telephone number when answering the telephone. No response is the best response to such calls. Technology now allows the police to tap and trace such calls.

**Frotteurism**

In DSM-IV, this refers to the pleasure from touching and rubbing against a non-consenting person. It usually occurs in crowded or confined spaces such as a busy train. The term originates from the French word *frottage*, meaning ‘rubbing’.

**Sadism**

In DSM-IV, sexual sadism refers to recurrent, intense, sexually arousing fantasies, sexual urges or behaviours involving acts in which the psychological or physical suffering, including humiliation, of the victim is exciting to the person. Sometimes the act is with a consenting partner who has sexual masochism. It includes sexual arousal by violence, which contrasts with rapists, who are aroused by forced sexual intercourse. *Biastophilia* or *raptophilia* is the sexual preference for rape. Sadistic violence allows emotional distance but physical proximity. Such individuals find that indulging in aggressive acts bolsters their low self-esteem. Individuals with sexual sadism paraphilia should be contrasted with those attending S and M fantasy clubs, where the behaviour is not developmental. Brittain provided the classic clinical description of the sadistic murderer syndrome. Such individuals may have a past history of working in positions of power over people and animals, such as in butchery, and having interests in Nazism, torture and weapons, which they collect and often store at home, reflecting the content of their mind. Such individuals may have schizoid introspective personalities and, in the absence of relationships and normal rewards, may develop sadistic fantasies to which they habituate, resulting in them...
proceeding to follow or stalk and later act out those fantasies towards others. Individuals with sadistic personality traits may be very resistant to specific psychological treatment and, if they violently offend, in spite of subsequently often being model prisoners, given the opportunity are likely to seriously harm or murder others in future – and they know it. Compared with rapists, sexual murderers are more overcontrolled, bottling up their temper, have more past convictions for rape, and are more socially isolated and more likely to lack a sexual partner in the year before the offence.

### Serial killing

The first sadistic act against an individual is very reinforcing but never matches exactly the individual’s fantasy. This may lead to repetition and, in its extreme form and if not caught, serial killing. Such individuals, who often feel powerless and inadequate, may seek the notoriety and power associated with serial killing. Although there has always been serial killing, the 1992 film *The Silence of the Lambs*, with its depiction of Hannibal Lecter, the cannibal psychopathic psychiatrist, has led to serial killing becoming a postmodern hyper-real spectacle of morbid public interest.

Literature on serial killing is limited by the fact that offenders often commit suicide following offending, but profiles suggest that they tend to be non-psychotic, white males, aged 20–30 years, from social classes III–IV, and who often have a history of using firearms and dramatic scenarios to express resentment and anger at frustrations in their life and personality difficulties. Some individuals may be psychotic, in which case the victims tend to be strangers. Mutilation before death is associated with psychopathy (organized), while mutilation following death (disorganized) is seen among psychotic serial killers, including those with schizophrenia.

### Masochism

In DSM-IV, sexual masochism refers to recurrent, intense, sexually arousing fantasies, sexual urges or behaviours involving the act of being humiliated, beaten, bound or otherwise made to suffer. Examples given in DSM-IV include being forced to crawl, being kept in a cage, bondage, being blindfolded, and being whipped, spanked, pinched, beaten, bruised, cut, raped, stabbed or tortured.

In masochism, individuals are aroused by violence to themselves and, indeed, may make others angry with them to this end. *Algolagnia* is the love of pain alone.

### Necrophilia

This involves sexual desire for corpses. Described as increased in occurrence among mortuary attendants, it is, in fact, less rare than might be apparent and sometimes occurs following homicide, perhaps in a manner akin to when elephants indulge in sexual intercourse with fellow elephants who have died, as if to bring them back to life. To protect the relatives of victims, such behaviour is often not revealed in court.

### Autoerotic asphyxia (hypoxophilia or asphyxiophilia)

This relates to the enhancement of orgasm by reducing oxygen intake, for example by using a noose around the neck. Such behaviour is associated with the risk of fatality, which in turn may be the first indication to others of such behaviour. Partial drowning has also been described.

### Other paraphilias

*Coprophagia* is the ingesting of faeces. *Coprophagia* is the ingesting of faeces. The presence of either usually reflects a very low self-esteem. *Urophilia* or *undinism* (from the Greek for ‘water spirit’ or ‘nymph’) includes being urinated on (*urolognia* – ‘golden shower’), the drinking of urine and urinating during sexual relations. Such practices are referred to as ‘water sports’. In *urethralism*, objects are inserted into the urethra, which may include a liking for *catheterization* (*catheterophilia*). In *klimaphilia*, rectal enemas are used. These paraphilias are included under the DSM-IV category 302.9 Paraphilias not otherwise specified (NOS).

*Vampirism* includes sexual gratification at the sight of and contact with blood. Vampirism and *cannibalism* have been reviewed.

*Infundibulation* or *stigmatophilia* includes the boring of holes, body-piercing and the wearing of rings through the skin. An example is the insertion of the so-called ‘Prince Albert ring’ through the penis, which is said to intensify the effects of masturbation.

*Apotemnophilia* refers to sexual preference for being an amputee. It may lead to individuals, known as ‘wannabes’, disabling or injuring themselves. *Acrotomophobia* is a paraphilia dependent upon a partner being an amputee. This corresponds to those known as ‘devotees’. These two paraphilias should be contrasted with *amputee identity disorder* (AID), in which individuals are referred to as ‘needtobes’.

*Pygmalionism* is the sexual preference for objects in the form of people.

In *vogueing*, individuals dress up as a celebrity, such as Elvis Presley or Madonna.

*Trashcanners* take objects from celebrities’ dustbins, including for sexual purposes.

The digital age has heralded *cybersex* and *teledildonics*.

Other paraphilias include *narratophilia* (listening to accounts of sexual activity), *gerontophilia* (sexual gratification from an elderly partner), *hybristophilia* (sexual gratification from a person who has committed a crime), and *chrematistophilia* (being charged for or forced to pay for sex, or being robbed by the sexual partner).
Some individuals are described as being polymorphous perverse, in that they have an infantile sexual development and may be aroused by multiple stimuli, such as the wind, and in turn may present with a history of a number of apparent paraphilic behaviours and, indeed, may sexually offend in a number of ways. King has described a case where an individual was aroused by his own sneezing and by the sneezing of others, the sneezing being conceptualized as a fetishistic interest.40

Hypersexuality

This is sometimes referred to as nymphomania or satyriasis. There is a much wider range of sexual drive between individuals than is acknowledged in society. However, only very rarely is hypersexuality due to high testosterone levels. It can be associated with high levels of tension and anxiety.

RELATED OFFENCES

Incest

This is when an individual has a sexual relationship with a first-degree relative and is aware of this. Sibling incest may be the most common form of incest, but father–daughter incest is most reported to authorities and may often be associated with collusion of the mother to prevent unwanted sexual advances. Such behaviour has been classified into three types: endogamic, paedophilic, and promiscuous. It is said to be associated within families where there is overcrowding and poor personal boundaries.41–43

Prostitution

Prostitution itself is not an offence, but soliciting and keeping a brothel are offences. Economic motives are commonly given as a rationalization for prostitution, and the financial rewards can be high. However, prostitutes as a group show an excess of mental disorder, self-harm, alcohol or drug abuse, physical disorders, personality disorders and bisexuality and are more likely to have been sexually abused.

Pornography

This is sometimes cited in court as the primary cause of a sexual offence. In reality this is rarely so, but pornography is used more often by people with personality disorder or paraphilias.

Sexual acts and aggression

Where aggression accompanies sexual acts, it can clinically be useful to conceptualize the act along a continuum, as shown in Figure 47.3. The link between sex and violence may theoretically be through the limbic system and testosterone.

**ASSESSMENT OF PARAPHILIAS**

Referrals for assessment may be due to the following:

- **Formal referral by authorities following law involvement:** such individuals may have limited, if any, motivation to change. They may already be serving a custodial sentence.
- **Individual’s distress caused by their paraphilia:** these individuals may fear that their behaviour will impair their health, career or result in law involvement. Such individuals may vary in the degree to which they wish to develop normal sexual desires and behaviours.
- **Distress of the individual’s partner caused by the paraphilic behaviour:** such individuals may, in turn, be concerned at their partner’s reaction.
- **Sexual dysfunction:** e.g. erectile difficulties, secondary to paraphilias or reliance on paraphilias for arousal, e.g. fetishistic objects. The individual’s partner may also be concerned at the resulting sexual dysfunction and wish for help to this end.
- **Gender identity disorder.**

Clinical risk assessment

Sexual fantasies and impulses will need to be explored, but this may not always be easy.

Freud referred to individuals not telling the truth in the area of sexuality.44 It is important to determine whether the fantasies or impulses are egosyntonic or egodystonic. It is also important to establish whether there has been an escalation in behaviours, for example to attempt and act out the fantasies. It is important to establish whether fantasies are about specific known individuals, and whether the fantasies involve consent or force. The relationship, if any, of paraphilic behaviour to alcohol consumption, drug abuse or the use of pornography needs to be established.

Information-gathering should include talking to informants such as the person’s partner. In the case of sexual offenders, depositions or statements should be considered, usually available only in the cases of serious sexual offences before a Crown Court, along with a list of previous convictions and social enquiry reports for the court prepared by probation officers. Previous psychiatric records and, when
relevant, general practice records should be obtained and formal psychiatric disorder confirmed or excluded.

Clinical risk assessment is open to bias and poor consistency and is difficult to qualify. It is often inductive, for example based on past cases or cases that went wrong.

A risk assessment should be undertaken, but categorizing risk from low to high is often arbitrary unless its meaning and likelihood are explained, for example by giving the immediacy, frequency or consequences of risk.

**Standardized structured risk assessments**

Formal psychological testing, for example with the Thorne Sex Inventory, may assist. For sex offenders, actuarial risk assessment instruments that look at static risk factors such as age, number and type of previous offences, type of victim and history of cohabitation, such as STATIC-99 and Risk Matrix 2000, are objective, unbiased and deductive, but they are only moderately predictive and first offenders score less. The Risk Matrix 2000 categorizes sexual and violent offenders from low to very high risk. However, instruments that look at dynamic (changeable) risk factors, both relatively stable, such as personality factors (e.g. STABLE 2007), and acute (e.g. ACUTE-2007), can assist professional judgement further. Other examples include Sexual Violence Risk-20 (SVR-20), Risk of Sexual Violence Protocol (RSVP) and Sexual Assessment of Risk and Need (SARN). The SARN is useful in developing treatment plans and measuring change.

**Penile plethysmography or phallometry**

Penile plethysmography or phallometry with the subject’s consent may elicit deviant arousal patterns, for example to children or rape, and may counter the tendency of sex offenders to denial or self-report errors. Penile plethysmography, however, tends to be less reliable in institutions compared with in the community, where there may be more stimuli to paraphilic interests and behaviours.

**Polygraph as lie detector**

This has been found to be useful in countering denial among paedophiles in the community, for example revealing more high-risk behaviours such as unsupervised contact with children than is apparent from the history given by the individual.

**Management**

The aims of management need to be realistic and, ideally, the goals agreed with the individual. Elimination of the paraphilia is often not possible, but control is more often achieved. Attempts to remove or reduce paraphilias usually require the enhancement of other outlets. In general, individuals with a stable personality, who are well motivated and who have some past adult sexual fantasies or experience, do best. However, motivation may be difficult to assess when an individual is under the stress of a forthcoming court appearance and facing custody. There are no good controlled trials of long-term as opposed to short-term treatment for people with paraphilias, particularly if they have committed sexual offences. In addition, negative countertransference among professionals may lead to rejection from treatment.

Regarding sex offenders, 80 per cent do not re-offend once first convicted, but it is the recidivist who seeks or is sent for treatment. However, if an individual has committed more than two sexual offences and has had no adult sexual experience, then one must assume that the offending will continue. The deterrent effect of the law may be more effective than treatment, although Home Office statistics suggest that recidivism rates among sexual offenders released from prison are less compared with those of other offenders during the first 2 years (16% v. 56%). However, long-term follow-up studies of sexual offenders indicate more pessimistic outcomes.

In prison, paedophiles may be subject to more victimization compared with rapists. Sex offenders are often scapegoated, even by those who have committed rape or homicide, and this may relate to the psychodynamics of being in single-sex custodial institutions. Since the introduction of the Criminal Justice Act 1991, sex offenders may be subject to indeterminate supervision.

Any intercurrent mental illness should be treated. Coexisting problems such as social anxiety, social skills deficits, poor sex education and marital difficulties should be tackled, but it is unlikely that this alone will stop paraphilias or associated sexual offending. Individuals often present requesting to be made to stop their paraphilic behaviour, when really they need to be made to want to stop.

Psychodynamic approaches, as described by Zachery, by both individual and group therapy (e.g. at the Portman Clinic in north London) have been attempted, but the stress of such therapy may in some individuals increase the risk in the short term of offending due to acting out and perhaps by the inducement of guilt, leading to them being more readily apprehended.

There is a stronger evidence base for cognitive-behavioural approaches. Nagayam-Hall showed that of those sexual offenders who completed a CBT programme, only 19 per cent re-offended, compared with 27 per cent among controls. Cognitive-behavioural approaches include the following:

- **Reduction of deviant sexual arousal**: aversion therapy, including electrical aversion, is now almost never used. It involved repeated pairing of the stimulus for paraphilias, e.g. in the form of visual images, with unpleasant stimuli such as electric shocks. In covert sensitization, the aversion is imaginal: for example, the individual is asked to fantasize about their paraphilic behaviour and then to imagine an aversive scene, e.g. the attendance of a police officer or others observing the act.

- **Increasing non-deviant sexual arousal**: this may be undertaken by masturbatory orgasmic reconditioning,
in which there is reinforcement of non-paraphilic arousal and desires by asking the individual to switch to fantasies of conventional sexual stimuli when orgasm is imminent as a result of masturbating to paraphilic fantasies – that is, an attempt is made to pair arousal with normal sexuality. The point of switching to conventional fantasies is gradually brought forward. The goal is that the entire episode takes place to non-paraphilic fantasies. Another technique is fading or satiational therapy.\(^57\) In this the individual is instructed to fantasize and masturbate to the paraphilic act for extended periods, perhaps up to an hour, as a result of which it is theorized that satiation to the paraphilia should take place. More controversially, surrogate therapy has been used to increase non-deviant sexual arousal.

- **Self-control training:** CBT approaches can be used to clarify and modify faulty cognitions, e.g. that the victim enjoyed it, to enhance empathy for the victims, and to learn to avoid high-risk situations.

- **Partial incorporation of paraphilia to sexual repertoire:** this is practical only if the paraphilia is acceptable and legal, as would not be the case in paedophilia, and something that the individual’s partner can tolerate. Individual sessions with the partner may need to be undertaken in order to establish this; thereafter, the couple may be helped to reduce the role of the paraphilia in their sexual relationship, e.g. in a leather fetish, leather worn may be reduced to merely an armband. A negotiated timetable approach may also lead to temporal control, e.g. to certain days of the week for the paraphilia.\(^58\) Success with such an approach has also been described in people with fetishism.\(^59\)

Sex offender treatment programmes have been developed for both those in the community and those in prison. They involve, usually in group work, understanding offence cycles, challenging distorted cognitions (e.g. paedophiles believing that they satisfy children’s natural sexual urges), understanding the harm done to the victim, fantasy modification, social skills training, anger management control and relapse prevention work. Booster programmes, for example pre-release from custody, may be required.

Evaluation of such programmes has differentiated high-risk from low-risk offenders, with high-risk offenders being characterized by social inadequacy, lack of empathy for victims, distorted thinking, increased sexual obsessions and abnormal emotional congruence, leading to distorted emotional attachment, for example to children.\(^60,61\)

The psychological management of child sexual abusers and high-risk sexual offenders has been well detailed by Craissati.\(^62,63\)

### Anti-libidinal treatment

Anti-libidinal treatment reduces sexual drive but is not concerned with the direction of that drive. It is, therefore, most effective when sexual activity is directed towards orgasm but least effective when such activity is directed primarily to forming a relationship, for example in some paedophiles, where anti-libidinal treatment may not affect re-offending rates. Anti-libidinal treatment may suppress both ‘normal’ sexual drive and paraphilic interests, and individuals may fear losing their sexuality as a result of such treatment. An unspoken fear of prisoners in general is that medication may result in loss of libido.

Castration has never been used as an anti-libidinal treatment in the UK. Oestrogens have been used in the past, but these have severe feminizing effects. Benperidol is a major tranquillizer that may not be any more effective than other such neuroleptic medications in reducing sex drive, but it has the advantage of avoiding the need for the detailed written consent and the pretreatment work-up required with cyproterone acetate.

More recently, selective serotonin reuptake inhibitor (SSRI) antidepressants have been used as a first-line medication treatment where preoccupation and rumination over the paraphilic behaviour are apparent, for example with exhibitionism. The evidence base, however, is case studies and small open trials of such antidepressants. Most used and reported is fluoxetine.

Medroxyprogesterone acetate is widely used in the USA. It induces the liver enzyme testosterone A reductase, leading to increased metabolism and reduced plasma testosterone levels. There are also antigonadotropic effects.

Cyproterone acetate is used more widely in the UK, Europe and Canada. It specifically blocks androgen effects and has an antigonadotropic action. It inhibits the production of testosterone by enzyme block, competitively antagonizes testosterone, acts on the hypothalamic centre and is progestogeneric. The usual dose is 50 mg orally twice daily, but an injection is also available from Germany. Indications include hypersexuality (including for females), indecent exposure and unwanted sexual fantasies. It has also been used in aggression in severe learning disability, and as a male contraceptive in small doses. It does not work if sexual behaviour is associated with alcohol abuse. It has some effect within 48 h and reduces sexual drive after 10–14 days. There is a reduction in spermatogenesis (oligospermia) and loss of ejaculation. It reduces sexual thoughts and behaviour.\(^64\) Unwanted effects include gynaecomastia in 10–15 per cent of patients, which often remits, especially if it is not extensive, when treatment stops. Previous concerns about inducing breast cancer have been discounted. There may be loss of body hair with prolonged treatment. Occasionally depression is seen in the third week, and sometimes there is habituation requiring an increased dose. The effects are reversible, although this takes some months. Some patients retain erections and sex drive in spite of high doses. In the testes, germinal cells are reversibly damaged (seminiferous tubular arrest – fertility is preserved) and Leydig cells are irreversibly damaged.

Before treatment, it is essential to conduct a full physical examination, obtain written consent and undertake liver
function tests, sperm count and testosterone levels as baselines, including to counter any subsequent litigation, especially where the medication is blamed for infertility.

Goserelin is a luteinizing hormone releasing hormone (LHRH) analogue. It is licensed only for treatment of cancer of the prostate and breast, but it may be effective as an anti-libidinal treatment in patients resistant to cyproterone acetate.

Hormone treatments are emotive, but if psychological treatments do not work and serious sexual re-offending is certain (e.g. high-risk offenders leaving prison after a custodial sentence), then their use appears justified. However, those people most in need of treatment may not consent. Some treated individuals who re-offend blame their medical practitioners for inadequately treating them with doses that are too low. Some individuals cite the resulting lack of sex drive as a cause of increased subsequent aggression.

**LEGISLATION RELEVANT TO SEX OFFENDERS IN ENGLAND AND WALES**

The public and media concern that something must be done to better manage sex offenders has led to new legal initiatives in recent years in England and Wales and, indeed, elsewhere.

The **Criminal Justice Act 1991** has resulted in sex offenders receiving longer sentences and longer periods on licence than otherwise would have been the case in order to protect the public from serious harm.

The **Crime (Sentences) Act 1997** introduced a mandatory life sentence for a second serious offence, such as rape, attempted rape or sex with a girl under 13 years.

The **Sex Offenders Act 1997** specifies that offenders must notify the police of their name, date of birth and address and any changes of address, not only if they are convicted of a sexual offence but also if they are cautioned, unfit to plead or not guilty by reason of insanity, and whether the individual is in hospital or prison, on penalty of a fine or up to 6 months’ imprisonment. Under this Act, a defendant can face trial even if the offence occurred abroad.

Under the **Crime and Disorder Act 1998**, the police can apply for a sex offences prevention order (SOPO) to prohibit an individual from being in certain areas at specified times (e.g. children’s playgrounds), if (i) the individual has been previously convicted or cautioned for a sexual offence, or (ii) the individual is behaving in a way that suggests the public is at serious risk of harm.

Extended sentences under **Section 85 of the Powers of the Criminal Courts (Sentencing) Act 2000** have been introduced ‘to protect the public from serious harm from the offender’ (violent or sexual). There are two components: a standard custodial term and an extended period of licence, up to 10 years for a sexual offence and 5 years for a violent offence.

The **Criminal Justice Act 2003** introduced ‘indeterminate sentences for public protection’ in respect of high-risk offenders, a measure equivalent to a life sentence. This Act also described Schedule 15 offences, which supercedes the **Children and Young Persons’ Act 1993 Schedule 1** offences, includes all offences against children up to the age of 17 years. The management of such offenders is covered by guidance from the Home Office for interagency cooperation.

Following the **Criminal Justice and Court Services Act 2000**, under Sections 67 and 68, multi-agency public protection arrangements (MAPPAs), in force since 2001, have placed a legal responsibility on the police and probation services to assess and manage those at risk of serious harm to others, including sex offenders, with a duty on psychiatrists to cooperate with this.

Dangerous severe personality disorder (DSPD) units in special hospitals such as Rampton and Broadmoor hospitals and in prisons such as HMP Frankland and HMP Whitmoor in England have also taken individuals who are primarily sexual offenders, such as paedophiles.

**CONCLUSIONS**

It is important to remember that paraphilias may be non-problematic and may not lead to sexual offending, and that only a small proportion of individuals with paraphilias are referred for psychiatric assessment and help, including because such individuals may not be motivated to change. On the other hand, individuals with paraphilias may present with sexual and marital dysfunction, depression and anxiety without acknowledging the underlying paraphilia. In addition, paraphilias may not be eliminated by treatment, and only control may be achievable – hence the importance of realistic agreed goals with a patient presenting with a paraphilia.

**KEY POINTS**

- Paraphilias (DSM-IV) or disorders of sexual preference are persistently preferred to normal adult sexual behaviour.
- Primary (fixed) paraphilias should be distinguished from facultative deviation due to unavailability of normal sexual outlets and from latent perversion (repressed) that follows stress (e.g. marital conflict, disinhibition by alcohol or drugs) or is released by mental illness.
- Although paraphilias can result in sexual and marital dysfunction, depression and anxiety, only a small proportion of people with paraphilias are ever referred to psychiatrists.
- Not all paraphilic behaviours are against the law, and not all sexual offenders have a disorder of sexual preference.
- The most common sexual offence is indecent exposure, which is associated with the paraphilia of exhibitionism. Most such offenders are inhibited, non-violent young men who do not re-offend once
Convicted. A few are more psychopathic and become sexually aroused by exhibitionism.

- Paraphilias may not be eliminated by treatment, and only control may be achievable. Cognitive-behavioural approaches have been found to be most effective.
- Standard structured risk assessments that assess static and dynamic risk factors in sex offenders (e.g., SVR-20, RSPV, SAPIN) can supplement clinical risk assessment and are better than actuarial risk assessments alone (e.g., Static-99, Risk Matrix 2000).
- Penile plethysmography and the use of a polygraph as a lie detector may assist in the management of sex offenders.
- Anti-libidinal medication, for example cyproterone acetate, reduces sexual drive but is not concerned with the direction of that drive. It is most effective when sexual activity is directed towards orgasm but least effective when such activity is directed primarily to forming a relationship, such as in some paedophiles. Anti-libidinal treatment may not affect re-offending rates.

INTRODUCTION

Physical and psychiatric illnesses are so inextricably inter-related\textsuperscript{1,2} that the ability to assess the mental state of physically ill patients is an essential skill required by all clinicians.\textsuperscript{3} The development of a physical illness, either acute or long-term, substantially increases the likelihood of a wide range of psychiatric disorders, which add considerably to the level of disability and which may worsen the prognosis of the physical condition.\textsuperscript{4}

BACKGROUND INFORMATION

Knowledge of the nature of the physical illness, its severity, its prognosis and the response to treatment is essential. Clinicians in primary and secondary care are usually well aware of these details. For a psychiatrist who is asked to assess a physically ill patient, it is necessary to discover as much as possible about the underlying illness from the referring doctor and from other sources, such as the medical notes and correspondence from the general practitioner (GP). These may also provide evidence of previous psychiatric disorders or episodes of deliberate self-harm. It is important to know whether the patient is currently in contact with a mental health service. There may be evidence of family and social problems which could influence the patient’s response to the illness and create difficulty when planning discharge from hospital. The medical diagnosis, if established, must be understood, and it is important to know the severity of the condition. For example, in cases of cancer, is there evidence of metastatic spread or is the disease localized and likely to be cured completely? In neurological disorders, it should be established whether there is cerebral involvement that could cause generalized intellectual impairment or whether there is a discrete lesion giving rise to specific neuropsychiatric disorders such as dysphasia and amnesia. It should be established with the medical team whether the patient is aware of the diagnosis and prognosis. Current practice usually involves an open discussion of the medical condition but, despite having been fully informed, some patients deny any knowledge of their condition and may use denial as a protective shield.

Investigations

The clinical findings should be reviewed in the light of results of available investigations. Laboratory results should be scrutinized for evidence of metabolic disturbance (urea, electrolytes, liver function tests), endocrine abnormalities (particularly thyroxine, thyroid-stimulating hormone (TSH) and cortisol levels) and infection (raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)). Elevated figures for \(\gamma\)-glutamyltransferase (GGT) and mean corpuscular volume (MCV) are sometimes the first indicators of hazardous alcohol consumption. Computed tomography (CT) and magnetic resonance imaging (MRI) results should be reviewed for evidence of localized cerebral pathology or diffuse changes as are seen in the dementias.

Treatment

The drug chart must be examined to establish which drugs the patient has been taking recently and is currently being prescribed. Many medically prescribed drugs have adverse psychiatric side effects,\textsuperscript{5} which include anxiety, depression, mania, delirium and isolated psychotic experiences. Corticosteroids are among the best-recognized culprits, but other potential causes include adrenergic antagonists, anticonvulsants, antiparkinsonian drugs and anti-retrovirals. An adverse psychiatric reaction to a drug can be diagnosed with some confidence if the reaction follows closely after the administration of the drug and resolves on stopping the drug. There may be a history of a similar response when the drug was administered previously.

Other treatments should also be noted, including previous and proposed operations, radiotherapy and bone-marrow transplantation. The wider treatment environment is also important. Many people feel threatened by the high-technology environment of an intensive care unit (ICU) or
high dependency unit (HDU).\textsuperscript{6} Isolation is another source of stress and can contribute to the development of anxiety, depression and psychotic disorders in patients being treated for severe infections or following immunosuppression.

\textbf{Reason for referral}

The psychiatrist should establish what particular issues the referring medical team want to be addressed. These include a diagnostic opinion, assessing suicidal risk, advice on medication and adherence to treatment regimes, help in managing challenging behaviours, and establishing whether the patient has capacity to consent or withhold consent to treatment that is considered medically necessary. The psychiatrist should confirm that the patient is aware of the referral and has agreed to an assessment by a psychiatrist.

\textbf{PRIVACY AND COMMUNICATION}

Ideally, all psychiatric assessments should be conducted in privacy, either in the patient’s home, in an out-patient office or in a side room of a medical ward. However, a single room cannot always be obtained, and in hospital the interview sometimes has to be conducted by the bedside in an open ward if the patient is too ill to be moved. If this is the case, then it is preferable for the interview to be conducted with the curtains drawn around the bed.

If the patient is not fluent in English, a translator should be arranged. Most hospital trusts now have a panel of available translators covering a wide range of languages likely to be encountered in the area. In my opinion, it is better to involve a professional translator rather than a relative, at least in the first instance. If the translator is familiar with the patient’s cultural background, then the translator may be able to advise the clinician of particular cultural beliefs concerning health, illness, healthcare and treatment that may impinge on the patient’s mental state and coping abilities. Several of these beliefs stem from religious teaching. In a culturally diverse society, a clinician needs to know as much as possible about the different ways in which people interpret bodily symptoms and the need for treatment.

Many illnesses are associated with communication problems, and the clinician should be aware of these so that special provision can be made. For patients with visual impairment, the interviewer should avoid sitting with a source of light behind him or her. The source of light should be on the interviewer’s face, and eye contact must be established as far as possible. Written information must be given in a large font. For patients with hearing difficulties, the clinician should speak clearly but avoid shouting. The clinician should face the patient when speaking and use simple sign language where appropriate. Providing written information is very helpful. Similar considerations apply if there are communication problems due to dysphasia, dysarthria or cognitive impairment. Speech is impossible for patients who are treated in an ICU or HDU and who are being ventilated via endotracheal intubation. In these circumstances, only a limited assessment can be undertaken, and it will be necessary to use closed rather than open-ended questions, with printed cards giving the patient the opportunity to give ‘yes’ or ‘no’ answers.

\textbf{THE HISTORY}

In most cases, the history is taken in much the same manner as in any psychiatric assessment. This includes the family background, noting especially any family history of psychiatric and medical illnesses that may have a genetic component, and the patient’s developmental and personal history. A tactful enquiry about childhood abuse should be made. Sexual abuse in childhood is now established as a predisposing factor for several psychiatric disorders in adult life, including the functional somatic syndromes that are seen so commonly in medical practice. Previous medical illnesses must be discussed, with emphasis on how the patient coped with them and whether they were associated with psychological symptoms. Frequent attendance at a GP’s surgery for minor or unexplained symptoms raises the possibility of a somatization syndrome. The onset and evolution of the current physical illness should be established before proceeding to determine how the patient has coped with the symptoms, functional disability and the need for treatment.

\textbf{Coping styles}

Coping strategies in the face of illness usually reflect coping styles that have been developed since childhood, but it must be remembered that coping is a dynamic and flexible process, changing with time and with the varying demands of the illness. It is when the usual coping strategies break down that serious psychiatric problems emerge.\textsuperscript{2,8} All illnesses except the very trivial involve some degree of adjustment of lifestyle, including the fundamental decisions of whether to seek medical advice, agree to treatment, take time off work and curtail leisure activities. In the case of chronic illnesses, these lifestyle changes may have to be permanent, and the illness is then perceived as involving a loss of status, income, ambition or social supports.

Some people cope with illness by finding out as much information about the illness as possible by consulting medical books and websites; they involve themselves closely with the treatment regime and are often critical of what they perceive as medical ambiguity or shortcomings. Others, in contrast, cope by distancing themselves from the emotional impact of becoming ill, tending to minimize symptoms and disability and continuing to follow existing or new leisure interests. This strategy reflects a degree of denial. In extreme cases of denial, the coping is
maladaptive, in that it leads to rejection of medical advice and treatment and continuation of an unhealthy lifestyle.

Depression and anxiety

Mood changes should be elicited. Was there evidence of anxiety, depression or any other psychiatric disorder before the onset of the physical illness? If so, have the psychological symptoms been affected adversely by the illness and its treatment? If psychological symptoms have developed after the onset of the physical illness, their course and severity should be elicited, particularly whether they fluctuate in parallel with the course of the underlying illness. The patient’s understanding of the illness should be discussed. There is not always a close relationship between the severity of the physical illness and the development of a psychiatric disorder. The patient’s perception of the illness appears more important. It is therefore important to understand the implications of the illness for the patient’s relationships, career prospects, financial circumstances and ability to pursue leisure activities. Sometimes illness is perceived as a punishment, particularly if the patient believes that some aspects of their behaviour have been responsible for causing the illness. The patient may then feel guilty, sometimes with psychotic intensity, which leads to severe depressive reactions for some people. Suicidal ideas need to be explored whenever a depressed mood has been elicited.

Not much emphasis can be placed on somatic symptoms when assessing depression in medically ill patients. Anorexia, weight change, fatigue, reduced libido, sleep disturbance and bodily pains can all be explained by the underlying condition. Diagnostic attention has therefore to be focused on the psychological symptoms that accompany depressed mood, including anhedonia, reduced interest, lack of motivation, guilt, hopelessness and self-blame.

Anxiety is commonly associated with medical illness. It is often related to the illness itself, particularly when there is uncertainty about the diagnosis, treatment or prognosis. Clarity of communication on the part of the multidisciplinary team does much to alleviate this anxiety. Anxiety is a prominent feature of hyperthyroidism, phaeochromocytoma and hypoglycaemia from any cause. In some people, anxiety is related to specific aspects of the medical treatment, such as having intravenous injections or undergoing radiotherapy, or to investigations such as bronchoscopy, colonoscopy or blood tests for human immunodeficiency virus (HIV) infection. In severe cases, the anxiety has a phobic element and leads to avoidance of the medical treatment or investigation. Sedation with a benzodiazepine or cognitive-behaviour therapy is then required to enable treatment to proceed. Episodic anxiety, which is a cardinal feature of panic attacks, is a common reason for medical referral and can create much diagnostic difficulty, particularly when associated with physical conditions such as ischaemic heart disease presenting with chest pain.

Following exceptionally threatening events, such as major accidents, physical assault or natural disasters, symptoms of post-traumatic stress disorder (PTSD) develop in up to one-third of cases. It is important to enquire about recurrent episodes of reliving the trauma through flashbacks or nightmares, together with emotional blunting, hyperarousal, hypervigilance and an avoidance of situations that evoke memories of the original stressor. PTSD is most likely to be diagnosed in patients admitted following road traffic and other major accidents and following serious assault. It has also been described as a response to medical illness9 and following childbirth10 when this has been a traumatic experience for the mother. Symptoms of PTSD may emerge up to 6 months after the triggering event, and so the diagnosis has to be considered in patients who have long since been discharged from hospital.

Psychotic symptoms

Psychotic symptoms should be explored. If present, they are usually related to a pre-existing schizophrenic or affective illness. It is important to establish what medication, if any, the patient is taking for these illnesses and to ensure this is maintained during a medical admission, unless there are side effects that necessitate changing to an alternative drug. This should be done in conjunction with the patient’s GP or community psychiatrist. The development of psychotic symptoms during the course of a medical illness usually indicates the onset of delirium or, less commonly, an affective disorder. Visual or tactile hallucinations are the most common sensory disturbances. Secondary delusions may be superimposed on these false perceptions. The level of consciousness is impaired, but the symptoms fluctuate, and so a history from nursing staff is essential to chart the course of the delirium.

Body image

Disturbance of body image should be considered in young women when there is a history of weight loss, extreme dieting, binge eating or use of laxatives or purgatives. If associated with amenorrhoea for more than 3 months, these symptoms are indicative of anorexia nervosa. However, it must be remembered that the characteristic drive to become thin and the abnormal eating habits may be denied at a first interview and admitted only when the patient has gained confidence in her doctor. Localized disturbance of body image may be seen in people who request cosmetic surgery for minor physical abnormalities.11 A psychiatric opinion may be requested before a decision to operate is made. The most common operations requested involve the nose (rhinoplasty), breasts (enlargement or reduction) and ears. Body dysmorphic disorder is characterized by a preoccupation with a perceived defect in appearance that, to an observer, is entirely normal or only slightly abnormal. The person’s concern is highly excessive, and there are unrealistic expectations that an operation will resolve the physical
problem and all the psychosocial difficulties attributed to it. Surgery is usually contraindicated in these cases.

Cognitive function

A history of progressive cognitive decline involving memory, concentration, orientation, thinking, learning capacity and judgement is highly suggestive of dementia. There may be little insight into these intellectual changes, and so it is important to take a history from a close relative or friend. Difficulty coping at work, problems with driving, and loss of social skills may all be described by the informant. Executive function involves the ability to plan, initiate and organize behaviour in general and certain tasks in particular. Loss of executive function suggests frontal lobe pathology.

In the context of an acute medical illness, reports of drowsiness, impaired concentration and disorientation indicate the possibility of delirium due to infection, drugs or metabolic upset. The patient may be unaware of these problems, and so reliance has to be placed on accounts from relatives and nursing staff who are in close contact with the patient.

Alcohol misuse

The association between alcohol misuse and medical problems is so well established that screening for problem drinking is a routine part of a medical assessment, but the psychiatrist may need to amplify what a primary care or hospital doctor has already established. Alcohol-related problems comprise a substantial proportion of the clinical work in all departments of a general hospital, with accident and emergency departments having a particularly high prevalence. Consumption of alcohol is increasing in the UK, and so alcohol-related medical admissions are likely to continue rising for the foreseeable future. Early detection is crucial if permanent damage is to be avoided. The following clinical presentations are particularly likely to be associated with alcohol misuse:

- **Deliberate self-harm**: drug overdose, self-cutting, jumping from a height, attempted drowning
- **Trauma**: road traffic accidents, falls, assaults
- **Cardiovascular**: hypertension, arrhythmias, cardiomyopathy
- **Gastrointestinal**: dyspepsia, gastritis, haematemesis, diarrhoea, malabsorption, pancreatitis, fatty liver, acute hepatitis, cirrhosis
- **Neurological**: stroke, peripheral neuropathy, withdrawal fits, Wernicke–Korsakoff syndrome, cerebellar ataxia, dementia
- **Musculoskeletal**: myopathy, osteoporosis, gout
- **Malignancies**: oopharynx, oesophagus, liver, colon, breast, lung
- **Haematological**: bleeding disorders, thrombocytopenia, neutropenia
- **Dermatological**: multiple bruising, psoriasis, increased capillarization of facial skin, acne rosacea
- **Respiratory**: aspiration pneumonia, rib fractures, pneumothorax
- **Others**: impotence, infertility, obesity, diabetes.

A careful account of the patient’s drinking habits should be recorded. It is useful to ask about a typical week’s consumption and maximum weekly consumption. Alcohol intake is calculated in units, 1 unit being equivalent to 8 g of alcohol. This has traditionally been equated to a single measure of spirits, half a pint of beer or a 100-mL glass of table wine. However, this calculation needs to be revised for higher-strength beers and New World wines, some of the latter having an alcohol content of 15 per cent or more. Hazardous drinking is defined as an average daily consumption of over 40 g (5 units) of pure ethanol for men and over 20 g (2.5 units) for women. These are the self-reported levels of consumption above which there is an increasing risk of medical harm.

An alcohol dependence syndrome is suggested by a history of morning tremor, anxiety, insomnia, retching, morning drinking to relieve tremor, visual hallucinations, withdrawal fits and concurrent use of benzodiazepines. Withdrawal symptoms are likely to emerge following admission to hospital, where the patient no longer has access to alcohol.

Drug misuse

Illicit drugs are also highly associated with medical problems and can affect every organ system. Drugs greatly increase the risk of traumatic injury, and so drug users are overrepresented among accident and emergency patients following road traffic accidents and assaults. Canning and colleagues reported that 6 per cent of acute medical admissions were drug-dependent and 14 per cent were drug users. The most common drugs taken by these patients were cannabis, amphetamines, ecstasy and cocaine. Polydrug use appears to be increasing in frequency. Clinical presentations associated with a particularly high prevalence of drug misuse are deliberate self-harm, HIV/acquired immunodeficiency syndrome (AIDS), hepatitis and septicaemia.

A high index of suspicion is essential. It is important that specific questions about drug use are asked. These should cover the nature and dose of the drug, the duration for which the drug has been taken, and the time of the last dose.

Sexual problems

Taking a sexual history is one of the most sensitive areas covered by a psychiatric assessment. Unless sexual problems are among the patient’s presenting complaints, it is advisable not to broach the subject until a good rapport has been established. This may mean deferring until a second or...
subsequent interview and then discussing the subject in stages. The patient’s sexual partner should not be interviewed without the explicit agreement of the patient being obtained and recorded in the medical notes.

It is well established that sexual problems are common among medical patients. The emotional impact of becoming ill, with its associated sense of loss of attractiveness, can adversely affect sexual interest, performance and desire, but an increasing amount of evidence points to the role of physical factors in the aetiology of sexual problems. Peripheral neuropathy and vascular disease are among the most common causes. Sexual problems are therefore frequently seen in association with diabetes, hypertension, arteriosclerosis and chronic alcoholism. Other neurological causes include multiple sclerosis, spinal cord lesions, Parkinson’s disease and stroke. Localized diseases of the genitourinary tract are also important causes. In men, these diseases include prostatitis, sexually transmitted infections (STIs) and lesions of the penis such as Peyronie’s disease; female conditions include endometriosis, pelvic inflammatory disease, and vulval infections and tumours. A wide range of medically prescribed drugs have adverse sexual side effects. Chief among these are antidepressants, antihypertensives and anti-androgens. Alcohol and illicit drugs are often taken in the hope that they will enhance desire and performance, but the reverse is usually true.

Privacy is important to enable a full history to be taken. The patient’s current sexual relationship must be discussed. It is important that the patient’s态度 to the assessment should be recorded. Is the patient cooperative, or is there resentment or even aggressive behaviour towards the psychiatrist, medical and nursing staff and other patients?

MENTAL STATE

A full mental state examination may not be possible, and not all aspects listed below can be explored at the first assessment. It is often necessary to conduct the examination on several occasions, particularly when there is reason to suspect that any psychological changes elicited are fluctuating.

General appearance and behaviour

It is usually the case that a full physical examination has been conducted by the referring doctor, and this should not be repeated unless there are indications from the history that undetected pathology is present. However, the patient’s general appearance should be described. Several clues might indicate that the medical condition could adversely affect the patient’s mental state, such as weight loss, cyanosis, jaundice, a cushingoid face, and evidence of thyroid over- or underactivity. When alcohol is a problem, acne rosacea or facial reddening due to increased capillarization may be evident. Alcohol may be smelled on the breath, and there may be tremulousness and apprehension, indicative of a withdrawal state.

Withdrawal from opiate drugs occurs when drug-dependent individuals cannot get access to their usual supply, as happens when they are admitted to hospital. The characteristic signs are yawning, sneezing, rhinorrhea, runny eyes, goose flesh, tachycardia and muscle twitching. Signs of sedative withdrawal include agitation, tremor, postural hypotension and tachycardia.

Evidence of psychomotor retardation, overactivity or agitation should be noted. The facial expression and bodily posture may give strong clues to a disturbance of mood. Disinhibited and overfamiliar behaviour are features of manic states or frontal lobe lesions.

The patient’s attitude to the assessment should be recorded. Is the patient cooperative, or is there resentment or even aggressive behaviour towards the psychiatrist, medical and nursing staff and other patients?

Speech

Any problem of the articulation of words (dysarthria) should be noted. In the absence of local pathology in the oropharynx, dysarthria is suggestive of cerebellar pathology. Speech production is diminished in rate and volume in depression; it is speeded up in manic states, when speech may also indicate flight of ideas, with rapid change of content from one topic to another and with only minimal connection between them. In stuporous patients, there may be no speech production at all and there is little or no generalized motor activity.

Evidence of dysphasia should be assessed because this is a strong indicator of focal cerebral pathology. Difficulty in the production of spoken language – motor or expressive dysphasia – is associated with lesions in the posterior part of the third frontal convolution in the dominant hemisphere, Broca’s area. Speech production is sparse and hesitant, words are chosen incorrectly, and the patient usually appears flustered when attempting to speak. Written language is affected similarly. Nominal dysphasia refers to difficulty in naming familiar objects, such as a pen, watch or spectacles, when the examiner points to them. This disorder can occur in widespread cerebral pathology and with focal lesions of the dominant angular gyrus.

Receptive dysphasia involves difficulty in the comprehension of speech and is associated with lesions in the first convolution of the dominant temporal lobe, known as Wernicke’s area. The patient has difficulty understanding the meaning of words and therefore in responding to commands. Speech is impaired, with grammatical errors, wrong words and neologisms, but the speech is produced in a fluent rhythm and apparently without distress to the patient.
Mood disturbance

Subjective mood should be explored by asking how the patient is currently feeling in his or her spirits. Unusual sadness, hopelessness, loss of interest and anhedonia are common manifestations of depression. Less commonly, psychotic symptoms are seen in patients who are severely depressed. Delusions of guilt and punishment may involve beliefs about the causation of the physical illness. Conversely, there may be a delusional conviction of bodily organs having ceased to function or of having cancer, AIDS or some other potentially fatal illness even though medical reassurance has been given that no such illness has been found. It is important to follow the evolution of depressive symptoms. Many resolve with improvement in the medical condition and are best regarded as part of an adjustment disorder. Others are more persistent and do not improve with physical recovery; specific psychological or anti-depressant treatment is then indicated.

Mania is much rarer than depression in medically ill patients and is often related to drug therapy, particularly with steroids. There are the characteristic features of elation, grandiose beliefs, overactivity and disinhibited behaviour towards staff and other patients. Not surprisingly, nurses find these patients extremely difficult to manage on a medical ward.

Interviewing terminally ill patients poses special problems. Doctors often feel uncomfortable in these situations, not knowing how far to probe into the patient’s concerns. However, most patients want to be told if their condition is terminal. Psychiatric problems are common, and patients generally welcome the opportunity to discuss them. Religious and spiritual matters may be very important, and access to religious counselling should be available. For patients who deny the implications of their condition, it is important to respect defence mechanisms but also to offer the opportunity for the patient to ask questions so that they can be given as much information as they request. Not all questions will be raised at the first interview, and so follow-up interviews should be arranged.

Many patients admit to feeling anxious during treatment for a medical illness. Anxiety is most marked in the early stages of the illness, when the diagnosis may be unclear, or before stressful investigations or operations. In a few cases, anxiety is disabling and leads to signs and symptoms of autonomic arousal that cause considerable distress. Anxiety in relation to particular procedures, such as venepuncture, chemotherapy or radiotherapy, can lead to avoidance and refusal of further treatment.

Patients admitted to hospital following trauma are at risk of developing PTSD and describe the characteristic symptoms of nightmares, flashbacks, sleep disturbance, hyper-vigilance, hyperarousal and avoidance of cues associated with the original trauma. However, these symptoms may not emerge during hospital treatment but become apparent only several weeks after the patient leaves hospital.

Assessment of suicide risk

This is a crucial aspect of the psychiatric assessment. Medically ill patients are at increased risk of committing suicide and may be specifically referred by medical staff because suicidal thoughts have been expressed. But most assessments of suicidal risk are conducted on patients who have been admitted to hospital after acts of deliberate self-harm. The assessment should identify patients with a significant psychiatric illness and those who are at high risk of attempting or repeating self-harm. It should enable a management plan to be devised and it can, in itself, have a therapeutic effect. The topics to be covered are as follows:

- Motivation for committing suicide
- Immediate predisposing stressful events
- Current social difficulties
- Degree of planning an attempt
- Whether there are plans anticipating death, e.g. suicide note written, personal affairs sorted
- Previous attempts
- Previous psychiatric history
- Family history of suicide and psychiatric illness
- Tendency to misuse alcohol and other drugs
- Coping resources and plans for future
- Evidence of personality disorder.

As a general principle, the following features increase the risk of suicide:

- Advancing age
- Previous episodes of self-harm
- Male sex
- Evidence of psychiatric illness, especially depression and schizophrenia
- Personality disorder
- Unemployment
- Social isolation
- Recent separation or bereavement
- Alcohol or drug misuse
- Lower social class.

Further psychiatric care should be organized on the basis of this assessment. Most patients can be discharged home safely following an episode of self-harm if adequate support and ongoing care from a community mental health team can be provided. Patients identified as being at high risk should usually be transferred to a psychiatric unit. If medical factors preclude this, then consideration should be given to arranging observation and therapeutic intervention from an experienced psychiatric nurse until transfer can be effected.

Psychotic symptoms

If there is evidence of an antecedent psychotic illness, the characteristic delusions, hallucinations and thought disorder will be apparent or revealed by appropriate questions concerning unusual beliefs or sensory experiences. An
Cognitive function

In view of the frequency of cognitive impairment in medical patients, it is often necessary to evaluate cognitive function at an early stage in the examination. Any impairment that is elicited may influence the interpretation of other mental symptoms. Level of consciousness should be assessed according to the patient’s alertness, ability to concentrate on the interview or tendency to drift off to sleep. Impaired alertness is a cardinal feature of delirium, but apparent lucidity at the time of assessment does not exclude delirium because symptoms fluctuate markedly, typically being worse at night. Importance should therefore be given to nursing reports of varying alertness and other symptoms during the course of a day.

Attention and concentration can be assessed by asking the patient to carry out some simple mental tasks, such as repeating the months of the year backwards, serially subtracting 7 from 100, and repeating a number of digits forwards and backwards.

Orientation, which involves registering and retaining information, should be checked by asking the patient to give the date, the day of the week, the month and the year (orientation for time) and to name the present location, floor of the building, name of the hospital, street address and town (orientation for place). Orientation for person is assessed by asking the patient his or her name. This information is lost in advanced cases of dementia, in some psychotic illnesses and in dissociative amnesias.

Memory involves the ability to register, retain and retrieve information. Short-term memory is assessed clinically by presenting new information, such as a name and address or a series of words, asking the patient to repeat it immediately to check registration, and then asking the patient to repeat it again after an interval of 5 min or so, during which time the patient’s attention is diverted to other topics. Memory for recent events such as major items of news should also be noted. Remote memories are more difficult to assess, but it is helpful to note the ability to recall memories from childhood, particularly if these can be verified from other sources. Confabulation refers to a tendency to fill in gaps in memory by inserting false memories; these are often memories of events that have taken place but that have become grossly displaced in time. Confabulation is classically seen in Korsakoff’s syndrome.

Mental capacity

Mental capacity is required if patients are to understand the nature of their illness and the need for treatment and to be able to withhold or give consent to treatment. Its assessment should be an integral part of the psychiatric examination and is sometimes the specific reason why a psychiatric opinion is sought. All medical clinicians should be able to assess capacity, but a second opinion may be requested if the decision has major consequences and if the physician believes the patient has made an unwise choice. The assessment of a patient’s capacity should be undertaken specifically in relation to the decision that the patient is required to make. Lack of capacity is more common than is often thought to be the case. Raymont and colleagues assessed 159 acute medical admissions and judged 31 per cent of the patients to lack capacity according to legal criteria. Only a quarter of these patients were identified as such by their treating medical teams. Mental capacity has important legal implications because, in the absence of capacity, patients have to be treated under common law or the Mental Capacity Act (2005), provided that the treatment is considered to be in their best interest. The least restrictive treatment option should be used but, before deciding that the patient lacks capacity, every effort should be made to facilitate his or her ability to make a decision. The law assumes that people have the capacity to make decisions about their own treatment, even if refusing treatment may lead to permanent damage and premature death. Before the introduction of the Mental Capacity Act in England and Wales, no other person could give or withhold consent on behalf of an adult patient, but the Act has now allowed proxy decision-makers to be appointed. A person who has capacity can now grant lasting power of attorney to one or more people, who can then decide on that person’s treatment, should capacity subsequently be lost. There is also provision for the court to appoint one or more deputies who can decide on treatment on behalf of a patient who already lacks capacity.

Lack of capacity exists if the patient is unable to:

- understand information relevant to the decision;
- retain the information;
- weigh up the information in order to make a decision;
- communicate a decision.

In most cases in medical practice, lack of capacity results from cognitive impairment. This may be transient, as seen in delirium, or permanent, as is the case in dementia.
Pre-existing psychiatric disorders such as schizophrenia, depression and, in certain cases, phobias can also impair capacity.28

The use of questionnaires

Diagnosis in psychiatry rests firmly on the basis of an interview conducted by an experienced psychiatrist. Questionnaires do not replace the clinical assessment, but they can be useful as screening instruments and in quantifying the severity of symptoms and following their temporal evolution, particularly in response to treatment. The following are some of the questionnaires that have been found to be helpful in assessing medically ill patients:

- Hospital Anxiety and Depression Scale (HADS): this is a short simple scale that measures anxiety and depression separately, each on a 21-point scale.29 It has been specifically designed to exclude somatic symptoms of mood disorder, and thus it is particularly suitable for use in a medical population.

- General Health Questionnaire: the full questionnaire contains 60 items, but shorter versions consisting of 12, 28 or 30 items are more appropriate for medical patients. This questionnaire has been used widely as a screening instrument and is acceptable to people who do not regard themselves as mentally ill.30 The sensitivity and specificity vary according to the population studied, and the threshold score is affected by the degree of physical illness, and so the questionnaire needs to be standardized for the group of patients with whom it is being used.

- Beck Depression Inventory: one of the earliest structured questionnaires, this has been used widely with medical patients.31 It is a 21-item scale, but it contains somatic questions, so it can lead to false-positive results.

- Mini Mental State Examination: this is the most widely used test to assess cognitive impairment.32 It is administered by the clinician and assesses orientation, registration, recall, attention, concentration and language. It can detect cognitive deficits in dementia and following head injury, but it lacks sensitivity to detect subtle loss of memory, particularly in well-educated people.

- CAGE: this brief screening test is used to detect severely affected problem drinkers.33 It asks four questions, concerning whether the patient has: (i) attempted to cut back on drinking, (ii) been annoyed at criticism of their drinking, (iii) felt guilty about their drinking or (iv) used alcohol as an eye-opener. It does not detect hazardous drinking and can seem too confrontational for use with this group.

- Alcohol Use Disorders Inventory (AUDIT): this is more suitable for the detection of hazardous drinking.34 In briefer form, it has been used successfully to identify hazardous drinkers in a maxillofacial unit15 and in an accident and emergency department.36

COMMUNICATION

Once the history and mental state examination have been completed, the psychiatric opinion should be communicated immediately to the referring doctor. This is best done verbally but supplemented by a written entry in the clinical notes. A typed summary should follow later. The opinion should include a definitive psychiatric diagnosis, a review of aetiological factors, and clear advice on management. If a diagnosis cannot be reached at the first interview, a differential diagnosis should be given, together with advice on further investigations and other sources of information. The psychiatrist should review the patient once these are available. No assessment is complete without informing the patient what conclusions the psychiatrist has reached and what further treatment, if any, is being recommended.

KEY POINTS

- The development of a physical illness, either acute or long-term, substantially increases the likelihood of a wide range of psychiatric disorders, which adds considerably to the level of disability and may worsen the prognosis of the physical condition.

- Knowledge of the nature of the physical illness, its severity, its prognosis and its response to treatment is essential.

- Ideally, all psychiatric assessments should be conducted in privacy, either in the patient’s home, in an out-patient office or in a side room of a medical ward.

- Many illnesses are associated with communication problems, and the clinician should be aware of these so that special provision can be made.

- In most cases, the history is taken in much the same manner as in any psychiatric assessment.

- It is often necessary to conduct the mental-state examination on several occasions, particularly when there is reason to suspect that any psychological changes elicited are fluctuating.

- Assessment of suicide risk is a crucial aspect of the psychiatric assessment.

- Questionnaires do not replace the clinical assessment but can be useful as screening instruments and in quantifying the severity of symptoms and following their temporal evolution, particularly in response to treatment.

- Once the history and mental-state examination have been completed, the psychiatric opinion should be communicated immediately to the referring doctor.

REFERENCES

GENERAL CONSIDERATIONS

These illnesses, summarized in Figure 49.1, have variously been described as 'syndromes of uncertain origin' and 'unexplained illnesses'. They are the subject of much controversy and not a little polemic.

It is helpful to define the term ‘syndrome’, which has been the subject of much, sometimes acrimonious, debate when applied to these illnesses, particularly Gulf War syndrome (GWS).

The Greek origin of syndrome is syn-, together, and -drome, a track for running. One must determine the tracks of travel and observe the travel of the patient’s syndrome components. Because research definitions define a static collection of symptom entities, they have ignored or downplayed the critical dynamic features of this syndrome, as lived by patients... It is important for the clinician to observe the dynamics of the whole cluster of symptoms in their interaction, additive effects, and the disruption to patients’ lives over a period of time.3

A recent Congressionally-mandated American research report on Gulf War Syndrome avoids the debate on semantics that has resulted in casuistry and delay in addressing this condition and names it, Gulf War illness, GWI.4 GWI is defined as a complex chronic multi-system illness characterized by a coherent pattern of symptoms and now shown to be causally associated with exposures to organophosphate pesticides and pyridostigmine bromide (given prophylactically to protect against the nerve agent soman) whilst other toxic exposures are not ruled out. Extensive and advanced SPECT neuroimaging studies have found changes in normalized blood flow to deep brain areas that would not be identified in routine scans. The brain structures affected include the caudate, amygdala, hippocampus, putamen and thalamus and are consistent with the multiple symptoms reported.5

The similarity of these symptoms in different conditions has been interpreted by some as an indication of common psychogenic origin, but this is no longer tenable in the light of the extensive biomedical studies reported in all these fields, particularly myalgic encephalomyelitis (ME)/chronic fatigue syndrome (ME-CFS).
fatigue syndrome (CFS). The inclusion of multiple sclerosis (MS) and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) in Table 49.1 points to the involvement of both the nervous system and the immune system in these complex multi-system illnesses/syndromes.

The challenge of these illnesses/syndromes has given rise to a stark conflict between psychiatry and biomedical science, which has been set in opposition by some psychiatrists who espouse somatization as the basis of these many other illnesses/syndromes. Patients, other clinicians and scientists see them as biomedical illnesses of organic origin. This debate has been particularly aggressive in the UK, but it is pursued elsewhere in the developed world and is associated with concerns about diagnosis, treatment and the care of people who suffer from the illnesses/syndromes. The latter involves the global insurance industry and national benefit systems for people disabled by these illnesses. These wider concerns reach into the heart of government and national and international policy, particularly with regard to the activities of large multinational corporations involved in the insurance industry and others responsible for the release of chemicals into the environment. Ordinary people, without the support of governments and

HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome.
without the necessary resources to challenge these policies, are often unable to find a voice for their concerns and those of their children.

It is no longer necessary to regard these illnesses/syndromes as of ‘unexplained’ or ‘uncertain’ origin, since we now have a much better understanding of their aetiology and the biological processes underlying them.

Figure 49.2 summarizes the major stressors that may give rise to these illnesses/syndromes and points to a way forward for the future in which science and medicine, including psychiatry, can contribute to helping those who are ill.

Somatization has a poor track record, having been offered as an explanation of previously ‘unexplained’ medical conditions, including diabetes, Parkinson’s disease and MS. The growth of modern science and the introduction of powerful investigatory techniques such as magnetic resonance has uncovered details of brain chemistry that clearly show damage to the areas of the brain, which in some cases can be linked to the specific clinical symptoms observed in patients.9,10 Dalen, a psychiatrist, has published a powerful critique of the concept of somatization that shows that the use of this idea to explain previously unexplained illnesses, often in excess among women, is often founded on ignorance and a failure to investigate new clinical phenomena.11

An alternative view involves the biopsychosocial theory that is offered as an understanding of these multi-system illnesses. This has received short shrift from another psychiatrist,12 who has criticized the lack of a credible intellectual basis for this concept. In contrast, the intellectual underpinnings of the biomedical studies are becoming increasingly understood (Figure 49.3).13

These oppositional attitudes lead to confusion in diagnosis, treatment and care and have resulted in some truly horrific cases in which people have been sectioned against their wishes, families divided and patients shown no compassion. Parents of young people have been accused of Munchausen’s syndrome by proxy.14 The result is bitterness and accusation, leaving patients and carers feeling abandoned and distressed.

Diagnosis has become a major issue in relation to all these illnesses, but it is now becoming clear that the currently accepted diagnostic criteria are inadequate and lump together people with disparate conditions. Figure 49.4 summarizes the Medical Outcomes Study 36-item Short-Form health survey (SF-36) scores of three different groups that meet the most widely used Centers for Disease Control and Prevention (CDC) 1994 definition for CFS.15 ME/CFS patients were significantly less impaired than the other two groups in terms of role emotional and mental health.
Organophosphate poisoned patients were significantly less impaired than the other groups as regards physical functioning and social functioning. However, GW patients reported significantly greater levels of bodily pain and had a significantly poorer general health scores. The latter is consistent with one of the seven clinical phenotypes identified in a genetics study by Kerr and colleagues. Distinctive tests that differentiate between the different groups of subjects are now being identified. In patients with ME/CFS, the delayed vascular response to acetylcholine is unique and differentiates such patients from patients with fibromyalgia. An initial genetics report identified single nucleotide polymorphisms (SNPs) characteristic of severe forms of fibromyalgia that distinguished patients with fibromyalgia from patients with severe ME/CFS. Differential pathology has been reported in neutrophils obtained from Gulf War veterans (mainly necrotic) and patients with ME/CFS (mainly apoptotic).

Figure 49.2 makes clear that psychiatry and psychology have a place and a role in these complex illnesses. Reactive depression is not uncommon among sick patients and needs to be treated in some cases. Other profound and long-established human activities such as meditation and prayer can also help some patients who are ill. It is of paramount importance to make clear diagnoses using the best and most appropriate investigations followed by the most effective treatments available.

Because of the dichotomy between the psychiatric and biomedical approaches to these illnesses, and the failure to provide clear diagnostic criteria, many patients are misdiagnosed and referred unnecessarily for psychiatric assessment. This places avoidable demands on the mental health services, which are already greatly overstretched, and leads to inappropriate and ineffectual treatment of patients with these illnesses.

These illnesses/syndromes are a challenge to contemporary medicine and science, but above all to our common humanity, as we seek to engage with people who are ill and need our full support.

Chapters 50 and 51 consider in detail aspects of these multi-system, multi-organ illnesses/syndromes, particularly ME/CFS, fibromyalgia and multiple chemical sensitivity.

**KEY POINTS**

- All of these illnesses are complex, challenging, chronic organic illnesses.
- They are not primarily stress or psychiatric in origin.
- The recognition of subgroups within each illness is important for diagnosis and treatment.
- Thorough and careful physical examination and the use of judiciously selected tests are important.

Multiple chemical sensitivity

Malcolm Hooper

INTRODUCTION

Multiple chemical sensitivity (MCS) is a complex, multi-symptom, multi-system multi-organ illness that is induced by exposure to a wide variety of toxic environmental insults. It is often co-morbid with other overlapping syndromes and evokes a similar range of symptoms (Table 50.1).1-5

WHAT’S IN A NAME?

MCS goes under many names and overlaps with many other syndromes and conditions (see Table 50.1). The most frequently used terms recognize that chemicals and the environment are understood by the affected people to be associated with their disabling illnesses. Among the overlapping syndromes are disorders, diseases and misdiagnoses that any competent physician would be expected to identify, for example coeliac disease, carbon monoxide poisoning and hypothyroidism.

Other descriptors are drawn from particular locations, for example ‘Gulf War syndrome’ (GWS) from the first Gulf War (1990–91) and ‘new buildings syndrome’ with new furnishings. Occupations such as carpet-fitting, commercial flying and cabin crew, and shepherding are associated with the same constellation of symptoms. Other descriptors indicate the comprehensive nature of the illness and try to place it within known clinical conditions such as allergy. More specific terms seek to identify the mechanism of the illness (e.g. toxicant-induced loss of tolerance, TILT) or cause of the illness (e.g. systemic candidiasis). An interesting inclusion in the list is electromagnetic sensitivity; this often follows chemical exposure but can be a primary event.6,7

The bewildering number and origins of so many names reflects the problems of grappling with such a complex illness and trying to understand it in order to effectively diagnose and treat patients who have it.

The World Health Organization (WHO) classifies MCS under chapters S00–T98 – injury, poisoning and certain other consequences of external causes, specifically at T66–78 – other unspecified effects of external causes and T78.4 – allergy, unspecified; hypersensitivity not otherwise specified (NOS), idiosyncracy NOS. Among the exposures specifically listed are pesticides of various chemical types, fungicides and rodenticides, although the important chemicals polychlorinated biphenyls (PCBs) are not included (Table 50.2).8

This confusion is reflected in the prolonged and sometimes acrimonious debate that surrounds MCS and involves clinicians, patients and patient support groups, and demands for recognition from governments, the chemical, pharmaceutical and insurance industries, and regulatory authorities in many countries.

DEFINITION AND DIAGNOSTIC CRITERIA

Definition

The 1999 consensus is widely accepted and defines MCS as follows:9

• A chronic condition
• With symptoms that recur reproducibly
• In response to low levels of exposure
• To multiple unrelated chemicals
• Improves or resolves when incitants are removed
• Symptoms occur in multiple organ systems.

The major symptoms of MCS are summarized in Table 50.1, but a more extensive list is given in Table 50.3. Objective clinical signs have been identified in a wide variety of tissues and clinical systems in MCS (Box 50.1).

Diagnosis

Diagnosis should be made in the light of the above criteria. A comprehensive paper by Heuser emphasizes the need for the following:10

• A very thorough history
• A thorough physical examination, with special attention to the skin, blood pressure (orthostatic hypotension), movement and coordination
The use of appropriate clinical, laboratory and psychological tests.

Single-proton-emission computed tomography (SPECT), positron-emission tomography (PET), magnetic resonance imaging (MRI)\(^\text{11}\) and quantitative electroencephalography (qEEG) all provide details of any abnormal lack of function in the central nervous system. Magnetic resonance spectroscopy (MRS) also provides a powerful tool that has identified brain damage in veterans of the first Gulf War.\(^\text{12}\) Current perception threshold studies are especially important in investigating the peripheral nervous system, as they assess the small but important C-fibres (see below). Autonomic function needs to be assessed with regard to temperature, perspiration, vascular tone, heart rate, smooth muscle tone and other functions. The eyes are important, since dry eye syndrome is common in MCS. Ear, nose and throat complaints are also common and need to be investigated fully, as nasal and pulmonary passages are frequently damaged or dysfunctional. Gastrointestinal problems occur regularly, with malabsorption and weight loss. Liver function tests are valuable, while low salivary immunoglobulin A (IgA) levels often indicate an impaired mucosal defence mechanism. Kidneys and the urinary tract may be

International recognition of MCS

MCS is increasingly recognized by legal and medical systems. It was first officially recognized in Germany and described, using the WHO’s ICD, as ICD-10-SGB-V, November 2000, under the code T78.4, ‘allergy, otherwise not specified’. Reports from Australia and Denmark have also been published. The Australian report includes a literature assessment, evidence from 22 witnesses, and 167 written submissions from Australia and overseas. It makes a recommendation for classification of MCS under its own...
modification of the WHO codes as ICD-10-AM. The Danish report is more limited, drawing largely on a published review assessing the situation in the UK.20

In North America, MCS is widely recognized. In the USA, official recognition takes the form of reports from the Department of Justice, the Department of Housing and Urban Development, and the Department of Education, which accept MCS as a legitimate condition for their purposes. Medical resistance to MCS has begun to evaporate among the American College of Physicians.20 The American Medical Association and American Lung Association and Environmental Protection Agency state that ‘Claimants should not be dismissed as psychogenic and a thorough workup is essential .’. Large population surveys report 16–33 per cent of people as being sensitive to everyday chemicals.

In 1998, 25 US federal and 28 US state authorities were listed and summaries of medical and legal/compensation papers and cases provided. Canada has recognized MCS in ten state authorities21 and has published a major review of the evidence linking its recognition to human rights.22

In contrast, official sources in the UK have been resistant to any recognition of chemical sensitivity. The British Society for Allergy, Environmental and Nutritional Medicine (BSEANM; now the British Society of Ecological Medicine, BSEM) has published substantive evidence in recognition of MCS as an organic illness that can be diagnosed and treated effectively.23,24 Although MCS does not fit comfortably into current views on allergy, the Royal College of Physicians’ report *Allergy: The Unmet Need* records a huge increase in allergy in the UK.25 Currently one person in three in the UK has some form of allergy, a total of 18 million people; of these, some 3 million have severe allergies. The Royal Commission on Environmental Pollution identified the need for a proper understanding of the health effects of novel chemicals used widely and distributed ubiquitously in the environment.26 A further report by the Royal Commission endorsed the validity of GWS, myalgic encephalomyelitis (ME; chronic fatigue syndrome, CFS) and MCS in its appendices.22 The Research Advisory Committee on Gulf War Veterans’ Illnesses from the USA summarized epidemiological studies indicating that 28–32 per cent of veterans from the first Gulf War are now ill with symptoms, including MCS.22

Veterans of the first Gulf War represent large cohorts of fit, young, mainly male military personnel from the USA (n = 697,000) and the UK (n = 53,000) who were exposed to a wide variety of biological and chemical toxins.28 Such large numbers of personnel allow considerable statistical analysis of their illnesses (GWS). There is extensive evidence of damage to the central, autonomic and peripheral nervous systems, to the cardiovascular system, and to other organs and bodily systems, and there is evidence of birth defects in some offspring.

In Sweden, electroosensitivity is officially recognized but is seen as a condition rather than a disease.

---

### PREVALENCE OF MCS AND ESTIMATED COSTS IN THE USA

The confusion and lack of uniformity in trying to assess the prevalence of MCS in various communities makes any figures open to questioning; however, various large population surveys report 16–33 per cent of people being sensitive to everyday chemicals, with the best estimates coming from studies and reports in the USA (Table 50.4).29

All studies report MCS as more common in women but not associated with socioeconomic status.

Source: Centers for Disease Control and Prevention.30

A surprising number of people report sensitivity to ordinary everyday chemicals. The figures range from an average of eleven to seventeen percent, with spikes as high as thirty percent of subjects who report reactions to multiple chemical incitants. The figures reveal that at least two percent, and as many as six percent, have been so bothered by chemical exposures that they sought medical care and received a doctor-diagnosis of multiple chemical sensitivity (MCS). Applying the case definition criteria to the average reported chemical sensitivity, it appears that 1.5 out of 10 people suffer from MCS. Health care utilization costs directly related to MCS have been estimated at approximately $1581 annually per patient. The United States population is estimated to be 302.8 million. Prevalence studies predict that approximately 15% of the United States population, now estimated at 302.8 million, suffers from MCS; therefore, direct health care utilization costs amount to a staggering $71.8 billion dollars per year. Estimated costs for MCS and other disorders linked to neurotoxicity amount to an additional $81.5 to $167 billion annually in lost productivity. Cumulative social and economic costs identified in four case studies of illnesses that are candidates for environmental causation totalled between $568 billion and $793 billion dollars per year.30
By any criteria, the impact of MCS on individual and community health and the cost to the nation (healthcare budgets) and those directly concerned with the illness (carers and dependants) is considerable.

CHEMICALS INVOLVED

The number and nature of chemicals associated with MCS is huge and covers many different chemical classes, biological activities and sources. Table 50.5 summarizes the major chemicals, their sources and their biological activities.\textsuperscript{21,29,40–43} American national studies commenced in 1999, but so far these cover only 148 different compounds.\textsuperscript{30,44} There are important concerns about how to interpret the data and the need to avoid a one-size-fits-all approach. It is necessary to take into account individual factors, including absorption, distribution, metabolism, excretion, genetics, age, sex, environment and nutritional status.\textsuperscript{45}

Various studies have found extensive chemical contamination of people throughout the world.\textsuperscript{46–48} Of particular interest is the identification of hundreds of toxic compounds in cord blood, indicating that even in utero, when cellular replication is at its greatest, there is no protection against many very toxic compounds.\textsuperscript{49,50}

Of special note is a report that identified 287 different chemicals in cord blood from newborns. Of these chemicals, 217 were toxic to the brain and nervous system, 208 could cause developmental problems, and 108 cause cancer in humans and animals.\textsuperscript{50} American organizations have emphasized the connection between mental retardation and other developmental disorders, including autism-spectrum disorders, and learning and developmental conditions in children,\textsuperscript{48,51} and they stress the lack of any testing of individual chemicals and mixtures for these disorders. Chronic neurological and neuropsychiatric conditions are increasing in older people, possibly as a result of the massive increase in environmental toxins.\textsuperscript{52}

The problem was first highlighted in Rachel Carson’s groundbreaking work \textit{Silent Spring},\textsuperscript{53} which was then followed by other publications.\textsuperscript{54} Many compounds have been withdrawn but, because of their persistence in the environment and people, contamination is now widespread. For example, PCBs were banned in 1979 in America, but people born after that date are commonly contaminated with these compounds.

A comprehensive study provides considerable data on extensive biological damage to fertility, intelligence and survival as a result of the untrammelled use and irresponsible spread of numerous untested environmental chemicals.\textsuperscript{55}

*Bioaccumulative and biomagnified through the food chain.

DDT, dichlorodiphenyltrichloroethane; DDE, dichlorodichlorophenylethene (major metabolite of DDT); PAHs, polyaromatic hydrocarbons; PBDEs, polybromodiphenylethers; PCBs, polychlorobiphenyls; VOCs, volatile organic compounds.
The challenge is to understand:

- how such diverse chemicals can provoke very sensitive responses to chemically unrelated compounds – this raises new question about drug and chemical receptors and how they operate;
- how very low levels of exposure well below those affecting the majority of people can provoke such extensive and profound biological effects – this questions the basic understanding of toxicology, particularly the relationship between dose and response and genetics;
- how the damage to one generation can be transmitted to succeeding generations.

In response to these challenges, new mechanisms of drug and chemical action have been proposed, coupled with technologies that provide hidden details of bodily systems, particularly the brain. A further challenge is to understand:

- how so many different chemicals, which have not been evaluated for adverse biological effects, have come to be released for general use;
- how novel chemicals can be assessed effectively before release into general use.

In response to these challenges, new regulatory systems have been advocated, particularly Registration, Evaluation, Authorisation and Restriction of Chemical Substances (REACH) in Europe. In the USA, action is being demanded to establish a similar regulatory authority.

Estimates from various sources indicate that 80 000–100 000 compounds currently used commercially and distributed in a wide variety of products have never been assessed toxico logically or have been assessed only as single entities and not in the complex mixtures in which they are delivered in most products.

Clearly, in addition to the concerns about health, there are important commercial, political and economic considerations around the use and development of chemicals in today’s world. There is no doubt that there is considerable vested interest and even secrecy when MCS is being considered, not unlike the activities and attitudes around tobacco-smoking, nuclear power, and genetically modified (GM) crops. A big divide lies between those espousing a purely psychogenic, psychiatric or psychological understanding of the illness and those seeking to understand the illness as an organic illness with a clear biological basis.

**PSYCHOGENIC, PSYCHIATRIC AND PSYCHOLOGICAL VERSUS THE BIOLOGICAL UNDERSTANDING OF MCS**

This is well exemplified by the following titles:

- ‘Allergic to life: psychological factors in environmental illness’
- ‘In search of non-disease’.

In marked contrast are the following:

- *Stop the 21st Century Killing You*
- *Chemical Exposures: Low Levels and High Stakes*
- *Chemical Sensitivity*, a large medical publication in four volumes with an allied website.

The website ‘Chemical sensitivity in mainstream medical documentation’ considers all aspects of the debate about MCS, with a strong emphasis on the implications for people who are affected by MCS.

A major two-stage population study of MCS found that only 1.4 per cent of the population studied had emotional problems before exposures occurred, but that after the development of MCS 37.7 per cent of the population had emotional problems, indicating that MCS had a biological rather than psychogenic origin. This is hardly surprising, since any chronic illness is likely to precipitate emotional problems.

**THE DEBATE**

MCS and other illnesses from a variety of medical specialties have been described as functional somatic syndromes in order to provide a comprehensive scheme for understanding these complex and little-understood conditions/illnesses. This approach has been severely criticized as a disguise for medical ignorance that seeks to label emerging illnesses as psychiatric when they present with symptoms very different from those of established mental illnesses:

*It must be noted that there is no proof that it is justified to apply the label somatisation to such conditions as chronic fatigue syndrome and several more illnesses that established medicine has so far failed to explain scientifically... Don’t hesitate to ask questions about scientific evidence behind this talk about somatisation. Be persistent, because a diagnosis of somatisation is definitely not an innocuous label. It will close various doors and lead (to) treatments that usually get nowhere.*

Somatization has a poor track record, being used at one time to ‘explain’ diabetes, Parkinson’s disease, multiple sclerosis and Grave’s disease. All of these now have clear, well-established biological foundations.

The biopsychosocial theory is now offered as the basis for understanding these complex illnesses/conditions. However, although this appears to embrace a more holistic view, one of its major critics states: ‘The biopsychosocial theory lacks an intellectually sound basis, and spells the failure and possible imminent extinction of modern psychiatry.’

The intellectual basis for the biological understanding of MCS is found in the neuroendocrine–immune (NEI) paradigm (Figure 50.1). This integrated communication system includes messenger molecules that are released in response to a wide range of challenges. Since these challenges include stress, it is important that the impact of stress is recognized in patients with MCS, but not by denying the
biological impact of chemical exposures. Many patients with MCS report high levels of stress if they are disbelieved or falsely accused when seeking medical help for this syndrome.

A German multicentre study on MCS examined 291 consecutive out-patients between 2000 and 2003 in considerable depth and concluded that:\(^{50}\)

- there was no characteristic set of symptoms for MCS, although many symptoms and clinical signs were identified;
- there was no systematic connection between complaints and any triggers;
- there was no evidence for any genetic predisposition but only metabolic variations in specific alleles;
- there was no obvious disturbance of the olfactory system;
- patients with MCS suffered more often from mental disorders that had commenced ‘many years before environment-related health complaints’;
- ‘overall the study did not support a toxicogenic-somatic basis of the MCS phenomenon’.

These serious and comprehensive conclusions contradict many other studies.\(^{21,25,27,28,30,43}\) However, the same study noted some real problems when engaging with MCS:

- A lack of biomarkers, which are now being identified in specific cases\(^{58,69}\)
- A lack of clear-cut parameters of dysfunction

- Case criteria were usually formulated only vaguely and were open to multiple interpretations
- ‘... despite all efforts of standardisation ... such attempts [were] very limited in clinical-based studies ... for each individual case completely different examination may be used which makes standardisation of diagnostic procedures much more difficult’.\(^{50}\)

This final statement points to two different approaches to environmental medicine: (i) a one-size-fits-all approach when considering a patient population and (ii) an approach that sees patients as unique individuals who require individualized medicine for their effective treatment and support.

The study was restricted to volatile organic compounds (VOCs) and olfaction and used the 1987 Cullen criteria rather than the more widely agreed 1999 consensus.\(^{45}\) Even here, an important study involving capsaicin, a classical vanilloid receptor agonist, has been ignored; this study concluded:

**Upper and lower airway symptoms induced by chemicals and scents represent an entity of chronic disease, different from asthma or chronic obstructive pulmonary disease, with persistent symptoms, a reduced health-related quality of life and unchanged sensory hyperreactivity.**\(^{70}\)

Other papers conclude that the combined environmental annoyance, smells and electrical equipment is a better predictor of chemical intolerance\(^{71}\) and that above-average odour discrimination ability was associated with lower ratings of odour intensity and nausea.\(^{58,59}\)

There was no consideration of any possible influence of extensive and multiple contamination by xenobiotics. People from Central Europe were found to carry the highest burden of such compounds.\(^{58}\)

Additive and synergistic effects of such contamination were not considered. There was no consideration of mutagenic and developmental effects of chemical exposure.

There was no consideration of possible brain damage from other widely dispersed toxins such as pesticides.\(^{44,72,73}\)

No psychometric tests\(^{55,51}\) appear to have been carried out. Sickness behaviour is well-known to be associated with changes in levels of important cytokines that influence the brain-immune axis,\(^{50}\) but this does not appear to have been investigated.

Overall, the firm conclusions are less secure than they may at first appear.

More recent papers report that exposure to VOCs increases plasma levels of vasoactive intestinal peptide (VIP), substance P and nerve growth factors in self-reported MCS patients (sMCS).\(^{24}\) Exposure to diesel fumes induced both Th-1 and Th-2 chemokines.\(^{25}\)

A major conference hosted by the Chemical Injury Information Network (CIIN) provided a comprehensive survey of MCS with copies of important papers in the field.\(^{56}\)
CONCEPTS AND MECHANISMS

Triggering

Many people with MCS can identify an event when they experienced a large exposure to a toxic chemical, such as a pesticide being sprayed outside or inside the house, a workplace exposure, an accidental spillage or an adventitious agricultural spraying. This is followed by an increasing sensitivity to the same or related chemicals and then to quite diverse chemicals in very different situations. Gulf War veterans show an increased incidence of chemical sensitivity and MCS. More than 40 possible battlefield exposures in 1990–91 have been identified, with the major ones being vaccines, pyridostigmine bromide (anti-nerve agent prophylaxis), pesticides (organophosphates, pyrethroids, lindane), nerve agents (sarin, tabun, VX), depleted uranium, oil and smoke. Frequently, veterans develop chemical sensitivity to perfume worn by their partners or children and previously enjoyed by the veteran, to alcohol and to petroleum fumes, which previously was not a problem. The chemistry of perfumes and petroleum products is extensive and diverse and very different from that of pesticides, vaccines and the major Gulf War exposures.

Chronic low-dose exposure to chemicals that may not be apparent to a person can also lead to MCS by a process known as 'kindling'. Rowat, as part of his proposed integrative defence mechanisms, defines kindling as follows:

Kindling refers to neural processes that mediate lasting changes in brain function in response to repeated, temporally spaced application of neurobehaviorally active agents.

Partial limbic kindling is a progressive and persistent lowering of the threshold for eliciting electrical after-discharges, but not motor seizures, in certain brain structures such as amygdala and hippocampus; behavioral consequences include increased avoidant behaviors.

The range of physical action for kindling includes various brain structures, e.g. the cortex and especially the limbic brain including the olfactory bulb and amygdala. Changes in brain chemistry are found, including a decrease in acetylcholinesterase enzyme activity that parallels the increase in sensitivity. Calcium-binding protein and tyrosine hydroxylase activity are reportedly reduced, and there are changes in β-noradrenergic binding. Benzodiazepine receptor binding is modified, as are transmitter GABA (γ-aminobutyric acid) and N-methyl-D-aspartate (NMDA) functions. Zinc may be implicated through GABA. Superoxide dismutase may also be involved. These changes may be irreversible.

The blood–brain barrier

The blood–brain barrier is the barrier of endothelial cells lining the blood vessels in the brain (Figure 50.2). The cells possess tight cell junctions that severely restrict access of compounds from the blood into the brain. This is a protective mechanism to restrict entry into the brain of biological and chemical toxins that may be ingested, inhaled or generated by infection in other parts of the body or by injury. There are selective transport mechanisms that supply neuronal and other cells with essential nutrients.

Tight cell junctions occur in other tissues, particularly the gut and the lungs. This protection limits transport across the gut wall (e.g. toxins and infections in food and water) and the lungs (e.g. inhaled toxins), but it is known to be breached by many chemicals, including various pesticides. The blood–testes barrier is similarly breached. Microbial zona occludens toxins (ZOT) also open the tight cell junctions of the blood–brain barrier. Inflammatory cytokines and other peptide molecules are also effective.

The bypassing of the blood–brain barrier by intraneuronal transport via the olfactory bulb allows toxins direct access into the brain.

A study in mice found that doses of parathion or permethrin at attomolar (10⁻¹⁸ molar) concentrations opened up the blood–brain barrier and increased transport of a marker compound into the brain by about 20 per cent. These tiny quantities correspond to the amount of residue that would be found on a single apple following spraying.

The blood–brain barrier is least efficient in the region of the paleolithic brain, and any leakage through the barrier will be greatest in the basal ganglia, brainstem, thalamus, hypothalamus and pituitary gland.

Essential tissue barriers can be opened or bypassed by various mechanisms that are known to be associated with MCS and related overlapping syndromes.
Toxicant-induced loss of tolerance

The concept of TILT was proposed as a useful alternative to MCS in 1998 and was fully developed later. A common mechanism is postulated for both drug addiction and multiple chemical intolerance, but with opposite responses – addiction (a demand for regular and repeated doses) and abdication (avoidance of a substance). In both cases, the intent is to avoid withdrawal symptoms associated with a lack or presence of the substance. The basic idea is set out in Figure 50.3, in which the normal response to a stimulant (e.g. caffeine) involves stimulation followed by recovery. Loss of tolerance leads to an increased response, which leads to alternative strategies, abdication (avoidance) or addiction (persistent reinforcing doses).

Allergy, neurogenic inflammation and switching

The association of MCS with allergy has been the subject of considerable debate, concerned mainly with the definition of allergy. One common scheme recognizes four kinds of allergy and hypersensitivity:

- **Type 1**: mediated by immunoglobulin E (IgE) and almost immediate (2–30 min). May lead to systemic anaphylaxis, which can be life-threatening, or to more localized anaphylaxis (e.g. insect bites, hay fever, asthma, hives, eczema, food allergies). IgE interacts with specific cells (basophils, mast cells), which are stimulated to release potent vasoactive mediators such as histamine and leukotrienes.

- **Type 2**: antibody-mediated. The antibodies immunoglobulin G (IgG) and immunoglobulin M (IgM) attack sites on cell walls, leading to total destruction of the cell. This process takes 2–8 h. The cell damage or loss can be very serious. Examples include blood-transfusion reactions and some types of anaemia.

- **Type 3**: involves antigen–antibody (IgG) complex formation and takes 2–8 h. The antigen–antibody complex precipitates in various tissues and induces an inflammatory reaction. Examples include a number of chronic illnesses, including glomerulonephritis, rheumatoid arthritis and systemic lupus erythematosus (SLE). A delayed response to insect bites or vaccines may operate by this mechanism.

- **Type 4**: cell-mediated. Hypersensitivity is slow (24–72 h). It involves sensitized immune cells, special T-cells that release chemical messengers (cytokines) that activate other immune cells, causing direct cell damage. Contact dermatitis, tubercular lesions and graft rejection are examples.

Not uncommonly, a single chemical or group of chemicals can induce more than one type of allergic response, for example penicillins can cause types 1–4 reactions.
Meggs and colleagues define allergy as a type 1 reaction. They regard MCS as the opposite side of the coin, sharing a similar mechanism to allergy.\(^{95,96}\)

- The response to an allergen or a chemical irritant is not limited to the immediate site of application or entry. For example, about 2 per cent of people with asthma have their asthma triggered by eating certain foods or alcohol.\(^{97}\) The inoculation of the gut leads to a response in the lungs: Meggs calls this ‘switching’. Bee stings may cause a generalized reaction involving the whole body and not only the local area affected by the sting itself. Similarly, chemicals that are generally inhaled can cause diverse symptomatology associated with the central nervous system, headaches, pain, rashes and gastrointestinal disturbances.

- Adaptation is a key four-stage construct in chemical exposures that has been known from the 1950s. The removal of the offending chemical(s) will lead to recovery, except at stage 3:
  - **Stage 0:** exposures are tolerated without illness.
  - **Stage 1:** exposure leads to multiple complaints, e.g. headache, nausea, itching, flushing.
  - **Stage 2:** inflammation occurs in one or more organs, e.g. rhinitis, asthma, arthritis, myositis (inflammatory muscle disease). Continued low-dose exposure at this stage will propagate the inflammatory condition(s).
  - **Stage 3:** fibrosis with tissue damage, irreversible lung disease, advanced asthma, deforming arthritis, etc. All the major systems can be affected, including musculoskeletal, respiratory, cardiovascular, gastrointestinal, genitourinary and nervous.

- Conditioning is a feature of MCS. In chemical sensitivity, the most common classes of chemicals to trigger a reaction are volatile and odorous. The odour threshold is many times lower than the chemical irritancy threshold, and this may explain the large difference in exposure levels that develop in people with MCS.

- Essentially, chemical irritants bind to receptors on unmyelinated sensory nerve C-fibres, which are found in the gut, airways, eye and genitourinary system and are more numerous in patients with MCS. Binding triggers an inflammatory response via an axon reflex, leading to release of substance P and subsequently other localized mediators of inflammation by interaction with mast cells (Figures 50.5 and 50.6).

Central pathways also activate parasympathetic or sympathetic nerves with effects on more distant organs.\(^{98}\)

Meggs and colleagues make much use of data from studies on Gulf War veterans; they report extensive intolerance to petrol, diesel, oils and exhaust fumes.\(^{99}\) Many veterans describe their response as loss of awareness (‘spaced out’), loss of motor control and ataxia. In some cases, this was so marked that driving became dangerous. Some veterans are unable to fill up their vehicle at a petrol station because this would render them incapable of driving safely. Mortality studies on Gulf War veterans show that there is an excess of deaths from motor vehicle accidents in this group.\(^{27}\) Although this has been dismissed by the UK Ministry of Defence (MoD) and the US Department of Defense (DoD) as a legacy of military service resulting in extravagant and risk-taking behaviour and an inability to cope with a return to civilian life, no other explanation has been forthcoming. MCS offers another explanation that better accords with the evidence and military training, which requires that extravagant risks be avoided and makes motor control and awareness paramount.

A useful summary of the varied responses to chemical exposures is given in Figure 50.7. This includes the recognition of the importance of perception and central integration of the experience (Figure 50.8).
Damage to deep brain structures

Haley found clear evidence from MRS of cell death in the basal ganglia and brainstem of sick American veterans from the first Gulf War (Figure 50.9). Later studies in animals and from historical exposures found more areas of the brain to be damaged, leading to the conclusion that "While preliminary, such findings raise the concern that ill Gulf War veterans may have neuronal damage in multiple regions of the brain." Undoubtedly, the major chemicals involved are inhibitors of acetylcholinesterase, organophosphate insecticides, the nerve agent sarin and pyridostigmine bromide – the so-called 'cholinergic triple whammy'. A useful paper analyses studies of sick veterans, agricultural workers and shepherds.

Damage to the deep brain structures is consistent with penetration of the blood–brain barrier by toxic chemicals either via the bloodstream or by intraneuronal transport.

Figure 50.7 Summary of responses to chemical exposures.
(a) More sensitive = a decrease in the magnitude of exposure required to initiate the response; more reactive = an increase in the slope or in the maximum level of the exposure–response curve.
(b) The threshold for perceiving symptoms may occur in the mid-position of the exposure–response curve (T). As a result, the clinical report of increased sensitivity could mean that the individual has become more reactive (R) or more sensitive (S).
(c) Recognition of symptoms may require the response to be present for a certain duration. The clinical report of increased sensitivity could mean that the response has become more prolonged.
(d) Habituation = decreasing responses with single repeat exposures; adaptation = progressive decrease in magnitude of response with prolonged exposure.

Figure 50.8 Potential interactions between chemical sensitivity and the domains of neurogenic inflammation, perceptual and central integration, and non-neurogenic inflammation.

Figure 50.9 Basal ganglia wrapped round the thalamus, deep in the brain.
METABOLISM AND CHEMICALS

The liver is the main but not the only organ of metabolism and is crucial in removing both endogenous and exogenous compounds/xenobiotics from the body. Metabolic processes are generally well understood and involve a range of established chemical reactions. Of particular importance is a two-stage process involving phase 1 and phase 2 metabolism. Phase 1 involves a large family of haem-containing enzymes, mono-oxygenases and cytochrome P450 enzymes (CYP450),39,102 which introduce oxygen atoms into organic compounds that are largely lipid-soluble, creating highly reactive intermediates. In phase 2, these intermediates undergo conjugation with a variety of molecules to generate water-soluble products that can be excreted in the urine (Figure 50.10).103 An important but secondary process involves excretion of some lipid compounds in the faeces.

Human CYPs play an important part in the transformation of many key endogenous compounds (e.g. steroidogenesis) but they have been studied most widely in connection with drug metabolism and some carcinogenic compounds (e.g. polycyclic aromatic hydrocarbons, PAHs). The metabolism and elimination of xenobiotics is now an important area of toxicology.104,105 CYP450s are involved in the metabolism of about 75 per cent of drugs and xenobiotics and are present in many important areas in the body, including the mitochondrial membranes, the blood–brain barrier, the gastrointestinal tract and the liver. Many xenobiotics distributed widely in the environment are PAHs. Phase 1 metabolism transforms PAHs via the introduction of active oxygen species into very reactive compounds such as epoxides, which in turn undergo phase 2 conjugation into more polar compounds, which can be excreted in the urine. If oxidative phase 1 processes are not controlled carefully and coupled with phase 2 reactions, then destructive reactive oxygen species (ROS) are produced, leading to oxidative stress, which can cause considerable tissue damage – a feature of all complex multi-system illnesses.2 Reliable data along the olfactory tract, as suggested by Ashford and Miller.64 Undoubtedly, veterans of the first Gulf War were exposed to a large number of diverse chemical and biological toxins and considerable electromagnetic radiation from many sources. Some 25–30 per cent of these veterans are now ill,27 and for this to happen to healthy young people in the prime of life serves as a warning to the whole of society about taking care with the manner in which we expose even the healthiest people to novel chemicals. The counter view, that seeks to establish Gulf War illness (GWI)/GWS as a psychiatric illness,101 is typical of the debate that rages around MCS in the face of incontrovertible and replicated evidence of significant brain damage in sick Gulf War veterans.99 It is important to examine the implications for mental health rather than to claim that there is no such evidence.
are available for ME/CFS, organochlorine pesticides and organophosphate pesticides, alone or in combination with other xenobiotics. Both mitochondrial function and the nervous system are affected.

Oxidative stress, defined as an imbalance between reactive oxygen species and free radicals and antioxidant compounds, can also arise from other defence processes such as inflammation, which are also tightly controlled under normal circumstances.

This insight into multi-system illnesses suggests useful ways of providing treatment for patients with MCS.

Bioactivation can be a result of the metabolic conversion of xenobiotics ( aflatoxins) and drugs ( ethyl carbamate, troglitazone, terfenadine) to more toxic compounds. In contrast, many persistent and bioaccumulative compounds possess bonds that are resistant to cleavage in metabolic reactions. This is particularly true of carbon–halogen bonds attached to aromatic or ethylenic carbon atoms. Such compounds accumulate up the food chain, leading to increasing doses in the organisms, including humans, that are at the top of the food chain. Significant contamination of fish oils with PCBs and dioxins and of tuna and swordfish with mercury have been reported, leading to advice to restrict the intake of these foodstuffs. Mercury is both concentrated and bioactivated to methyl mercury when it passes up the food chain, and this was the cause of the severe neurotoxicity associated with the oxidation of low-density lipid particles. It is now recognized as a key enzyme in removing toxic/psychiatric Minamata disease.

Phase 2 metabolism assists the elimination of many compounds by conjugation of reactive chemical groups present in endogenous and exogenous compounds. The classical example is paracetamol. The metabolic pathway involves conjugation with sulphate or glucuronyl groups, but when these become exhausted in patient who has taken an overdose, a toxic quinoneimine is formed, which binds to glutathione, the primary cellular antioxidant molecule. The progressive removal of glutathione is responsible for the slow but often inevitable fatal effects of paracetamol.

**GENETICS**

ME/CFS has been investigated extensively by Kerr and colleagues, who have identified some 88 genes that are mainly up-regulated in very sick patients with ME/CFS. The larger study identified seven clinical phenotypes for ME/CFS. Although such studies have yet to be carried out on patients with MCS, there is evidence of genetic susceptibility in some studies.

The importance of genetic variations in drug- and xenobiotic-metabolizing enzymes was recognized at the beginning of the twenty-first century.

The underlying genetic predisposition of each patient will reflect combinations of poor- and extensive-metabolizer phenotypes; if these enzymes cooperate in the same metabolic pathway for any given drug or environmental agent, such ecogenetic variability might be synergistic and lead to as much as 30- or >40-fold differences in activation or degradation. The end result can be large interindividual differences in risk of environmentally caused toxicity or cancer.

In one study, there was an 18-fold increase in the risk of MCS when interactions between CYP2D6 and NAT2 metabolizing enzymes occurred. Another study found that variations in NAT2 and GST genes were linked to increased chemical sensitivity. One study did not find any link with some allele frequencies, but it considered only NAT1, NAT2, PON1 and PON2 and did not consider CYP2D6 or GST genes. Because of the large number of genetic variants of the many enzymes involved in xenobiotic metabolism, this is a complex but urgent area of study that will be very fruitful in understanding the widespread variations in MCS. Analogous studies to those of Kerr and colleagues are urgently needed.

Although traditionally the major concern has been with drug metabolism (pharmacogenomics), the wider term 'toxicogenomics' has been introduced, and a paper describes how exposures to arsenic in drinking water can alter the gene function in babies born to mothers exposed in this way. This disturbing link of arsenic exposure to increased inflammatory responses in the succeeding generation increases the urgency to recognize and treat MCS, of which it is a part.

The enzyme paraoxonase 1 (PON1) has been particularly well studied. It plays a key role in protecting against oxidative stress associated with the oxidation of low-density lipid particles. It is now recognized as a key enzyme in removing organophosphates and nerve agents from the body. It is important in GWS, where initially it was proposed that genetic variants Q and R, respectively involving the amino acids glutamine and arginine at position 192 in the enzyme, were important; soon, however, it was found that it was the level of the enzymes and not their genetic form that was important. The use of leaded petrol in the Gulf War may well have depressed the levels of PON1, making the troops more susceptible to the toxic effects of organophosphates and nerve agents. This illustrates the complexity of MCS where two apparently independent factors have been found to impact on the same biological system. Later studies indicated that there is genetic control of the levels of the enzyme produced, particularly in connection with the recognition of organophosphates in aerotoxic syndrome.

**Polymorphisms**

Polymorphisms are defined as variations in gene structure that are too common to be due merely to new mutations. A polymorphism must have a frequency of at least 1 per cent in the population. They have become the subject of intense research, as small changes in gene structure can now be identified that have been associated with the risk of developing chronic diseases in later life and also predicting the
consequences of gene–environment interactions.\textsuperscript{132} In single-nucleotide polymorphisms (SNPs), a single nucleotide change occurs that alters the function of the gene; for example, in the \textit{PON1} gene, the trinucleotide sequences for the key amino acids at position 192 in the enzyme are glutamine (CAG) and arginine (CGG) and involve the single exchange of adenine (A) for guanosine (G). However, it is now clear that almost 200 polymorphisms have been found in \textit{PON1}, although not all are functional. The direct measurement of the enzyme itself is the most reliable way of investigating its role in disease:

We, along with other authors, would strongly suggest that all further epidemiological studies into the role of \textit{PON1} and disease should include a measurement of the enzyme itself in addition to the genetic polymorphisms.\textsuperscript{133}

This conclusion is a measure of the difficulties of investigating complex multi-system illnesses such as MCS.

\textbf{Epigenetics}

Epigenetics concerns changes in the phenotypic expression of inherited genes by chemical modification of DNA and chromatin, which results in changes of gene function (transcription, replication, translation, combination). Such modifications involve methylation of DNA or methylation, acetylation, phosphorylation, ribosylation or ubiquitination of chromatin. These processes result in remodelling of chromatin, with subsequent changes in gene expression. Genes may be silenced or activated by these processes, which can cause permanent and heritable, or transient, changes in the phenotype.\textsuperscript{134} These changes can occur throughout life: pre-conceptually, in either parent; periconceptually; early or late gestation; and in neonates, children, young adults and older adults. Animal and epidemiological studies have identified changes in the reproductive organs, uterus and mammary glands, including cancers in later life (diethylstilboestrol, DES; bisphenol A, BPA), prostate problems (methoxychlor), sperm-counts, fertility problems, hypospadias (phthalates), nutritional effects, obesity (DES, tributyltin (TBT), BPA) and early-onset parkinsonism (parquat, maneb).\textsuperscript{135} The major factors are presented in Figure 50.11.\textsuperscript{136}

It is a matter for concern that the nutritional status of the mother may have serious developmental outcomes for her offspring when they reach adult later life (Figure 50.12).\textsuperscript{137} Combined with these adverse developmental effects, environmentally encountered heavy metals such as arsenic, manganese\textsuperscript{138} and lead\textsuperscript{139} will exacerbate the deficits imposed on children, particularly in the developing world, where parents, especially mothers, are under prolonged
socioeconomic stress. This avoidable loss of human potential is a grievous loss to the world community.

**Mitochondrial DNA**

Mitochondrial DNA is derived only from the mother and is known to more readily undergo mutations and damage compared with nuclear DNA. Pathogenic mutations in mitochondrial DNA have been reported to be common. The question arises as to what effects environmental toxins have in this process. Are epigenetic changes involved? Since oxidative stress, a feature of MCS, is associated with compromised mitochondrial function, these latest findings may be very important for the future.

**THE NO/ONOO HYPOTHESIS**

Pall brought together a long series of papers and reviews concerning the NO/ONOO (nitric oxide/peroxynitrite) hypothesis (Figure 50.13). This provides a comprehensive disease paradigm for ME/CFS, MCS, fibromyalgia, post-traumatic stress disorder (PTSD), GWS and related illnesses.

![Figure 50.13 NO/ONOO (nitric oxide/peroxynitrite) cycle](image)

At the heart of this paradigm is the formation of the potent free radical and oxidant, nitric oxide (NO). NO reacts with superoxide, which is generated mainly in mitochondrial DNA in small amounts, as part of the normal synthesis of adenosine triphosphate (ATP), the body’s principal energy molecule. Nitric oxide and superoxide combine to form peroxynitrite (ONOO), a very potent oxidizing molecule. This, in turn, generates oxidative stress, which is already a feature of the overlapping syndromes that include MCS. Oxidative stress activates the gene transcription factor NFκB, increasing the activity of inducible nitric oxide synthase (iNOS) and the levels of inflammatory cytokines (e.g. interleukin 6, IL-6), which also stimulate iNOS. At the same time, ionic calcium is released from intracellular stores, which stimulates the activity of neuronal nitric oxide synthase (nNOS) and endothelial nitric oxide synthase (eNOS). Oxidative stress and superoxide further stimulate the vanilloid receptor, VR1, which is a promiscuous chemoreceptor found on C-nerve fibres. The vanilloid receptor and NO evoke stimulation of the excitatory NMDA receptor and NO activates stimulation of the excitatory NMDA receptor.

**THE CHALLENGE TO TOXICOLOGY**

Table 50.6 shows some conceptual shifts in Toxicology.

**Low-level exposure**

There are many examples of low levels of exposure having significant effects on biological organisms and humans some 100-fold lower than the no observable adverse effects level (NOEL or NOEL) or allowed daily intake (ADI). Tributyltin, with a NOEL of parts per billion (ppb), killed most water invertebrates at 5–10 ppb. In mammalian systems, endocrine-disrupting chemicals with oestrogenic activity evoke responses at very low doses, comparable with those found in the environment and consumed by people, but higher doses had contradictory effects, making it essential to develop biological testing systems that will be responsive to low doses of environmental toxins. An important aspect of testing chemically sensitive people is the need to allow a period for adaptation before exposures in order to ensure reliable and reproducible experimental measurements.
Multiple chemical sensitivity

Additivity, antagonism, synergism, non-monotonic dose–response curves and hormesis

Environmental toxicants are usually encountered in complex mixtures, but most are tested individually. The combined effects of such compounds might be expected to be additive, antagonistic or synergistic. The study of these relationships is complex and varied, but examples of such interactions have been found experimentally in whole animals and in isolated biological in vitro systems:

- **Additivity**: using a yeast oestrogen screen, the effects of four different oestrogenic compounds (4-nonylphenol, 4-octylphenol, *o,p*-dichlorodiphenyltrichloroethane (DDT), genistein) in two to four component mixtures were found to be additive.

- **Antagonism**: this was described in a study of the teratogenic effects of mixtures of PCBs. It was found that the immunotoxic effects of one PCB congener were antagonized by another closely related congener.

- **Synergism**: this arises when the overall toxic effects of a mixture are greater than the sum of those of the individual components. This has been observed with acetylcholinesterase inhibitors and *N,N*-diethyl m-toluamide (DEET), an insect repellent used in the first Gulf War in 1990–91, in pesticide formulations and in herbicide formulations. The so-called ‘inerts’ in product formulations can increase toxicity and should be included in routine testing of any products, which commonly involves only a single active ingredient. These effects can be very large, with increases in toxicity of more than 100- or 1000-fold. Disturbingly, commonly used food additives also show synergistic increases in developmental neurotoxicity tests.

- **Non-monotonic dose–response curves**: classical toxicology uses linear dose–responses to estimate the limits for exposure to environmental toxins (Figure 50.14). This effect involves the assumption that dose–response is linear and, at a sufficiently low dose, becomes zero – the NOEL. The data, usually from animal experiments, are then adjusted arbitrarily by reducing the identified dose by one or more orders of magnitude in order to obtain the reference dose. The reference dose is chosen to accommodate possible differences between animal and human responses, and the different sensitivities of children and elderly people. The NOEL is, in this way, reduced to an estimated reference dose some 100–1000 times lower than the observed experimentally determined dose.

Figure 50.14 Dose–response curves found in toxicology: inverted U–curve for cell signalling disruptors
Courtesy of Professor Vyvyan Howard.

Figure 50.14 shows that at doses below the NOEL, toxic effects are found in a bell-shaped or inverted U-shaped dose–response curve. Note the large concentration differences associated with the conventional linear part of the dose–response curve and those with the non-monotonic part of the curve.

Figure 50.15 illustrates the different forms of non-monotonic curves that have been found for many environmental toxins. Among the earliest investigators of this phenomenon was Frederick Vom Saal, who studied the oestrogenic effects of drugs and environmental toxins, particularly BPA, in mice. In a paper published in 1997, Vom Saal and colleagues wrote (author’s italics):

Our findings show for the first time that fetal exposure to environmentally relevant parts-per-billion (ppb) doses of bisphenol A, in the range currently being consumed by people, can alter the adult reproductive system in mice.

Endocrine disruptors have been studied widely. Doses as low 10^{-11} molar have evoked immune responses similar to those caused by oestradiol that involve the release of histamine and cytokines from mast cells in cell culture, providing further evidence of the interrelationship between the endocrine and immune systems.

The situation is complicated by the discovery of two classes of oestradiol receptors, one in the nucleus and one that is membrane-bound. The membrane-bound receptor is equally sensitive to oestradiol and bisphenol A, while the nuclear receptor is much less sensitive to bisphenol A.

The crucial nature of the test systems must be considered when determining the NOEL and reference doses.

**Hormesis**

Hormesis is defined as low-dose stimulation and high-dose inhibition and follows a non-monotonic dose–response curve. It has been used to claim that low doses of environmental toxins should be regarded as beneficial and be the default position adopted by regulators and clinically. There has been a thorough evaluation of this view, which emphasizes that:

- underlying mechanisms of action, and not simply empirical data, must be considered;
- stimulatory effects are not always beneficial and may be harmful;
- all the induced effects of a toxicants, and not only the beneficial ones, must be considered;
- any health decisions based on beneficial effects must address interindividual differences, including susceptibility, genetic factors, life stage and health status;
- any health decisions based on beneficial effects must address the fact that other environmental and workplace exposures may alter the low-dose response of a single agent.

This excellent paper puts all these considerations into a generalized theoretical framework and includes many telling experimental examples. For instance, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), an environmental carcinogen, has been quoted as having low-dose beneficial effects. Closer examination of the data shows this to be false, since the incidence of tumours of the liver, lung, tongue and nasal turbinates increased, while incidence of tumours of the pituitary, uterus, mammary glands, pancreas and adrenal glands decreased.

In one study claiming the hormetic effects of cadmium, a non-statistical decrease in testicular cancer in rats was accompanied by a statistical increase in prostatic hyperplasia and an increase in prostate tumours per animal in the hormetic range.

Ethanol is cited as a classic hormetic agent, since beneficial outcomes – reduced risk of coronary heart disease and a reduction in mortality – have been identified with low consumption, in contrast to increases at higher doses of, among other things, neurological disorders, cancers and liver cirrhosis. However, small amounts of alcohol (0.5 units per day) in pregnancy have been associated with adverse behavioural outcomes such as aggression in children.
Developmental effects of environmental exposures

Intergenerational effects
Diethylstilboestrol (DES) is known to cause malformation of the uterus in daughters born to women who received DES during pregnancy, predisposing the daughters to rare uterine cancers. In rats, androgen receptors were permanently raised in male offspring of females given DES during pregnancy, with an increase in the size of the prostate gland. BPA caused similar changes. DDT lengthened the time to pregnancy (fecundability) in the daughters of mothers exposed to DDT; the probability of pregnancy fell by 32 per cent per 10 µg/L in maternal serum.

Effects on the fetus and babies
The most rapid multiplication of cells and differentiation of tissues occurs during fetal growth and development within the womb. This is when key biological processes are most susceptible to disturbance by xenobiotics. The notion that the developing fetus is protected during its growth and development within the womb has been shown to be wrong. Many xenobiotics cross the placental barrier and can disrupt many crucial stages of development.

A ruling by the USA high court awarded damages of $4 million to John Castillo, who was born without eyes (anophthalmia) following his mother’s exposure to the fungicide benlate when she was 6–7 weeks’ pregnant with her son. The exposure occurred on a single day when Mrs Castillo was accidentally sprayed while walking. The initial case was hotly contested by DuPont, the manufacturer of benlate, but the case was upheld and then lost on appeal before the final ruling of the Florida supreme court in 2003. The time of the exposure in the Castillo case corresponded to the time of maximum cellular replication and organogenesis in the developing fetus. The company had funded a 2002 study that showed benlate to be concentrated in the eyes in rats. This report was unpublished but reported by the Guardian newspaper. Benlate has been the subject of numerous other cases and has now been withdrawn, after 33 years on the market.

Cord blood studies identified hundreds of toxins to which the fetus had been exposed, many of them developmental neurotoxins. This is of particular concern to the American Association on Mental Retardation (AAMR; now the American Association on Intellectual and Developmental Disabilities, AAIDD), which stated: ‘The evidence is mounting that exposure to environmental pollutants and toxins are contributing to poorer health and significant increases in chronic disease and disabilities in our society.’ Some 17–18 per cent of Americans under age 18 years are claimed to be affected.

A scientific consensus statement on environmental agents associated with neurodevelopmental disorders brings together the most up-to-date information of a large group of concerned scientists in the USA and emphasizes the following:

- Children and young people cannot be considered as ‘small adults’ and show marked differences in physiology and routes of exposure. They are often more susceptible to environmental exposures.
- Low doses of toxicants can alter gene expression and affect learning and development.
- Effects can be delayed.
- Genetic polymorphisms render some subgroups more sensitive than others to certain chemicals.

Autism, attention deficit hyperactivity disorder (ADHD), dyslexia, mental retardation, lowered intelligence quotient (IQ) and other disorders of learning and behaviour are highly prevalent among American children. These conditions appear to be rising, with presently 5–15 per cent of all children under the age of 18 years in the USA affected – more than 12 million children. ADHD has been shown to be linked to food additives used in children’s drinks and foods. Autism-spectrum disorder appears to be ten times more prevalent now than in the 1980s. The costs of providing special educational services in the USA have been estimated at $77.3 billion, twice the cost of regular education. In addition, there is the human cost for families and communities.

Agents definitely found to be associated with learning and development disabilities (LDDs) are alcohol, lead, mercury, manganese, arsenic, PCBs, polybromodiphenylethers (PBDEs), solvents, PAHs, pesticides and nicotine in tobacco smoke. The damaging effects of these toxins have been known for many years, but the development of products containing them has been allowed to take place on economic grounds. A good example is lead. The toxic neurodevelopmental properties of lead have been known for years; however, its use in paints and in petrol was stopped only after much struggle. The failure of policy-makers to protect young children by not acting quickly in response to the science has laid waste countless young lives. The Centers for Disease Control and Prevention (CDC) has not changed the standard for acceptable blood levels of lead in children since 1985, although the most recent proposal for a level of 2 µg/dL is some 12.5 times lower than the 1985 level.

Solvents and solvent-based products (Table 50.7) are frequently involved as neurotoxins and are ubiquitous in the environment.

Effects on elderly people
The Pritchard Report examined changing patterns of adult (age 45–74 years) neurological deaths in the major Western world in the period 1979–97 and found significant increase in chronic illnesses, for which the report suggested possible environmental factors.
Delayed effects

One of the most worrying aspects of chemical exposures and MCS is the development of delayed neurotoxic effects years after the initial exposure, which may have been at low levels. This has been found with GWS\textsuperscript{129,166–168} and in survivors of terrorist attacks using the nerve agent sarin\textsuperscript{129,166–168} Such temporal relationships are easily missed without a very thorough history.

### Treatment

A survey of 917 people with MCS enquired about illness rating: the results were mild (7%), moderate (32%), severe (45%) or totally disabling (13%), with the respondents being mainly white (95%) and predominantly women (82%).\textsuperscript{169} A total of 101 treatment and management techniques procedures, and their perceived efficacy, were assessed. A help/harm ratio was devised that allowed comparison of the different treatments tried by the respondents (Table 50.8). The higher the ratio, the more helpful the treatment, with a ratio of 10 indicating that ten times more people found the treatment helpful compared with those who found it harmful. The lower the ratio, the more harmful the treatment, with a ratio of 0.1 indicating that ten times more people found the treatment harmful compared with those who found it helpful. A ratio of 1 indicates that there was an equal balance between help and harm.

The three most highly rated treatments were:
- a chemical-free living space (ratio 155.2);
- avoidance of chemicals (ratio 118.6);
- prayer (ratio 48.3).

Other reports emphasize the importance of a chemical-free living space and avoidance of chemicals in health, education, legal and benefit provisions.\textsuperscript{21,22,27,28,40,61,62} It is clearly common sense to avoid known chemicals that cause the patient problems and to avoid contact with other chemicals on the precautionary principle. Chemical-free living space is humane and less costly than attempting to provide long-term medical care for this complex condition. The inclusion of prayer is striking and indicates the need to consider...
people with MCS holistically. Prayer is not defined in any specific terms but excludes meditation, hypnosis and faith healing. Cognitive-behavioural therapy (CBT) is not considered specifically, but psychotherapy as a cure is rated as of no noticeable effect (65.3%) or as very harmful (6.6%). However, as a coping procedure, 47.7 per cent of patients found psychotherapy somewhat helpful, with 24.1 per cent of patients reporting no noticeable effect. Exercise is reported as causing harm (14.7%), of no noticeable effect (23.7%) or helpful (61.6%). Exercise is reported by severely ill people with ME/CFS to be positively harmful, with only 5 per cent of patients finding it helpful.170,171

The interventions rated as more harmful than helpful include:

- conventional medicines, particularly all antidepressants and anxiolytics (tricyclics, selective serotonin reuptake inhibitors (SSRIs), benzodiazepines) and anti-seizure drugs (help/harm ratio 0.1–0.5);
- provocation–neutralization (P–N) testing for chemicals with preservatives (help/harm ratio 0.9).

Since MCS includes heightened sensitivity to chemicals, it is not surprising that the response to drugs is also heightened. When any drugs are given, it is imperative that the initial dose is much lower (one-quarter to one-eighth) than the starting dose recommended in the formularies in order to avoid any possible (severe) reactions. The drugs generally found harmful are those that work by modifying brain function, which is a major area of damage in MCS and part of the neuroendocrine immune paradigm.

More surprising was the inclusion of P–N among the more harmful treatments. P–N is used widely and recommended among some practitioners of ecological/environmental medicine.56,62 P–N can take different forms, but these were not specified.

Initially, saunas were three to four times more helpful than harmful and feature among the recommended treatments that offer a means of detoxification.61,62,80 However, over a longer time, saunas proved less helpful. The type of sauna used (wet or dry) was not specified. Reducing the total toxic load is seen as a desirable goal in treatment.61,62,80,96,172,173

Diet was also generally helpful. Only a rotation diet was mentioned, although other exclusion diets, in which dairy and gluten are the first to be removed, using a food diary61,62,80 or following the Stone Age diet62 may also be helpful. Other aspects of diet modification include using acidophilus to support gut flora, which, with related probiotics, features in many diets.

Detoxification includes removal of dental fillings, with a help/harm ratio of 4.8, and the use of UltraClear®, a combination product designed to comprehensively support the gut, with a health/harm ratio of only 1.

Many people had tried a range of mineral, vitamin and co-factor formulations, but the individual help/harm ratio scores varied between 8.6 and 4.1. No specific mineral, vitamin and co-factor combinations were used. One study found that MCS was not associated with vitamin deficiency or thyroid function, but lower lymphocyte counts suggested immune dysfunction with VOCs.160 The advent of specific tests that allow the identification of toxins permits more precision in designing treatments. Such tests identify block-ade of mitochondrial function, DNA adducts161,174–176 and analysis of needle-fat biopsies. Pesticide load has been reduced by choline and vitamin C.177 Vitamin B2 has long been used to treat neuropsychiatric disorders where no anaemia or macrocytosis is present.

Various combinations of supplements (vitamins, minerals and other co-factors) in a wide variety of combinations have been recommended. Among the most useful is one supporting mitochondrial function – N-acetyl-β-carnitine, co-enzyme Q10, niacin, ribose and magnesium. A more complex mixture of potent antioxidants is being trialled in the USA.2

An important question about the testing of adults for environmental chemical contamination is: 

**Could we be trying to correlate exposure and effect at the wrong time?** If it is prenatal, or early life stage, exposure that is critical to disease susceptibility, why are we measuring environmental chemicals in people once they have developed breast cancer? The critical exposure window may have been much earlier.178

This underlines the urgency to recognize many chemicals as major developmental hazards, which must be addressed at the earliest possible moment in order to avoid longer-term and adverse consequences.

### POLITICAL, SOCIAL AND MEDICAL ACTION

The response of governments, global corporations, industry and society to the accumulating evidence of the hazards of chemical contamination has been to minimize the observed effects, to accuse the scientists involved of poor science,73 scare-mongering,161,179 unrealistic attitudes180 and, in a number of extreme cases, vilification and character assassination.181,182 Government activities and research funding have been dictated by policy and not open, independent, transparent science. In an article that called for research, not propaganda, the reluctance of the medical establishment to embrace change was challenged. US Representative and physician Dave Weldon said:

Mind you, half of Dr. Wakefield’s theory has been proven correct and accepted in the medical community. Hundreds of children with regressive autism and GI [gastrointestinal] dysfunction have been scoped and clinicians are seeing the inflammatory bowel disease he first described. The NIH [National Institutes of Health] is finally funding an attempt to repeat Dr. O’Leary’s findings of measles RNA in Wakefield’s biopsy specimens, though I am disappointed it has taken this long.
A similar story is described by Arpad Pusztai, whose work upset the establishment’s ideological commitment to GM crops and food.\textsuperscript{181} Evidence has been sought to support policy rather than to design policy in response to medical and scientific evidence. Disturbing scientific and medical studies are being denied rather than replicated in order to establish their validity.

The failure of government and regulators to act on a report on food colouring and ADHD in this matter is regrettable and symptomatic of the unwillingness to make changes in our chemical environment that are resisted by the industry, even in the light of good science.\textsuperscript{184} Both the Food Standards Agency (FSA)\textsuperscript{185} and the European Food Standards Agency\textsuperscript{186} refused to endorse the precautionary principle and withdraw the products immediately.

The phthalates reveal a similar story. These were banned in some countries from 1977,\textsuperscript{187} but in the USA the toy industry launched strong resistance to a ban in America.\textsuperscript{188} One study reports a positive association between urinary phthalate metabolites and adult male (age 20–59 years) obesity.\textsuperscript{189} There were other positive associations with adverse health effects among young women and elderly people, but not in children.

The attitude to xenobiotics in the environment is reminiscent of the fight against tobacco and smoking. It seems that many people and organizations are prepared to sacrifice the health of present and future generations in order to make a fast buck or allow national tax income to be protected.

GULF WAR SYNDROME/ILLNESS

In November 2008, a second report on GWI was released by the Congressionally mandated Research Advisory Committee on Gulf War Veterans’ Illness (RACGWVI).\textsuperscript{190} The 450-page report with some 1800 references validates the earlier conclusions of the 2004 report and states:

The illnesses suffered by veterans were a result of unique circumstances in which they were exposed to a considerable number of toxic insults. The most important of these were:

- receiving multiple vaccines, some experimental;
- pyridostigmine bromide, also experimental, in Nerve Agent Pre-treatment Set (NAPS) tablets;
- pesticides, especially organophosphates, used to keep down disease vectors;
- exposure to low levels of chemical warfare agents in the form of nerve agents.

GWI has the following features:

- It is a chronic multi-system physical medical condition with a coherent pattern of symptoms.
- Many veterans show evidence of physical brain injury in the form of neuropsychological impairment, which cannot be detected by routine tests.
- It is not a stress-related condition.
- There is a twofold increase in motor neuron disease and brain cancer in people with GWI.

CONCLUSIONS

MCS is a medical, scientific, political, legal and social issue that needs to be addressed within our society as a matter of urgency. It is now beyond argument that xenobiotics have the potential to damage present and future generations.

The role of psychiatry is to embrace the science and medicine that provide the evidence of chemical and environmental damage and to support those people who have to cope with this condition.

The role of industry, science and medicine is to carry out comprehensive and independent chemical, toxicological, pharmacological and clinical studies to ensure that all products in the marketplace are safe for widespread use in the community. All data should be available for examination in the same way that scientific papers are scrutinized before publication by independent scientists and clinicians.\textsuperscript{191} Vested interest should have no part in this process.

The role of politics is to protect its citizens with independent funding, coupled with robust and clear regulations, without any influence from vested interests that pay thousands of pounds in lobbying fees to exert control over the political process.

Where people are physically, chemically or biologically exposed to any hazard and develop MCS and related conditions, their welfare should be put first and every provision made to ensure that they have the resources required to cope with the environment of the twenty-first century.

KEY POINTS

- MCS is a complex, chronic multi-system condition.
- It is associated with exposure to a wide variety of novel chemicals, environmental, agricultural and dietary.
- It requires a much more responsible and careful assessment and regulation of all novel chemicals in line with the precautionary principle.
- It requires recognition of the new understanding emerging from recent studies in toxicology, metabolism, genetics, epigenetics and developmental biology.
- Recognition of the condition by clinicians, education, health authorities and government authorities is required for effective treatment, the most important of which is the removal of incitants and the provision of a clean and controlled living environment.
- Research is needed in order to establish other treatments that may help at various stages of the condition.
- There may be a need for subgrouping of people with MCS.

Mental health problems in patients with myalgic encephalomyelitis and fibromyalgia syndrome

Byron Hyde

INTRODUCTION

Since 1934 at least 70 myalgic encephalomyelitis (ME)-type epidemics have occurred around the world. Yet most physicians and the public remain unclear as to the cause and characteristics of ME. Many physicians debate the existence of ME as a valid medical entity. To put it kindly, many physicians simply find ME and patients with ME an unwanted bother. Since 1934, when the first well-documented ME epidemic ravaged the Los Angeles County Hospital, ME as a diagnosis has refused to go away and the mental health aspects of ME and chronic fatigue syndrome (CFS) not only remain but also appear to increase. We require a better understanding of ME and CFS. Even with knowledge, treating the mental health problems of the patient with ME will remain a formidable task.

Since 1984, I have been asking the question, ‘What is ME?’ First I sought out the few original ME experts in various countries who had examined patients with ME and the ME epidemics since 1934. I examined patients and questioned physicians from the 1934 Los Angeles epidemic, the 1947–48 Iceland epidemic, and the various UK, New Zealand, Australian and Canadian epidemics, and I visited each of these epidemic sites. For the next 24 years, I have intensively investigated patients with ME and asked: ‘What are the pathologies of the patient with ME that cause them to remain ill and unable to carry out the tasks that they were so good at before their illness onset?’

During the past 24 years, I have confined my practice to patients with ME and CFS. As much as possible, I have examined every organ and system of each of thousands of patients with ME, thanks to the totally free access that patients and physicians have to all tests and specialists in the Canadian health system. The following chapter represents a small amount of what I have discovered during the years that I have questioned ME experts, studied the considerable ME literature, and examined thousands of patients with ME and CFS. What became obvious to me is that we cannot understand the patient with ME without examining the patient in great detail, along with his or her environment, social system and belief structure. We must also examine the limitations, usually imposed by government bureaucracy, that prevent physicians from adequately examining patients with ME.

THE WRITER’S PREJUDICE

Allow me to start by first acquainting you with my prejudice of what I believe constitutes a patient with ME, since it may interfere with any preconceived perceptions that you bring to this discussion. My prejudice is this: the patient with ME has been with us a very long time, undoubtedly many centuries, but it was only in the twentieth century that we had the technology and medical organization to distinguish ME as a specific illness category and a communication system (the Internet) that enabled these patients to find each other and group together, often much to the regret of the physicians and often with an inaccurate diagnosis not based upon scientific evidence.

A succinct definition of ME is this:

ME is an acute-onset, diffuse injury of the central nervous system (CNS) that in turn either provokes or is associated with organ, system and social pathologies that prevent the patient from effectively competing in their previous work and social culture.

Classically, ME occurs in epidemic and endemic periods, as in the 1934 Los Angeles, the 1947–48 Akureyri or the various UK epidemics. The onset of illness in both the historical and today’s patients is often associated with an apparent infectious disease, immunization, and traumatic or toxic exposure in the immediate previous days or by repeated traumas in the prior weeks and months.
The key terms in this definition are:

- acute-onset;
- diffuse CNS injury;
- complex organ, system and social pathologies.

Figure 51.1 shows a single-photon-emission computed tomography (SPECT) brain scan of a typical patient with ME.

In the clinical situation, both the physician and the patient are confronted with another problem. Which patient has ME? Which patient is misdiagnosed as having ME? Possibilities include the following:

- Chronic patients with ME and its associated organ, system and social pathologies
- Chronic patients with undiagnosed or missed single or cumulative major medical illness or pathology diagnosed as ME but suggesting low-grade or slowly progressive injury
- Patients with classical psychiatric disease that may or may not be complicated by organ or system pathology
- Acutely ill patients misdiagnosed as ME but with a potentially treatable progressive illness.

The first three patient categories above tend to have similar mental and social health issues and can be discussed as a group. By definition, the referring physician never diagnoses any of the missed major pathologies. If they did, then probably the patient would not be referred to as having ME or CFS. The big danger, the veritable mine in the minefield, is the last – the patient who, either diagnosed by a physician or self-diagnosed, has recent-onset ME. Too often have I seen fellow physicians who tell me they have ME, laugh and then say they do not require an examination, only to find that had they been examined properly an undiagnosed malignancy would have been discovered when it was still treatable. The greatest tragedy is to miss a diagnosis that could have been treated, and perhaps cured, by the physician who had taken the patient’s symptoms not as a diagnosis but as a medical mystery to be solved by scientific testing. This also represents my major criticism of the diagnosis of ME, either by the physician or by the patient. My criticism is not directed toward the psychiatrist but to the physicians who, for whatever reason, have failed to properly investigate and follow these reputed patients with ME before referring them to psychiatry.

THE PATIENT WITH M.E. AND HER MYTHOLOGIES

For the clinical psychiatrist and clinical medicine physician, it is the patient’s complex mythologies, perhaps more than scientific understanding, that overwhelm both the patient and the physician. It is essential to understand these patient mythologies in order to help the patient with ME. Our patient is more than an injured body and brain: she is an integrated part of a complex belief and social structure with all of its values and prejudices.

If you were to be referred four real patients with ME, on average three would be girls or women and one would be a boy or a man. This 75 per cent percentage of females corresponds approximately to many autoimmune illnesses, such as multiple sclerosis and rheumatoid disease, but this of course does not validate ME as an autoimmune disease.

Figure 51.1 Brain single-photon-emission computed tomography (SPECT) of typical patient with myalgic encephalomyelitis (ME). This is a typical severe ME brain, as visualized by SPECT at illness onset, with Brodmann areas indicated. Blue areas represent the significant typical hypoperfused areas of this dysfunctional brain. This schoolteacher fell ill following a severe influenza-like infectious episode 1 week after return to school. The patient went on to develop thyroid malignancy and Clostridium difficile infection several years later. Typical ME features: teacher, female, age 40 years at illness onset, post-infectious, no significant recovery during 15-year follow-up.
The patient before falling ill

From a mental health aspect, our patient with ME has a health history in addition to her present illness. Perhaps even more importantly, she has a vision of the future. The patient’s past truly is prologue and the future is existential necessity, both of which are capable of being destroyed. If you were to describe this young woman before the time when she fell ill, you would have acknowledged that she was a hard-working woman with many prior achievements and who contemplates realistic future goals. If she is a parent, then in most cases she would have aspirations for her children, real or imagined, to do even better than herself. If our patient is a student, in most cases she will have all of the uncertainties, fears of youth, physical vigour and boundless energy, but also wonderful potential aspirations. Like Goethe’s Faust, she has yet to learn that her existence is defined not by the goals but the very striving necessary to reach these goals.

Our patient before becoming ill will have already achieved a lot, including a higher education. Most often she will be a teacher or healthcare worker with one or more degrees. You will note a strong school and healthcare bias to this illness, suggesting an increased exposure to infectious diseases and with long hours of exhausting work. To a lesser degree, the patient’s occupation will mirror the local employment population bias, but the school and healthcare bias will be paramount.

The occupations of 2000 consecutive patients with ME were tabulated during the epidemic period of 1984–92 (Figure 51.4). These patients came from across Canada, the USA and, to a lesser extent, the UK. Consequently, the figures are not prejudiced by local employment. By percentage, the single largest occupation was among respiratory technologies, followed by healthcare workers, including physicians, nurses and technicians in residential institutions for disabled people, who may have an increased infectious rate.

Often our patient will have been active in sports, with repeat associated minor and moderate physical traumas, often to the head and neck region. If you check her school record from kindergarten to the present, she will have missed a negligible amount of school. In most cases, before falling ill she will have had a history of excellent health, with no psychiatric associations. In my experience, except for those patients with a significant psychiatric family history, few of these patients with ME will be psychiatric patients. If you are an old physician like me, then our patient before falling ill will have been a person you would be proud to call your daughter. She will have an identity, courage, achievements and a belief structure with which you can associate. However, it is this belief structure as much as her illness that will provoke a significant part of
what you perceive to be her illness. Thus, understanding her belief structure and her identity is important.

The patient’s pre-illness identity and health belief structure

Our patient simply does not think about illness. If she is a parent, perhaps she has the natural concerns of any mother for her children, obtaining the right immunizations and paying occasional visits to the general practitioner (GP). She has never been significantly ill herself. Why think about illness? Visits to the doctor are for her pregnancies, routine Pap smear tests and breast examinations.

If you ask her about falling ill, she will dismiss the subject; illness is something short-term, a cold, perhaps off for a day or two and then back to school or work again. As a worker, she enjoys her job, the camaraderie, the striving; she loves her paycheque, even if it is too small – and it always is too small. She could be your daughter, your best friend’s daughter or your granddaughter.

Life is simple for her. Should she fall ill and not recover sufficiently to return to work within a few days, she knows her GP will be able to diagnose and solve the problem with a pill or appropriate advice. Failing that, her GP will refer her to a colleague who will cure her and get her back to work.

If this first attempt fails, she knows that there will be a consultant or specialist out there who can appropriately diagnose, treat and cure her, but she never really gets to that concept, since the thought that her GP cannot treat and cure her simply never comes into her head.

Our patient has been working professionally or semi-professionally for over 15 years without ever falling ill. Let us assume our patient is North American. She believes she has taken adequate steps to ensure access to good and prompt healthcare. She has both short- and long-term insurance coverage deducted from her paycheque. She will have a mortgage, but she may not have taken out mortgage insurance, skimping on this to pay for her child’s piano lessons. In any case, if she does fall ill for a few weeks or months, say from a compound fracture in a skiing accident in the French Alps, then her disability insurance will cover her expenses. No, she has never looked at her insurance policy. Why should she?

In the more than 2000 or 3000 patients with ME and CFS who have consulted me during the past 25 years in Canada, the UK and the USA, before their illness the majority had a long history of health, free of any serious medical or psychiatric illness; very few ever imagined themselves becoming ill with a chronic illness. Illness triggers are not always reliable as a cause of illness in all cases, but the data in Figure 51.5, taken from a large survey of almost 2000 patients, are perhaps reliable as rough casual indicators.

The disintegration of the patient’s belief and identity structures

Our patient’s carefully constructed mythology of enduring health until old age, and her perceptions of the infallible medical world, are about to be destroyed.

What will now confront our previous worker bee and future patient amounts not only to a total destruction of her most important belief structures but also to the ultimate loss of her identity, an identity carefully constructed since youth.

The young woman falls ill. Her illness usually has an acute onset, but it is not short-term. From then on, nothing works, nothing unfolds in the manner she might have perceived it before the onset of this strange illness.

She does not become better in 2–3 days. In almost all cases, her doctor does not appreciate that he or she is dealing with the onset of a chronic illness. Since most acute illnesses tend to resolve on their own, her GP tells her that she will be fine in another week. That does not happen: her illness persists. Then or at the next appointment, her GP may prescribe a medication or treatment and may send her for a few tests, usually a complete blood count and a urinalysis and not much else. The tests tell her GP nothing because he or she does not know what tests to order; nor does the GP know at this point what he or she is dealing with. Sooner or later her GP will refer her to a consultant.

‘No findings of note,’ the reply comes back. ‘Perhaps your patient is depressed?’

If her GP has not made the diagnosis by now, he or she soon will. It is likely to be anxiety neurosis, depression, work avoidance or family dispute – all diagnoses that are safe to make, all of which have no proof. Often notations in the history are not told to the patient; these notations, when
sent on to the next doctor or other agencies, may undermine the patient’s later chance for insurance benefits or state incapacity or disability allowances. The doctor is thus protected, but not necessarily the patient. Our patient may even be given an antidepressant that, over time, succeeds only in significantly increasing her weight. Usually the patient is given a psychiatric diagnosis by the GP and referred to a psychiatrist, although there has been no previous psychiatric history. At times she may believe her GP that she is depressed; more often she does not. Even if the doctor diagnoses ME, he or she is unable to treat ME adequately. There simply is no magic pill and no remedy, and there is very little valid knowledge about the significance of the diagnosis. The psychiatrist immediately is at a disadvantage: he or she believes that physical disease has been ruled out. Yet physical disease has not been ruled out, and in most cases it has not even been seriously investigated. Our patient is now labelled ‘ME or CFS’, but often the doctor thinks anxiety neurosis, depression or conversion disorder. If the doctor thinks CFS, then this is no more than a poorly defined label; if he or she thinks ME, then this may be the least properly investigated epidemic and endemic illness in existence. In the UK, very few of these patients so diagnosed have ever been subjected to any significant scientific investigation; many have not even had a serious physical examination.

Weeks and even months go by. No medication and no treatment works. Nothing works and the illness persists.

Within 2 months, her disability insurance raises its head. Since there is no documented evidence for any significant illness, her insurer does not bother paying. Sweet soul that she is, she honestly believes that if the insurance company only knew how ill she were, then it would send her a disability cheque. The insurance company has a good cop who pretends to be the patient’s friend, talks her into going back to work or tells her the company is just waiting for a few more results to be sent in. She tries to go back to work and falls flat on her face. Before long, a year has gone by and in many cases the insurance company still has not honoured the disability pension. Some insurance companies actually guide the patient along until it is outside the time limits for her to make a qualified application for benefits. By now, much if not all of her savings have been dissipated. All ballast, including her child’s music lessons and the piano, have gone. Rapidly she is stripped to the economic bone. If she has not been frantic up to now, she soon will be.

The search

Our patient, worker bee that she is, after months and possibly a year or two, having failed to find a helpful doctor and failed to have been awarded her disability pension, searches the Internet for an expert who will treat her. Her GP and often her family and friends have given up on her. Yet she cannot believe that there is not someone out there who can diagnose and treat her and get her back to work, give her back her family, pay cheque and friends, and restore her identity. She amasses reams of garbled information, which is often misinformation – but she does not believe this. She is going to educate her doctor about the ‘true facts’ about ME. However, on the Internet, she also encounters mixed in with the facts some of the most incredible hogwash imaginable; she will meet some of the slickest charlatans in the business, the penny-and-pound thieves who sell her miraculous alternative medications that do not work and sometimes kill. Before long, our disabled patient is paying out, in effect gambling, incredible sums of her much-needed money in the vain hope that these miracle cures will soon make her better and get her back to work. They do not work.

Some of the more brilliant charlatans, the highwaymen of the twenty-first century, will guarantee to restore her health: ‘Our treatment has saved thousands of people, but this treatment is expensive, very expensive, but isn’t your health worth it?’ She bites! If she or her family are desperate enough, they will sell their house, invest their life’s income in a desperate gamble not to lose all. They lose all! Sometimes she will lose her family; but worse, she will lose her carefully crafted identity as a proud member of her community, a successful worker and a student of life. She loses all that she was and intended to be. She cannot even be a good mother. She thinks about the piano lessons that have stopped and the piano that has moved out, and she feels that she is now failing as a parent. Nothing works.

Several times she tries to go back to work but simply cannot endure. Since she has no adequate psychiatric or physical diagnosis, her long-term insurance policy has either stopped after a short while or in many cases has never begun. The insurance companies know these patients well. They know their client has no funds, no physical energy and no resources to fight back. Our patient’s partner may have left her; he can no longer take the expense or handle chronic illness, the lack of sex, his wife’s inability to even go out for a show. Alone, or with her children, she may return to live with her ageing parents. Without supportive parents, she may fall into a life of welfare benefits and despair, barely eking out an existence. She may kill herself. Only if she is one of the wealthy few, one with funds that are not wasted, or who succeeds in obtaining her disability pension, is our patient able to survive with any integrity. Many patients become bitter, writing diatribes, attacking authorities, doctors included. Many doctors simply lump them all into one more group of nutters.

She will have been referred to you, a psychiatrist. You are kind to her. You speak in a soothing manner. Having lost everything, at last she has found a friendly ear, someone who will believe her. She cries – a sure sign of depression – and out comes the prescription pad for the first of an endless series of antidepressive medications that succeed only in propelling this normal-looking athletic woman into a state of obesity, still unable to return to work. If our patient resists this treatment, she is written off as ‘not complying’.
Let me introduce you to a few of the doctors that this woman has consulted. Like our patient, these doctors have their own history and mythologies.

Most doctors were some of the top students in their primary and secondary school systems. Then they were enrolled in medicine, where they met hundreds of other medical students with a history of being at the top of their class. Only a few of the hundreds of these medical students can ever expect to be at the top. Only a handful would be considered to be the most brilliant and have honours bestowed upon them. No one doubts that the top students would be truly brilliant. But, depending upon the school and the teacher, their brilliance may in large part be the ability to give back a wide range of accepted facts in a clear, concise, organized manner. It is a curious thing that many of the very top students do not continue in clinical medicine. They are not always interested in people as much as they are in excellence. The majority of the other graduating doctors in their class fall into other groups, and those who have not lost their curiosity may become some of the very best clinical physicians and researchers. Yet others who have always been first, the best in their class, have been needlessly embarrassed at not being one of the exalted top few. For many such students of medicine, this may be the end of independent thinking, of exploring, of challenging the accepted wisdom. It is precisely this need not to be embarrassed further that caused doctors for centuries not to discover circulation or the concept of infectious disease and almost every modern aspect of medicine. For centuries, they survived by embracing the accepted wisdom.

There is another problem concerning the referring GPs who will refer the patient with ME to you. During the past 40 years, except for a few subspecialties, most doctors’ real taxable incomes in North America, the UK and Western Europe have fallen from one of the highest in the community to that of a modest middle-income person. You may be earning less than your patient with ME was earning before she became too ill to work. The doctor starts in practice with debts. Without help from their parents, in most cases there is no way that doctors in North America can afford to buy the house that any doctor purchased 40 years ago or even 20 years ago. The medical magazines talk about making your practice more efficient, which essentially means seeing more patients for less and less time. Essentially, that means getting the patient out of the clinic by giving them a pill, sometimes any pill. They and you pretend this is not so, but you too have a mortgage and your partner expects you to buy that magical piano, pay for your child’s piano lessons and the family trips to ski in France this winter, or simply take that cruise advertised in the doctors’ magazines. Unless you take a government, pharmaceutical industry or insurance company job as a doctor, or you succeed in getting one of the senior positions in the hospital on a salary, unless you work a 60-h week or see patients outside the National Health Service (NHS), not only will your income be modest but also you will be judging yourself against an unrealistic measuring stick of those doctors who have come before you and a few of your colleagues who appear to be wealthy. You simply do not need a troublesome, complicated patient with ME who will take up your valuable time.

I am still talking here primarily about the non-psychiatrist physician. Money is status. Time is money, and few can take the time to explore the incredible significance of the relatively young chronic patient with diffuse brain injury. These patients with ME simply take too much time. Consequence? The primary care doctor simply sends the patient with ME to the psychiatrist, who they believe has all the time in the world. The psychiatrist in turn will assume that, as in all reputed psychiatric patients, the primary care doctor and the consultant have adequately investigated the referred patient who now sits in front of them. Yet you, as a doctor, should know better – and many do. The system in the UK prevents most primary care doctors from even ordering a full technological evaluation of their patient. The system in the UK, North America and much of Europe does not give the doctor time or money to explore this fascinating patient. Worse, there are no specialty clinics working inside the NHS that have the time, authority or financing to properly investigate these patients with ME for physical cause of disease. This total chronic failure to systematically examine the patient with ME has not been helpful, either to the patient with ME or to the psychiatrist.

The relatively young, chronically physically ill public in the UK tend to be very critical of the psychiatrist, and often needlessly so. Yet, as a psychiatrist, you have both a disadvantage and an advantage over the regular non-psychiatrist. The disadvantage is that your income may be one of the lowest in the medical community. The advantage is that your expenses are less and you alone among your colleagues will be able to listen to your patient for a considerable time. Perhaps you will be the first doctor who has the time to listen to her and who can get to the physical root of her anxiety, even if you cannot improve her material life. It is here where your difficulty becomes even more complicated.

Like many of your medical and psychiatrist colleagues, you will not want this patient. She simply takes up too much time in the clinic, and you wish to see her depart so that you may get on to a treatable patient. Many of your own psychiatrist colleagues will believe that any patient with ME is simply expressing some form of hysterical behaviour, is a whiner, is someone who does not want to work, or, worse, is boringly uninteresting. The patient will believe she knows much more about ME than you do; perhaps she does, but that is irritating to you and often her information is as highly inaccurate as yours has been. We
are now looking at a major treatment impasse, including hostility, which may be mutual, and poorly organized information on both sides.

There is one final aspect to these patients with ME. Few patients realize the two-way nature of medicine, the great joy of being a doctor, of making a clear diagnosis of the patient and getting that ill patient either back to health or at least to a position where they can manage. Yet this patient with ME is not some fascinating patient with bipolar disorder from the Bank of England who has just ripped through a few billion pounds of your country’s money. She is not a schizophrenic poet of immense talent and immense self-destructive powers. This is not a case where there is a good chance you can bring banker or poet back to reality. It is so easy to tell yourself that this is one more case of ME hysteria.

How can you, the psychiatrist or for that matter any doctor, help this young woman?

If you catch the patient in time, you can attempt to help this unbelieving patient to stop wasting her valuable and decreasing funds on bogus care and treatments, usually from non-doctors. If you believe that the patient is significantly disabled, and in my experience few patients in this category ever lie and most are more disabled than even they realize, then you can help her obtain appropriate state benefits or her entitlement to disability insurance. More than any other assistance you can provide, this may help her save part of her identity and perhaps her life, and she will bless you for it forever. This may take work, and it would be good to have a psychiatrist colleague or ombudsman whose work is limited to handling these matters to whom you can refer this patient. It takes both significant time and skill in assisting these patients with the insurance industry and benefits systems.

It is not only the uninformed doctor who represents a problem but also the reputedly informed patient. Both doctors and patients have bought into the nineteenth-century Oslerian principle that the best way to treat and possibly cure a patient is to diagnose the illness as to the cause, treat the cause and, with knowledge and luck, cure the patient. The problem is the phrase ‘the cause’, since many of these patients have multiple causes giving rise to their disability. This unicausal theory of medical pathology worked for pulmonary tuberculosis, for syphilis, so why not ME? Well, what if there is not a single cause of the illness? What if the patient with ME is disabled due to multiple cumulative pathologies?

MULTIPLE PATHOLOGY PATIENTS

My clinic is in the process of an in-depth study of the last 53 consecutive patients referred to us with a diagnosis of ME or CFS. In this group:

- 100 per cent had missed measurable brain dysfunction;
- 98 per cent had measurable significant sleep dysfunctions that included (i) lack of type 3 and 4 sleep, (ii) abnormal, absent or significantly delayed rapid eye movement (REM), (iii) central and peripheral apnoea, (iv) restless legs syndrome and (v) oxygen saturation that fell below 88 per cent (interestingly, oxygen saturation below 88% caused loss of consciousness in an aircraft pilot);
- 74 per cent had measurable thyroid dysfunction;
- 47 per cent had measurable significant arthritic, rheumatoid changes or other indicators that were previously diagnosed as fibromyalgia;
- 47 per cent had other missed major disease, including cardiac disease, malignant disease, vascular injuries and autonomic nervous system dysfunction;
- at least 16 per cent had typical psychiatric illness but, in addition, missed physical disease.

The problem here is not the multiple pathologies but the fact that the primary or consulting doctors missed these multiple diagnoses.

We subdivided the 53 patients in this study under occupations. This is what we found:

- Nineteen patients (37%) were school-associated professors, teachers or students.
- Nine patients (17%) were civil servants, the majority with young children in school.
- Five patients (10%) were healthcare workers.

This study of a group of 53 patients with ME/CFS was biased due to the fact that in Ottawa, Canada, a large percentage of the inhabitants are government workers. In an earlier study that looked at 2000 patients from across Canada and the USA, school and healthcare workers represented over 70 per cent of the 2000 patients. This suggested that ME was usually associated with a high exposure to infections.

As noted in the group of 53 patients, the single largest group was 19 (37%) of the total. These were students and teaching staff at primary, secondary and university educational institutions. For brevity, I will confine this discussion regarding pathological findings to these 19 patients referred to me as patients with ME who were teachers and students. This dominant group also contained the largest number of youths and children.

Collectively, these 19 school-associated patients had been seen by over 200 doctors. All had missed the following pathologies, which were found by extensive history, physical and technological examinations:

Dysautonemia and postural orthostatic tachycardia

Check your patient’s arterial blood pressure, pulse pressure and heart rate when they are lying, sitting and standing. Have your patient stand without moving and check their
Measurable brain disease in patients with ME

A surprising 100 per cent of the 19 teachers and students had significant brain changes or anomalies by one or all of technical examination, measurement or history. If you can, order or have your medical colleagues order a brain SPECT, a magnetic resonance imaging (MRI) scan with contrast of the brain that includes pituitary, cerebellar tonsils and cervical spine area.

As mentioned earlier, the following pathologies were missed by over 200 examining doctors, who possibly did not believe they were dealing with significant physical disease and so did not do an extensive examination of these patients. We found the following:

- A patient with tertiary CNS syphilis and who was also positive for hepatitis B diagnosed as having simple major depression
- Leucoencephalopathy with ventricular hypertrophy in a youth
- One adult with significantly abnormal electroencephalograms (EEGs)
- One youth with missed nocturnal seizures and seizure-associated episodic complete heart block, causing syncope, significant hypoglycaemia and obstructive chronic tonsillitis that occluded his pharynx when sleeping on his back
- A youth with Chiari syndrome with ventriculomegaly
- An older patient with significant generalized brain atrophy and ventricular hypertrophy
- A patient who had been in the area of the Chernobyl disaster as a 1-year-old child and who had a subarachnoid cyst that had displaced two-thirds of the left hemisphere, including the entire left frontal lobe, the entire left temporal lobe and the anterior part of the left parietal lobe, but who had no observed neurological examination abnormalities either on neuromuscular examination or in gross intelligence. He simply had overwhelming exhaustion. He had graduated with a master’s degree
- A patient with complete atresia of the middle cerebral artery
- A patient with multiple CNS vascular changes.

In addition to these findings, many patients had major SPECT brain changes in both hemispheres, the midbrain and the brainstem.

The average age of these 19 students and teachers was 33 years.

Two of the 19 patients had incapacitating autonomic nervous system dysfunction. One, a master’s student who fell ill immediately following recombinant hepatitis B immunization and is now house-confined, has a highly positive tilt table test and is unable to maintain her blood pressure at a physiologically normal level while standing or on movement.

The rewards in properly investigating this group of patients are significant. Although we did not find any patients with multiple sclerosis (MS) in this group of 19, we did pick up a missed case of MS in the total group of 53 consecutive patients and a surprising number of single large (diameter ≤2 cm) CNS demyelinating lesions that do not qualify as diagnostic of MS. Each of the patients with non-MS single-lesion demyelination was associated with markedly abnormal SPECT brain scans. Also in the group of 53 consecutive patients, but not in the school-associated group, we found a missed significant brain aneurysm in addition to numerous other organ pathologies in the same patient. The aneurysm has since been repaired. Another patient had a right lenticular haemorrhage, which the neurologist then dismissed as minor; on SPECT we were able to demonstrate a 3- to 4-cm halo of abnormal activity around the lenticular lesion consisting of highly significantly hypoperfused brain tissue. In addition, we observed a decrease in perfusion in the entire right lobe of this patient, but with a normal left hemisphere perfusion. Clearly some localized non-motor cerebral accidents may provoke profound generalized CNS changes.

Are these all patients with ME? No, of course not; but in real terms, it does not matter. These individuals were all diagnosed as having ME or CFS by otherwise competent doctors who dismissed the patient when they came with a diagnosis of ME. These will be the same people who are referred to you as patients with ME by GPs and interns who simply think these patients complaining of acute or gradual-onset fatigue and cognitive dysfunction have ME or CFS and either have no idea how to investigate them or simply are unwilling to take the time to do so.

Thyroid disease in patients with ME

For some reason, the centuries-old medical knowledge of the physiological association of thyroid disease and intellectual, emotional, psychiatric, cardiac and other endocrine pathology seems to have escaped the 7 min-per-patient visits of many primary care and specialist doctors. Most non-psychiatrist doctors limit their examination of the thyroid to a cursory palpation of the gland for nodules and perhaps order thyroid-stimulating hormone (TSH) and free thyroxine (T4) tests. In most cases these doctors will not find disease. It is essential to request a thyroid ultrasound on all patients with ME. In addition, the doctor must ask the ultrasound technician to give the measurement of each
thyroid lobe; if you do not, the technician or the doctor reading the ultrasound result will often just say ‘normal’ if there are no nodules or the gland is homogeneous. Why the measurements? Simple: the Mayo Clinic normal thyroid sizes are 13–21 cm$^3$ for females and 15–23 cm$^3$ for males. They arrive at these figures by multiplying together the three dimensions of each lobe and adding the left and right lobe measurements as though the thyroid were a regular rectangle. This is not the actual size of the thyroid. If you have access only to an old ultrasound device, then the radiologist may give you these crude rectangular volumes. It is necessary to multiply these volumes by a factor of 0.51. This will give you the approximate normal thyroid volumes of two irregular solid spheres. The real volumes are then half the Mayo suggested volumes, or 6.5–10.5 cm$^3$ for females and 7.5–11.5 cm$^3$ for males. It is important to know this, since modern ultrasound machines give this calculation in terms of the 6.5–10.5 cm$^3$ female thyroid volume scales. These are not gold standards, but if you bring in a thyroid at less than 4 cm$^3$ or over 15 cm$^3$ you know you are dealing with an atrophic or hypertrophic thyroid, respectively, with possible intellectual, emotional and psychiatric consequences. Sometimes, simply by appropriately treating these patients with T4 or tri-iodothyronine (T3), you can cure their fatigue and cognitive dysfunctions. (Note: patients on previously prescribed or over-the-counter thyroid medications may have a hypotrophic thyroid.)

Nor can you count simply on the usual TSH, free T4 (FT4) and free T3 (FT3) thyroid tests that are stated as normal or slightly abnormal. If the basic injury to the thyroid is vascular, as I believe it to be in most ME brains, then often the parathyroid hormone (PTH) and the ionized calcium will become abnormal before the usual thyroid tests. I do all of these tests, including thyroglobulin, thyroglobulin antibodies and microsomal antibodies, as well as an ultrasound, on each and every patient with ME that I see. In the group of 19 teachers and students in our group of 53 referred patients with ME, we found 14 patients (74%) with abnormal thyroid activity. I have also found several patients with new-onset ME with normal initial thyroid chemistry but with a significantly shrinking thyroid when the ultrasound was repeated in 1–2 years, which may suggest a vascular problem.

In the last 100 patients with ME/CFS, we also have found missed thyroid malignancies in 6 per cent. Some doctors discount this figure, since thyroid malignancies are considered to be common and not particularly dangerous, but that is not true for a young population. In one of the group of 53 patients, we discovered a thyroid malignancy that had already disseminated.

There is one more thing you must know before we leave the thyroid. T4 does very little on its own: T4 must first be discharged into the bloodstream and then transported to the liver and kidneys, where one of the iodines is removed to make T3. If there is pathology in this conversion, then an isomer called reverse T3 is made. In simple terms, the importance of this is paramount. T3 is one of the keys that turn on each body cell. If your patient is producing too much reverse T3, then this reverse T3 fits into the cell’s energy receptor and breaks off, and the cell energy cycle cannot function normally. All the T4 in the world will not help this patient: she requires T3. Is it enough to ask for a reverse T3 level? No! Often the laboratory will give you a reverse T3 level in the normal or high normal range. You need also to order an FT3 at the same time and then divide the reverse T3 level by the normal T3 level; if the result reaches 10 per cent or more, your patient probably requires exogenous T3. But be careful; these patients with ME tend to be very medication-sensitive, so you should start at 5 μg daily, increasing every 2–4 weeks until you reach 25 μg and then stay at that dosage for some months before considering raising it to a normal dosage or subnormal dosage. If the patient has a heart condition as well, take advice from a cardiologist on the safety of giving T3 to this patient. All of these patients want to get back to normal in 5 min, but this is dangerous if part of the problem is thyroid dysfunction. Starting T3 at too high a dosage or increasing the dosage too rapidly may provoke seriously irregular heart rates, irregular cardiac rhythm and rapidly altering blood pressures. It may take up to a year or longer to slowly restore the patient with ME to normal thyroid levels.

**Sleep dysfunction**

All patients with ME should have at least one sleep study and some sleep studies with film monitoring to observe the presence of nocturnal seizures missed in daytime EEGs. In our group of 53 patients, we found only one patient with a normal sleep study; her dysautonomia was so severe that she was in a state of vascular collapse. Some authorities state that the abnormal sleep study can be blamed on the way the study is done, or the hospital environment in which these tests are performed, but generally these patients have non-restorative sleep. In our studies, 70 per cent of the 53 patients had no stage 3 or stage 4 sleep. This is the sleep phase where short-term memory is laid down. In addition, 77 per cent had grossly insufficient REM and very long REM latency. Among other functions that occur during REM is the burning into the neuron system of short-term memory: it is no wonder, then, that these patients describe short-term memory loss.

Interestingly, if the oxygen saturation falls below 92 per cent, commercial pilots become both colour- and night-blind and have difficulty landing their planes during the night. If the oxygen saturation in the cockpit falls below 88 per cent, the pilot has a good chance of losing consciousness and crashing the plane. Accordingly, oxygen saturation is monitored carefully in the cockpit, although less so in the passenger compartment. In our study of 53 patients, the oxygen saturation in 25 patients (53%) fell below 92 per cent during the sleep study; the oxygen saturation in 17 patients (30%) fell to 88 per cent or below. In other words,
they were not sleeping: they were unconscious. The oxygen levels at least are potentially correctable pathologies.

**Respiratory dysfunction**

In our group of 19 students and teachers, ten patients (53%) had some measurable respiratory dysfunction. We did not count a history of asthma in this group, although in many patients there was an obvious overlap. Had we included a history of asthma, it is possible that even more patients would have had measurable respiratory dysfunction.

**Missed miscellaneous disease**

In our group, 47 per cent of patients had major missed illness, including the following:

- A case of tertiary syphilis and hepatitis B
- Four patients with significant heart disease
- A patient with respiratory dysfunction with significant pulmonary valve disease
- One juvenile and two type II cases of missed diabetes
- One patient with Ehlers–Danlos syndrome
- Numerous rheumatoid and significant spinal anomalies.

Although two patients had significant incapacitating autonomic nervous system dysfunction, several had lesser degrees of measurable dysfunction.

One patient in the group of 53 patients was a young lawyer and Olympic runner. He was referred to me as a patient with ME due to extreme fatigue and had Marfan-like anatomical changes. He had a missed hyperelastic distended thoracic aorta picked up on echocardiogram. In addition, he had lumbar dural ectasia on computed tomography (CT) scanning (seen in 65–92% of patients with Marfan’s syndrome). At least seven doctors had each missed this diagnosis. The patient denied any family history of Marfan’s syndrome until he was asked to enquire of his remote cousins. Three of his second cousins had a family history of ascending aorta surgical replacement in their twenties. The cause of his thoracic aorta pathology was complicated by the fact that he had been infected with brucellosis while training in South Africa. Brucellosis can also cause aortic aneurysm. A detailed extended family history is essential in investigating ME-type patients.

**Psychiatric disease**

Patients with ME like to believe that there is no psychiatric disease associated with ME. Some psychiatrists and primary care and specialist doctors like to believe that 100 per cent of patients with ME have psychiatric disease. What did we find? Many of these patients with ME had been referred to psychiatrists before our examination of them; six patients (32%) were diagnosed with primary psychiatric disease. After we had finished our investigation, we found only three patients (16%) with treatable psychiatric disease. There are several reasons for this discrepancy. We believe that some psychiatrists, to assist a destitute patient with ME, may give a psychiatric diagnosis simply to assist the patient in obtaining their disability pension.

Let me give you a brief review of some of these psychiatric patients.

The patient with tertiary syphilis was first diagnosed with unipolar or major depressive disease. This patient also had hepatitis B.

Another patient had major childhood abuse, during which time she was placed in a reformatory and also various psychiatric hospitals in Switzerland by the woman who had adopted her as an infant. This incarceration first occurred when the patient reached puberty and may have been due to the mother’s sexual jealousy of having another female sharing her ambassador husband’s innocent affections. On her own resources, my patient obtained her master’s degree, became a secondary school teacher, and is fluent in English, French, German, Italian, Spanish and Latin. There was obvious trauma. Today, aged 53 years, she is exhausted, perhaps simply worn out, and she certainly has anxiety and depression.

A third teacher, also adopted, initially diagnosed as having depression, has serious food addiction, which in itself has caused multiple medical problems. He certainly has no overt psychiatric illness, but he does have brain dysfunction and memory disorder. He also had missed generalized vascular disease, missed diabetes and missed myocardial infarction and is one of the two patients in the school group with generalized atrophic brain syndrome.

The husband of another patient, also a teacher, committed suicide; the patient has made two attempts on her own life and was reasonably diagnosed as having unipolar or major depressive disease.

Two other patients were diagnosed as having unipolar depression. Both had seronegative rheumatoid arthritis and both had measurable significant heart disease.

Each of these six patients also had other major physical pathology. How many of the six were truly classical psychiatric diseases? Probably three, or four if you count the teacher with brain atrophy and cognitive dysfunction. What is most incredible is the truly remarkable resilience of some of these patients despite their multiple organ and system disease.

Do these 53 consecutive chronically ill patients have ME? Is that important? Doctors who believed that the patients had ME or CFS referred all these patients to me. The same patients will be referred to you with the same bewildering array of pathologies. Can you afford to dismiss them as psychiatric patients if they have not been properly investigated first? Since all of the definitions of CFS and to a lesser extent those of ME are based upon symptoms common to a multitude of serious pathophysiological illnesses, under the present understanding of ME and CFS, doctors, whether primary care, consultant or psychiatrists, cannot simply dismiss these patients without first documenting an extensive investigation of the individual
patient. A thorough investigation of the chronically ill younger patient is fundamental to good medicine.

DEFINITIONS OF M.E. AND C.F.S.

You may remember the lines of Mathew Arnold’s poem ‘Dover Beach’. ME and CFS definitions are a bit like that.

And we are here as on a darkling plain
Swept with confused alarms of struggle and flight
Where ignorant armies clash by night.

The reason that I did not start this chapter with a definition of ME is that there is no general accepted agreement on the definition of ME, or the pathophysiology of ME, or an accepted understanding of ME chronicity. Many doctors simply do not believe that ME exists except as one of various psychiatric or social disorders or as an Internet-constructed example of mass hysteria. One would think that this was bad enough, but it gets worse. There is disagreement as to whether ME and CFS represent the same disease spectrum. There are now thousands of scientific publications on ME and CFS, but those publications on physical dysfunction are much like the parable of the six blind wise men of Hindustan, who individually described the elephant as a wall, a spear, a snake, a tree, a rope and a fan. To my knowledge, since and including the 1932 ME epidemic in the LA County Hospital and the first excellent publication of that epidemic by AG Gilliam, no one has ever done a complete long-term systematic scientific study on any significant number of patients with ME or CFS. No wonder, then, that doctors and scientists are in disarray on ME and CFS. It is also obvious that many people diagnosed with ME and CFS are missed patients with multi-system, multi-organ pathology. Are these pathologies due to a specific CNS injury or generalized injuries acquired during the initial infectious, immunological, chemical or traumatic injuries, or are they genetically related illnesses? We simply do not know.

Nor is there any agreement as to whether ME represents the same disability as CFS. In the USA, the conflicting name for CFS is ‘chronic fatigue and immune dysfunction syndrome’ (CFIDS). In the UK, some doctors have used the term ‘postviral syndrome’ to describe ME. In addition to the above definitions, there are possibly better, more recent definitions, including the so-called ‘Canadian definition’ and the ‘children’s definitions’ by Jason and colleagues. Unlike any other medical condition, real or imagined, I simply do not believe that ME exists except as one of various psychiatric or social disorders or as an Internet-constructed example of mass hysteria. One would think that this was bad enough, but it gets worse. There is disagreement as to whether ME and CFS represent the same disease spectrum. There are now thousands of scientific publications on ME and CFS, but those publications on physical dysfunction are much like the parable of the six blind wise men of Hindustan, who individually described the elephant as a wall, a spear, a snake, a tree, a rope and a fan. To my knowledge, since and including the 1932 ME epidemic in the LA County Hospital and the first excellent publication of that epidemic by AG Gilliam, no one has ever done a complete long-term systematic scientific study on any significant number of patients with ME or CFS. No wonder, then, that doctors and scientists are in disarray on ME and CFS. It is also obvious that many people diagnosed with ME and CFS are missed patients with multi-system, multi-organ pathology. Are these pathologies due to a specific CNS injury or generalized injuries acquired during the initial infectious, immunological, chemical or traumatic injuries, or are they genetically related illnesses? We simply do not know.

Nor is there any agreement as to whether ME represents the same disability as CFS. In the USA, the conflicting name for CFS is ‘chronic fatigue and immune dysfunction syndrome’ (CFIDS). In the UK, some doctors have used the term ‘postviral syndrome’ to describe ME. In addition to the above definitions, there are possibly better, more recent definitions, including the so-called ‘Canadian definition’ and the ‘children’s definitions’ by Jason and colleagues. Unlike any other medical condition, real or imagined, I know of no other where there are two warring armies of very well-educated doctors who are so critical of the others’ views on the subject as to whether this is a real or imagined illness or whether ME is the same as CFS. There should be no surprise when I tell you that there is no accepted agreement on the treatment of ME or CFS either. This treatment quandary is particularly true if you examine the complexity of the pathologies hidden within the group of patients I have discussed above and whom well-educated doctors refer to as having ME and CFS. Let us briefly discuss the definitions.

Definitions of reputed infectious and other diseases come in various sizes and constructions, but essentially there are two types of definitions:

- **Epidemic-based definitions**: these are from the bottom up and are based upon episodic findings when large groups of individuals fall ill at the same time, usually in confined quarters. The clarity of such a definition changes with technological and clinical advancements, particularly if a single causative agent is found. Physicians and researchers who investigate the epidemics always construct these definitions. These definitions, often faulty, at least have the benefit of being based on physical findings and follow-up of actual patient illness by doctors and scientists who investigate the actual patients over a period of time.

- **Theoretical-based definitions**: these are based on a theory of preconceived limits of what an illness is supposed to be and what is supposed to happen in the illness. They are often based upon symptoms rather than pathological findings. The Centers for Disease Control and Prevention (CDC) definitions of CFS are typical of this type of bureaucratic definition. This type of definition excludes all patients who do not follow this hypothetically derived definition. This type of definition is often bureaucratic, dictated from the top down, and those that direct this definitional process at times tend to have little and often no experience in primary patient investigation of the illness process that they are attempting to describe. Unfortunately, this is not unusual in medicine today. Since the same symptoms are often common to a multitude of different illnesses, these definitions tend to be misleading.

Why is the derivation of a definition important? Before Pierre Marie and Ivan Wickman’s description of epidemic poliomyelitis based upon the first major poliomyelitis epidemics in 1887 and 1895 in Stockholm, what we now know as poliomyelitis was described under a multitude of different diseases, with multiple different names and different causes. Epidemic descriptions by clinical investigators with careful follow-up have the advantage of bringing together the multiple and varied aspects of a single illness. One eminent French neurologist in the 1890s described the Scandinavian polio epidemics discussed by Wickman as examples of mass hysteria, although he had never been to Scandinavia or examined any patient. It was only when doctors such as Wickman studied the outcome of the late nineteenth-century Scandinavian poliomyelitis epidemics that doctors and scientists were able to bring these previously multiple disease phenomena together under one classification. Unfortunately, in none of the more than 60 epidemics of ME has anyone thought to do a funded...
systematic pathophysiological investigation and long-term follow-up of these epidemic patients. This itself is perhaps the biggest tragedy.

Definitions of ME

Doctors and workers who studied patients during epidemics of ME developed the following definitions. The definitions were not good, since most were developed at a time when virology was in its infancy or later when scientific research was largely underfunded:

- **Onset and location:** these were acute, epidemic and concurrent endemic episodes that occurred in both children and adults starting in late summer and early autumn in the north temperate zone. Onset of new disease tended to decrease rapidly after October, finally trailing off during the Christmas–New Year period. Most frequently described epidemics occurred in schools, hospitals and military camps, particularly when associated with institutional residences and crowding. Increased endemic infection was often noted at the same time.

- **Symptoms:** the symptom picture is characterized by its acute explosive onset, the severity of the CNS, autonomic and vascular symptoms, the associated malaise, and the often fleeting muscle and joint pains, but with a paucity of physical signs on physical examination and very low death rate. Little is said about duration and long-term findings. In my experience, depending upon the individual case, after weeks, months or sometimes years, this acute symptom picture gradually decreases in intensity. However, the average patient’s intellectual, physical and emotional stamina, whose decrease tended to be noticed within 2–4 weeks of illness onset, rarely recovers sufficiently for the patient to manage in the competitive world if the illness continues beyond 2 years. As in any true disease, there is variable severity and simply misdiagnosis.

- **Pathology:** the few deaths that went to autopsy demonstrated CNS injuries to the basal ganglia and other brain areas, and injuries to the anterior horn cells and dorsal root ganglia (A Chaudhuri, personal communication, February 2009). Unlike in paralytic poliomyelitis, the anterior horn cells tend to be injured rather than destroyed. Deaths occurred during and following the epidemics, including three children under 12 years of age who died of Parkinson’s disease within 2 years of falling ill during the 1947 Iceland epidemic.

- **Clinical tests:** abnormal EEGs were found in the Royal Free epidemics.\(^{11,14}\) Abnormal electromyography (EMG) was found in the LA, Copenhagen, Royal Free and Coventry epidemics. Neurologist Charles Poser found oligoclonal banding in some sporadic cases in referred patients at Harvard’s Mount Sinai Hospital,\(^{15}\) but he is perhaps the only doctor to have taken routine spinal fluids. Oligoclonal banding suggests CNS injury. These were all earlier epidemics. Outside of our own work, to my knowledge little if any systematic investigation has been done of significant groups of patients in the multitude of post-1984 cluster, epidemic and endemic cases.

- **Cause:** in the more than 60 epidemics and clusters described, only in four was an infectious source actually recovered and described. In four of the instances, this virus was an enterovirus or ECHO enterovirus, which were recovered in the later Akureyri episodes,\(^{16}\) the Coventry epidemic\(^ {17}\) and the Ottawa 1984 clusters by DN Galbraith and C Nairn of Ruckhill Hospital, Glasgow (unpublished investigations). In Ontario, the provincial virologists also observed an association only with enteroviruses during the 1984–90 epidemic periods\(^ {18}\) and a negative association with Epstein–Barr virus (EBV). Concomitant gastrointestinal bacterial infection with Bethesda Ballerup paracolon group\(^ {19}\) was isolated in some of the patients in the Bethesda outbreak. It was not believed to be a cause. John Chia in California has recovered enterovirus from the gastric mucosa in multiple sporadic ME patients whom he has investigated.\(^ {20}\) The great difficulty in recovering polio enteroviruses in living patients should be remembered; almost all polioviruses in patients with polio were recovered from autopsy cases.

- **Incubation period:** in the 60 or so described epidemics, when an observed incubation period was noted, in most cases they were stated as 3–6 days.\(^ {21}\) Except for the 1934 LA epidemic, which was associated within days of immunization of the hospital staff, no other incidence of immunization association was specifically recorded. Most enteroviruses have an incubation period of 8–40 days, making EBV virus with a 40-day incubation period a highly unlike cause of epidemic ME.

Definitions of CFS

These are definitions that started with the 1988 National Institutes of Health (NIH)/CDC Holmes definition.\(^ {6}\) The important fact with regard to this definition is that only 2 of the 16 authors had routinely investigated patients with ME and published on ME or CFS before or after the publication. The 1988 definition was followed up by the 1991 Oxford Guidelines\(^ {22}\) and the 1992 NIH/CDC Fukuda definitions, which at best were copies of the 1988 definition. These three definitions are examples of theoretical definitions and are not based upon significant patient examination. If anything, they served to confuse the severity of ME that was associated with the term CFS. The later, so-called Canadian definition\(^ {6}\) is unique in the fact that the majority of the authors had long-term experience of examining patients with ME. This definition discusses many of the findings in this chapter. The definition is lacking in that it was not based significantly upon actual organ and system pathophysiology and examination. It does not distinguish
between ME and CFS. This definition is also much too long and complex; however, it remains the closest among the published definitions in describing the actual disease known as ME.

The fault is not in our stars nor among the doctors or the patients, but in the system in which these two often apposing forces, the doctor and patient, theory and scientific investigation, exist. Until we conduct systematic long-term and in-depth scientific investigation of these patients, we will see no progress. Until then, I can only recommend that the doctor offers kindness to and toleration of these chronically disabled largely mistreated patients with ME and CFS. To the government of the UK, I can only recommend the nationwide funding of a serious scientific approach to the long-term pathophysiological investigation of these chronically disabled citizens. And until then, to paraphrase Arnold, we remain ‘on a darkling plain …’

Swept with confused alarms of struggle and flight, Where ignorant armies clash by night.

KEY POINTS

- ME occurs as an epidemic and endemic disease. The injured patients as a group have rarely been investigated systematically during the past 50 years with the force of modern scientific and clinical investigational tools. Doctors investigating the patient with ME have rarely if ever received any significant funds for in-depth scientific investigation of organ and system pathologies.
- ME epidemic patients as a group have never been subjected to any long-term follow-up. Grufferman has suggested the possibility of increased cancer risk in the cohorts of epidemic ME-type patients.23
- ME and CFS are symptom-based definitions that have become simple garbage-bag terms for large numbers of patients with acute or gradual-onset physical and cognitive diseases affecting stamina, work and school ability. Thus, the terms ME and CFS have acted as an excuse to downplay the importance of these chronically ill patients and to not properly investigate these patients.
- The patient with ME has been largely disenfranchised from modern medical investigation and suitable medical assistance. Since most of these individuals tend to be relatively young, highly educated individuals in the medical and teaching professions, their loss of tax income to the government would more than offset their in-depth investigational costs.
- The majority of patients with ME or CFS that we have investigated in the UK, the USA or Canada represent multiple missed pathologies rather than any single disease entity. Whether these pathologies are caused by an initial CNS injury that deregulates the complex neuro-immune and neurochemical system and organ physiology of the patient or are simply co-morbidities is simply not known.
- There will never be a single treatment, whether pharmaceutical, physical, psychological or psychiatric, that will have any significant effect in the treatment of the majority of patients with ME and CFS, since they do not have a common trigger or common organ and system pathologies. It is necessary to first investigate the pathophysiological injuries and then treat them where possible to obtain a reasonable chance of a cure or treatment.
- The ME community continues to be a growing concern to many doctors and the state. This community is unlikely to disappear.
- Both patient and doctor mythologies continue to form a major part in the failure to assist the patient with ME.
- One group of patients with ME and CFS for whom we know their pathology – the patients with dysautonomia – have seen no advance in funding or investigation of treatment in the past 30 years, to such an extent that most major cities and university medical schools in the UK, Europe and North America simply have no investigational ability in this area.
- The major problems in understanding the illness and disability of patients with ME and CFS lie in the following areas: (i) the Oslerian concept of a single pathology causing a single disease spectrum; (ii) the misguided notion that patients with ME and CFS are people who can ‘think themselves sick’; (iii) the lack of funding and resources in the physical investigation into the pathologies and pathophysologies of these patients; (iv) the failure to do any long-term follow-up study of this group of chronically ill patients; (v) the patient mythologies that magic treatments can cure the patient; and (vi) the erroneous and facile belief that patients with ME and CFS simply have variations of hysteria, somatization disorders or somatoform disorders in general.

REFERENCES

INTRODUCTION

It is now well established that psychological and psychiatric factors are of considerable importance in the evaluation of pain. The subject of pain used to be considered the province of the physiologist, physician and surgeon. In a prominent medical textbook written in 1968, pain was simply defined as ‘A sensory experience evoked by stimuli that injure.’ This explanation of tissue damage that posits the generation of nervous impulses along recognized pain pathways is appropriate for most, although not all, pains arising from an acute injury. But if pain persists beyond the normal time of healing, which is normally less than 3 months but can be as long as 6 months, the correspondence between extent of injury and pain sensation is much less precise.

A measurable number of people with chronic pain show no demonstrable evidence of nerve or tissue damage, although many of these individuals will have sustained injury in the past. Other people sustain major injuries during intense physical activity or in highly emotionally charged situations such as the heat of battle and realize only subsequently that damage has occurred. It is for this reason that in 1979 the Taxonomy Committee of the newly formed International Association for the Study of Pain defined pain as ‘an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage’. The Committee amplified this definition further by stating that ‘activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not pain, which is always a psychological state.

HISTORICAL BACKGROUND

The word ‘pain’ comes from the Latin poena, which means punishment or penalty, after the Roman goddess of punishment. The term was originally used for the punishment of an offence against the law. Over time, the word was increasingly used to denote suffering, particularly if this had resulted from a blameworthy act.

Early writers equated emotional suffering with pain, and the words were used interchangeably. Aristotle argued that suffering, which included pain, was perceived as a non-material form. He stated that if the intellect were a specific material organ (or part of one), then it would be restricted to receiving only certain kinds of information, as the eye is restricted to receiving visual data and the ear is restricted to receiving auditory data. This reasoning is often referred to as ‘monistic’ or ‘monism’ and essentially derives all phenomena from a single origin – that is, body and mind are both aspects of the same underlying substance.

This view was challenged by Descartes in his Meditations on First Philosophy in 1641 (see www.iep.utm.edu/d/descarte.htm#h2). In this work, Descartes explained that he could doubt whether he had a body (it could be that he was dreaming of it or that it was an illusion created by an evil demon), but he could not doubt whether he had a mind. He reasoned, therefore, that the mind and body were different things. The essential distinction between what is now termed ‘Cartesian dualism’, in honour of Descartes, is that the immaterial mind and the material body, while being distinct substances, causally interact. Descartes identified the mind with consciousness and self-awareness, and clearly distinguished this from the brain, which was the seat of intelligence. There continues to be debate about this issue.

Shortly after developing this philosophy, and derived pari passu from it, Descartes showed that the experience of pain depended upon the integrity of the sensory nerve pathway from the periphery to the brain:

When I feel pain in the foot, this feeling is communicated by means of nerves in the foot, which are then carried in cords to the brain, where feelings are represented. The feeling of pain arises from the brain as though this pain was in the foot.

For over 250 years after this work, pain was largely described as an organic phenomenon. The experimental work then conducted supported the contention that, in people complaining of pain, there must be a source of injury. Non-organic pain was not considered. It was not until Breuer and Freud described in detailed case histories, originally published in 1895, that pain could be a manifestation of a psychological problem that the role of psychological factors in leading to pain was reconsidered.

The concept of ‘emotional pain’ occupied a select group of British psychiatrists in the 1960s. Erwin Stengel saw a
parallel of alteration in pain perception as a result of pari-etal lobe dysfunction in patients with vascular damage with the pain responses of people with schizophrenia and in people with intellectual disability. He recognized that people who deliberately inflict pain on themselves are often impervious to the pain arising from the consequent tissue damage. In work in Stengel’s department, the activation of pain by arousal and apprehension was recognized. Above all, Stengel was intrigued that no doctor had defined pain in a way that recognized that it was a subjective phenomenon. The controversy between Stengel and Eliot Slater about this issue, published in the *British Journal of Psychiatry* in 1966, illustrates the differences between Cartesian and modified monistic views of practitioners about the origin of pain.

Stengel’s work in this area led to a sprouting of interest in Sheffield, where he was the first head of the university’s Department of Psychiatry at this time. Three junior psychiatrists in his department have since become prominent researchers in this area – Harold Merskey, Izzy Pilowsky and Sir Michael Bond. All have contributed an extraordinary amount to the contribution of psychiatric and physical features to the perception of pain. Few UK psychiatrists now enter this area, illustrating perhaps the lack of resources allocated to liaison psychiatry at this time.

Shortly before the time when Stengel was articulating his views in England, psychiatrists in the USA were aware of the fact that many people with pain referred to physicians did not have sufficient physical factors to explain their symptoms. An esteemed medical physician and psychiatrist, George Engel, believed that, although pain may originally develop from an external source, it often becomes a psychological phenomenon. He described risk factors for developing chronic pain, including a history of defeat, significant guilt, unsatisfied aggressive impulses and a history of real or imagined loss. His work in this area convinced him that medicine had to assess the contribution of emotional and environmental factors in the development of disease, and he later elaborated his ideas in a seminal paper in *Science*, in which he was the first to posit the notion of a biopsychosocial model of illness.

Around the time Engel was proposing that psychological factors influenced the presentation of pain, a new model was developed by a physiologist and a psychologist. This model was termed the ‘gate theory’, as an integral part of the model was that cells in the dorsal horn of the sensory ganglia in the spinal cord acted as a ‘gate’ that allowed pain impulses to pass up to the cerebral cortex when open but restricted these when closed. The theory proposed that transmission of information about pain to the brain depends upon activation of cells in the dorsal horn of the spinal cord called transmission (T) cells (Figure 52.1). These cells are influenced by both myelinated and unmyelinated fibres; the larger myelinated A fibres inhibit T-cell transmission, whereas the smaller unmyelinated C fibres facilitate it. Activity in these nerve fibres depends in turn on the action of a further cell in the dorsal horn close to the T-cell. This cell, called the gate or gelatinoa cell (G-cell), is situated in the substantia gelatinosa of the dorsal horn; it is activated by branches from large myelinated fibres concerned with touch and proprioception and is inhibited by action of the C fibres. The greater the activation of the G-cell, the more T-cell transmission rostrally to the brain is inhibited. In other words, the greater the A nerve fibre activity, the fewer pain impulses reach the brain.

In addition to this peripheral modification of nervous impulses that have the potential to give rise to pain, there is also central control from the brain itself. This is achieved by both neurochemical and neurophysiological methods. Stimulation of encephalinergic neurons in certain regions of the midbrain (periaqueductal grey, hypothalamus), frequently using serotonin as the relevant neurotransmitter, reduces the intensity of the nervous traffic ascending up the spinal cord from the T-cell. Originally it was thought that there was a direct link between these descending pathways and the G-cell but, although this is probably the case, it is now recognized that control of this pathway also involves other mechanisms. Central influences can also increase pain perception and frequently do so. Increased anxiety and focusing attention on pain have been shown clearly to accentuate painful feelings.

**PSYCHIATRIC DISORDERS AND PAIN**

Psychiatric disorders are more frequently manifest in patients with chronic pain than in the standard population. This has been found in patients complaining of pain who attend general medical clinics, general practices and pain clinics. In some cases, psychiatric disorders may present with pain as the prime symptom. This is certainly known for chest pain in adolescents, abdominal pain in childhood, panic disorder, post-traumatic stress disorder (PTSD), and the rare presentation of psychotic disorders with delusional pain. However, even in these patients,
who have an apparent non-organic pain, it cannot be said categorically that the psychiatric disorder has caused the pain. The mechanisms by which pain is experienced in the absence of sufficient sensory stimuli to account for the intensity of the feeling are indicated in Table 52.1. The psychological processes involved in these include:

- anxiety and arousal;
- fear of pain;
- modelling;
- dissociation and guilt;
- identification;
- delusions.

### Anxiety

Anxiety disorders have been found to be correlated more closely than depression with chronic painful conditions in a large US sample of patients with chronic pain. In particular, people who are fearful of anxiety-related sensations, who interpret somatic symptoms as harmful and who avoid situations where these feelings are likely to arise have greater disability. The term ‘anxiety sensitivity’ has been used to describe this condition in these individuals. Such patients are on the lookout for any potential problem in their environment and show increased evidence of somatic anxiety symptoms and fear in situations that may give rise to pain.

### Fear of pain

Fear of pain explains the mechanism of psychological distress in vulnerable patients who become disabled with chronic pain. In predisposed patients, the perception of pain is interpreted in a malign way through a process of what has been described as catastrophization. The cause of the pain is viewed in a horrific light, and there is further rumination and worry about the effects of this on the body. This
process may occur because of previous life experiences, particularly those of episodes of situations involving pain, anxiety and perceived threats to physical integrity. The symptoms of distress persuade the patient to avoid activities that give rise to further pain. This reduction in mobility limits the process of re-establishment of physical routines that are essential in enabling recovery from injury, and the painful state is reinforced.\(^\text{21}\)

**Modelling**

It is frequently found that people with chronic pain have relatives with a similar condition. It is reasonable to posit, under these circumstances, that there is an expectation to follow the path of invalidism, which may be acquired through the patient modelling themselves on the affected relative.

**Dissociation and guilt**

There may be an aetiological association between the development of dissociation episodes and the development of chronic pain, but this is a very rare event. Dissociation fugue occurring at the time of chronic pain was found to occur in 0.16 per cent of referrals to a comprehensive pain facility.\(^\text{22}\) Engel found that a number of his patients were pain-prone because of guilt about a previous minor misde-meanour, usually involving a member of the family. He proposed that these people had aggressive feelings that they were unable to express.\(^\text{9}\) In practice, few patients seen in practice fit this description.

**Identification**

The incidence of dissociative identity disorder was found to be low in a major facility in Florida, at 0.08 per cent.\(^\text{22}\) Stengel describes a number of examples in his Maudsley lecture,\(^\text{7}\) but in practice this is a rare event.

**Delusional disorders**

Rarely, delusions of pain occur. When they do occur, they are usually found in people with delusional disorders or schizophrenia.

**EFFECT OF PAIN ON PRESENTATION OF ILLNESS**

In the majority of patients with chronic pain, it is much more common for psychiatric disorders to develop because of widespread pain.\(^\text{23,24}\) Pain affects enjoyment, reduces the opportunity to take part in pleasurable activities, and fundamentally changes the whole direction of a person’s life. The most common psychiatric diagnoses found in patients with chronic pain are described in the following sections.

**Depression**

According to standard psychiatric schedules, depressive illness is the most common associated psychiatric disorder found in patients with chronic pain. Between 20 per cent and 50 per cent of patients attending chronic pain clinics fulfil the criteria for this diagnosis.\(^\text{12,25,26}\) Some studies have challenged these findings, and it is now generally recognized that anxiety has more impact in determining the intensity and expression of pain. Depression is found so frequently in a population of people with chronic pain because loss of appetite or weight, changes in sleep pattern and poor concentration are found in patients with chronic pain who are not necessarily depressed. It has, therefore, been recommended in physically unwell patients that these somatic symptoms be replaced with non-somatic alternatives.\(^\text{27}\) If changes in appetite or weight are replaced by a depressed appearance, sleep disturbances by social withdrawal, fatigue by brooding, and diminished concentration by lack of reactivity to pleasant events, then the diagnostic confidence of depression in patients with chronic pain is increased.\(^\text{28}\)

The risk of death by suicide is increased in patients with chronic pain. In a systematic review, it was found that, relative to controls, risk of death by suicide was doubled in patients with chronic pain.\(^\text{29}\) A number of risk factors for suicidal intent in chronic pain were identified in this review, including:

- the type, intensity and duration of pain;
- sleep-onset insomnia co-occurring with pain;
- hopelessness about pain;
- desire for escape from pain;
- pain catastrophizing – negative thoughts in which pain is seen in terms of extremes, e.g. ‘I worry that it will never end’, which is highly related to hopelessness about pain.

There is debate about how far to treat depression in people with chronic pain. Cognitive-behavioural therapy (CBT) is sometimes utilized, but usually in the context of treatment aimed at altering attributions arising from the chronic painful state. Although there is a belief by some that standard antidepressant drugs are not effective in such patients,\(^\text{30}\) based in part on limited evidence that these agents are no more effective in depressed compared with non-depressed patients,\(^\text{31}\) studies have shown that depression is ameliorated in such patients\(^\text{32}\) and that these drugs also reduce pain.\(^\text{11-35}\) The serotonin and noradrenaline reuptake inhibitors (SNRIs) are more effective than the selective serotonin reuptake inhibitors (SSRIs) in reducing one type of pain, neuropathic pain.\(^\text{36}\)

**Anxiety and stress-related disorders**

The diagnoses included under this rubric comprise generalized anxiety disorder, panic disorder, phobias, PTSD, adjustment disorders and obsessive–compulsive disorder.
Early work suggested that female patients with chronic pain and who were not seeking compensation had a higher frequency of generalized anxiety disorder (GAD) than expected, although women with anxiety were not found to have a poorer prognosis compared with men in a more recent investigation. Higher degrees of anxiety were related to greater intensity of pain in this study. It has been suggested that patients with chronic pain may use worry to reduce the physical sensations associated with pain and thus fulfill the diagnostic criteria for GAD. This hypothesis does not have experimental proof.

CBT has been shown to be effective in chronic painful conditions. This treatment is also used in GAD associated with pain. It has been shown that in patients with low back pain who have pain-related anxiety and are receiving CBT combined with physical therapy, improvement in anxiety was more important than changes in physical capacity in predicting outcome. In a World Health Organization (WHO) survey, people with back and neck pain were over two and a half times more likely to have GAD than controls without such pain. This survey was not able to show the temporal relationship between pain and anxiety, but other studies have strongly suggested that anxiety sensitivity is a feature in this population.

**Panic disorder**

Although the pain sensitivity of patients with panic disorder has been reported to be no different from that of controls, patients with chronic painful conditions are more likely than average to have panic. People with migraine attacks may be particularly prone. These findings suggest that panic and migraine may be related directly through a single mechanism.

**Phobias**

A phobia may develop because of the experience of the event leading to the pain, for example travel phobia following a road traffic accident. The condition known as social phobia, in which the patient feels anxious in social situations and avoids such engagements, has been found to be overrepresented in disabled workers with chronic musculoskeletal pain.

**Stress disorders**

The only relevant stress disorder in this context is PTSD. There is clear evidence that the experience and management of pain can be aggravated by PTSD. One of the main reasons for this is because PTSD is associated with high anxiety, and we have seen that anxiety is associated comorbidly with chronic pain. Furthermore, the presence of PTSD is a poor prognostic sign. Hyperarousal, excessive attention to changes in the environment, and an inclination to focus on bodily symptoms are frequent accompaniments of both PTSD and chronic pain, which may explain these findings.

If PTSD is identified, treatment should be carried out by a specialized team familiar with treatment procedures in this condition. Debriefing and superficial treatments of this type are not valuable and have been found to worsen the prognosis in patients with more intense symptoms. Trauma-focused CBT and eye movement desensitization and reprocessing (EMDR), a technique that involves movement of the patient’s eyes in a systematic way while recalling disturbing memories, have been found to be effective in treating PTSD in a meta-analysis. Either of these treatments is recommended as first-line in the treatment of PTSD according to national guidelines. If facilities for such treatment are not available, or if these therapies are not successful, then treatment with the antidepressant drugs amitriptyline, mirtazapine or phenelzine has been shown to be effective.

**Personality disorders**

Although it has been said that personality disorders are more common in patients with chronic pain, there has been a dearth of good research in this area. People without any previous history of personality disorders may appear to have such a condition because of the exacerbation of premorbid personality characteristics resulting from pain and subsequent stresses. Originally it was thought that some patients who developed chronic pain had a ‘pain-prone personality’, but there is very little evidence for such a label.

A study of out-patients attending a chronic pain clinic in Germany showed that more than one in ten subjects had a paranoid or a borderline personality disorder, with passive-aggressive, avoidant and obsessive-compulsive personality disorders being significantly overrepresented compared with a control group.

Individuals with borderline personality disorder and other cluster B personality disorders are at greater risk of misusing medication, and benzodiazepines and opioid drugs should be prescribed very carefully in this group. There is very limited evidence that antidepressants, particularly the SSRIs and the monoamine oxidase inhibitors (MAOIs), have some benefits in the management of this condition; there is lesser evidence for the advantages of antipsychotic drugs and mood stabilizers. There is no basis to recommend different treatments for the different personality disorders.

A structured evidence-based review warns all pain clinicians to be sceptical about the assessment of personality in patients who are in pain. Personality profiles of patients who have chronic pain usually alter considerably if the pain is reduced. This was shown in 1975 but is not generally realized. This change has been shown convincingly for the widely quoted Minnesota Multiphasic Personality Inventory schedule (MMPI). These findings illustrate that many personality questionnaires are influenced by the current state of the individual, including physical and mental health.
Somatoform disorders

For a diagnosis of a somatoform disorder to be made, there should be continued presentation of physical symptoms together with persistent requests for medical investigations despite negative findings of organic illness and reassurance by doctors that the symptoms have no physical basis. In some patients, physical disorders may have been present but they do not explain the nature and extent of the present symptoms or the distress and preoccupation of the patient.

These disorders are frequent. In a survey of patients attending a general practice clinic in Holland, the prevalence of somatoform disorders was as high as 21.9 per cent. Many of these patients are severely disabled, but it is only the minority that are likely to be assessed by clinical psychologists or psychiatrists, despite a recommendation advocating joint working between liaison psychiatrists and pain physicians.

The value of the present classifications of these syndromes has been brought into question because of the imprecise categorization of such disorders and the fact that many patients fall into the category of undifferentiated somatoform disorder, a watered-down version of somatization disorder. Pain is only one of the symptoms that can occur in a somatoform disorder. Those somatoform disorders that are concerned with painful conditions are described in the following sections, together with their International Classification of Diseases, 10th revision (ICD-10) codes.

Persistent somatoform pain disorder (F45.4)
The main complaint in this disorder is of persistent, severe and distressing pain that cannot be explained fully by any bodily process or physical disorder. Furthermore, this occurs in association with emotional conflict or psychosocial problems that are considered to be the main cause. The threshold for a diagnosis of pain disorder in the Diagnostic and Statistical Manual, 4th edition (DSM-IV) is lower than in ICD-10.

There are two established treatments for this condition, antidepressants and CBT. Antidepressants that inhibit both serotonin and noradrenaline uptake, such as amitriptyline and venlafaxine, are more effective than the SSRIs. CBT has been shown to be of definite value in patients who have reached the stage of accepting that medical or surgical interventions are not indicated.

Hypochondriacal disorder (F45.2)
In this condition, the patient believes that he or she has a serious or progressive physical disorder that persists, despite negative investigations and reassurance. Some 1–2 per cent of the patients in the general population have been found to have hypochondriacal features; these features are more evident in older people. Fear of disease (disease phobia) is associated with anxiety, whereas a false belief of having a disease (disease conviction) is associated more with somatic symptoms. Although this condition may seem to be more frequent in patients with chronic pain, there has been no recent survey of this condition in a pain clinic.

Somatization disorder (F45.0)
Somatization disorder, formerly known as Briquet’s syndrome, is by far the most crippling somatoform disorder. Its main features are multiple, recurrent and frequently changing physical symptoms, which have been present for many years. Most patients have a long and complicated history of contact with both primary and specialist medical care services, during which time many negative investigations have been carried out. Personality disorders, particularly of the passive-dependent and histrionic types, are considerably overrepresented compared with control subjects with anxiety and depression. The female/male ratio of patients with this condition is 5 : 1. The prevalence rate has been estimated to be 0.5 per cent, but this is probably an underestimate and the true rate is probably higher.

In practice, the diagnosis of undifferentiated somatoform disorder (F45.1), which has a lower criterion for diagnosis, is found to be much the most frequent diagnosis in standard populations. This category comprises a raft of heterogeneous conditions in which physical and psychiatric disorders intermingle.

Psychoactive substance use

There is a higher rate of alcohol and analgesic misuse in patients with chronic pain. Between 12 per cent and 28 per cent of patients attending specialized pain clinic facilities reach the criterion for diagnosis under this category. High average alcohol consumption before developing a chronic painful state was found to be a poor prognostic sign in a large follow-up study of patients with lower limb pain.

Despite these findings of an increased prevalence of substance misuse, generally there has been a change in attitude about the use of opioid medication for patients with chronic non-malignant pain. Although it has been argued that long-term opioid use leads to increased drug dependency and further functional impairment in patients who have disproportionate pain and disability, studies have not found clear evidence that this is the case. In a large study of patients with chronic pain comparing opioid users with non-users, there was no increase in illness behaviour exhibited by the opioid users after controlling for other variables. Benzodiazepine use, on the other hand, was associated with reduced activity and disability.

Brief psychosocial interventions and contingency management (which consists of payment of money or tokens to patients if they succeed in reducing opiate use) have been found to improve compliance with therapy.

Factitious disorder

In factitious disorder, patients consciously fabricate symptoms and may even physically injure themselves in order to
produce symptoms and signs that are typical of an organic illness. The motivation for exhibiting such symptoms in factitious disorder is to obtain medical care. Abdominal pain, often suspected to be due to renal or biliary colic, is the most frequent presentation of a painful factitious disorder. Most people encountered in clinical practice with this disorder are healthcare professionals, with a considerable female preponderance. They are often found to have a number of different diagnoses at different times. Their families are closely involved and are convinced of an organic aetiology. Frequent attendance at emergency departments, coupled with negative investigations, raises suspicions that this disorder may be present.

Malingering

In malingering there is a conscious wish to fabricate symptoms. However, malingers behave in this way in order to obtain financial gain or to avoid situations for certain responsibilities.

CONCLUSIONS

When examining patients with long-standing pain, distress should be distinguished from illness. In the majority of cases, all avenues in alleviating the pain should be explored first, although treatment for any psychiatric illness should not be delayed.

KEY POINTS

- Until the middle of the twentieth century, the mind–body dualistic philosophy drove the interpretation of painful states. There is now recognition that a modified monistic view may be more valid.
- Patients in pain who develop a psychiatric disorder do so usually as a consequence of their chronic painful illness. Depression is common.
- Anxiety is the driving affect that affects the perception of pain.
- In many cases, it is appropriate to treat depression with antidepressant drugs, particularly if there is pervasive loss of pleasure. The SSRIs are usually employed first, but tricyclic antidepressants and SNRIs are more appropriate if there is evidence of a neuropathic pain state.
- PTSD is a poor prognostic sign in people with chronic pain who have developed pain following an injury.
- People with borderline and dependent personality disorders require a contract to be established early in therapy, applying particular care to the administration of drugs.
- Substance misuse, which includes both alcohol and drugs, occurs in one in between four and eight people with chronic pain attending pain clinics.

ASSESSMENT OF SLEEP DISORDERS

History and examination

It is often more difficult to take a history of a sleep disorder than to ask about complaints occurring during wakefulness. The patient may have little or no awareness of the problem. It may be only the patient’s partner who can describe the events. After establishing the nature and timing, relative to both the clock and the onset of sleep, it is important to establish the time that the patient goes to bed, how long it takes to fall asleep, how often and why the patient awakens during the night, and what time the patient wakes up and gets out of bed. Feeling unrefreshed on waking may be due simply to sleep inertia, but if it persists during the day it should trigger enquiry into the cause of excessive sleepiness. If enough sleep is being obtained at night, then causes of disturbed sleep, such as an adverse sleeping environment, sleep apnoeas or restless legs syndrome, should be asked for, together with specific symptoms for other conditions that may cause excessive sleepiness, such as narcolepsy.

If the main complaint is lack of sleep at night, it is worth establishing whether this is difficulty in initiating sleep, maintaining sleep or waking early in the morning, since these three types of insomnia tend to have different causes. The cause of the difficulty in sleeping may be sensed by the patient to be primarily mental or physical, and the details should be obtained. Many patients with insomnia feel physically and mentally fatigued during the day. This should be distinguished from true excessive sleepiness.

If the primary complaint is of abnormal behaviours during sleep, then the patient’s recall should be distinguished from the descriptions of the observer or partner. In contrast, with vivid dreams or nightmares, it is usually the patient who is able to give the most information, but occasionally, as in REM sleep behaviour disorder, the subject may forget the content of the abnormal dreams and the partner may be able to give useful information.

With patients who are excessively sleepy, the details of any naps or tendency to fall asleep during the day should be obtained. A simple measure of the severity of sleepiness is the Epworth Sleepiness Scale (Table 53.1). Details of the patient’s activities during the day, and particularly in the hours before sleep, together with the patient’s attitudes and beliefs about sleep, may give useful insights into the causes of difficulty in sleeping and excessive daytime sleepiness. A careful medical and psychiatric history is required. A family history is particularly important in sleep walking and restless legs syndrome. Many drugs influence sleep and wakefulness, and details of drugs taken both currently and in the past should be obtained.

Physical examination is usually less helpful than a careful history. It can, however, show enlarged tonsils in patients who snore or have sleep apnoeas, and reveal psychiatric abnormalities in a wide range of sleep disorders. A neurological examination may be required, particularly to assess the cause of daytime sleepiness or motor disorders during sleep.

Polysomnography

Polysomnography is the simultaneous acquisition of several physiological signals during sleep. The most important of these are the electroencephalogram (EEG), electro-oculogram (EOG) and electromyogram (EMG), which enable sleep to be distinguished from wakefulness, the states of NREM and REM sleep to be identified, and the stages of NREM sleep to be distinguished. The EEG electrodes sample cerebral cortical activity, which is very different in NREM sleep compared with REM sleep and wakefulness. As the stages of NREM sleep deepen, the frequency of the EEG falls and its amplitude increases. Delta waves are a feature, particularly of the deeper stages (3 and 4) of NREM sleep, which are often known together as ‘slow-wave sleep’. Other variables that are commonly recorded in polysomnography include respiratory sounds, air flow, chest wall and abdominal movement, oxygen saturation, heart rate, EMG from a limb (usually the anterior tibialis muscle in the leg) and sometimes oesophageal pH and pressure monitoring.

Assessment of daytime sleepiness can be aided by completion of sleep diaries and self-assessment scales such as the Epworth Sleepiness Scale. Behavioural performance tests such as reaction time tests and driving simulators are
not used routinely, but they can be helpful in specific circumstances. Tracking tests and tests of higher cognitive function, such as planning and decision-making, can help to assess the degree of sleepiness, the ability to maintain attention and other aspects of cortical function.

The multiple sleep latency test (MSLT), in which the subject is asked to try to fall asleep in a darkened room four times during the day, is an objective test of daytime sleepiness. It requires EEG, EOG and EMG signals to assess whether the subject is awake or asleep. In narcolepsy, not only is the MSLT shorter than normal, but also REM sleep is characteristically seen on at least two of the tests. The maintenance of wakefulness test (MWT) requires the same EEG, EOG and EMG monitoring, but the subject is asked to stay awake in a darkened room for as long as possible rather than to fall asleep.

### SLEEP, DRUGS AND PSYCHIATRIC DISORDERS

There are a variety of drugs used in psychiatric disorders that may affect sleep. Conversely, there are a large range of medical and social and recreational drugs that influence both sleep and psychiatric conditions.

#### Medical drugs

##### Hypnotics

Most of the hypnotics affect the functioning of \( \gamma \)-aminobutyric acid (GABA), which is a widely distributed inhibitory amino acid transmitter. GABA\(_A\) rather than GABA\(_B\) receptors are affected. The benzodiazepines, zopiclone, eszopiclone, zolpidem, zaleplon and indiplon fall into this group. Barbiturates and alcohol bind directly to the GABA receptors and to their own receptors.

Most of these hypnotics have a rapid onset, but they have a variable half-life. They may increase the total sleep time and shorten the sleep latency, but most of them have little effect on stages 3 and 4 of NREM sleep. They tend to increase the duration of stage 2 of NREM sleep. The exception is sodium oxybate, which increases the duration of stages 3 and 4 of NREM sleep; possibly through this mechanism, it improves daytime alertness in narcolepsy, consolidates night-time sleep and relieves cataplexy.

##### Antidepressants

Depression may be related to overactivity of cholinergic relative to monoaminergic systems in the central nervous system (Table 53.2). Most antidepressants tend to restore the balance of these two neurotransmitters. Almost all
Sleep disorders

Antidepressants increase the latency until the first REM sleep episode, reduce the total duration of REM sleep and increase the duration of stages 3 and 4 NREM sleep. The exceptions are moclobemide, bupropion and mirtazapine. Lithium has similar effects to conventional antidepressants but also delays the circadian rhythms slightly.

Antipsychotics
The older antipsychotics antagonize the dopamine receptors D2 and D3 in particular and inhibit the ascending reticular activating system, limbic system and cerebral cortex. Atypical antipsychotics antagonize 5-hydroxytryptamine 2 (5-HT2) receptors in particular. The older drugs increase total sleep time, reduce sleep latency and usually increase the duration of stages 2, 3 and 4 of NREM sleep (see Table 53.2). Atypical antipsychotics, particularly olanzapine, increase the duration of stages 3 and 4 of NREM sleep and often cause daytime sleepiness.

Cholinesterase inhibitors
These drugs, which are used in dementia, increase the duration of REM sleep and often cause insomnia, intense dreams and nightmares.

Social and recreational drugs
Alcohol
Alcohol has a similar effect on GABA receptors to the hypnotics, but it also has its own receptor and acts as a glutamate inhibitor. Low doses of alcohol increase the total sleep time, reduce sleep latency, reduce latency before stages 3 and 4 of NREM sleep, and suppress REM sleep. After larger intakes, stages 3 and 4 of NREM sleep are reduced and its diuretic effect causes awakenings from sleep. Chronic alcohol ingestion can severely disrupt the sleep–wake cycle, and even after abstinence abnormal sleep architecture often persists for a prolonged period.

Caffeine
Caffeine acts as an antagonist at adenosine receptors and tends to increase wakefulness. It reduces total sleep time, increases the sleep latency and reduces the duration of stages 3 and 4 of NREM sleep and of REM sleep. It commonly causes insomnia if taken later in the evening or in large doses.

Nicotine
Nicotine acts on nicotinic cholinergic receptors. In low doses it is excitatory, but in high doses it is inhibitory. It appears to reduce the total sleep time, increase sleep latency and reduce the duration of REM sleep in higher doses.

Amphetamines
Amphetamines increase activity at dopamine, noradrenaline and 5-HT synapses, particularly in the brainstem and cerebral cortex. They have an alerting effect, reduce total sleep time and reduce the duration of stages 3 and 4 of NREM sleep and of REM sleep.

Cannabinoids
These drugs act at CB1 and CB2 receptors. They reduce the duration of REM sleep and slightly increase the duration of stages 3 and 4 of NREM sleep. Withdrawal leads to REM sleep rebound.

EXCESSIVE DAYTIME SLEEPINESS
Excessive daytime sleepiness should be distinguished from physical fatigue or weariness and mental fatigue, which is characterized by the inability to sustain concentration, for instance on a conversation or while reading. The nature of sleepiness is probably similar whatever its cause, and the subject is usually aware of feeling sleepy before sleep is entered. Rapidly developing sleepiness with very little warning beforehand may, however, occur in narcolepsy and parkinsonism.

Effects of sleepiness
With increasing sleepiness, the level of alertness falls, concentration deteriorates and attention, particularly for

NREM, non-rapid eye movement; REM, rapid eye movement.
Excessive daytime sleepiness

847

Part 4: Mental health problems and mental illness

prolonged monotonous tasks, is impaired. Mood changes, particularly irritability and paranoia, are common. Stereotyped behaviour, with the loss of innovative responses, verbal fluency and mental flexibility, is characteristic. Working memory deteriorates, and planning and executive functions are impaired.

There is deterioration in physical performance, particularly for prolonged or monotonous tasks, with a sense of fatigue and even episodes of automatic behaviour, in which inappropriate actions are carried out with reduced vigilance and subsequent amnesia.

Excessive daytime sleepiness impacts on family and social life and recreational activities. In children it often leads to poor school performance and impaired concentration, which may be interpreted as attention deficit hyperactivity disorder (ADHD). In adults there is a fall in productivity at work, with an increased number of errors and a risk of occupational accidents, particularly with moving machinery.

Sleepiness and driving

It has been estimated that around 1–3 per cent of all road traffic accidents, perhaps 10 per cent of serious accidents and 20 per cent of motorway accidents are related to driver drowsiness. These particularly involve males under the age of 30 years who are driving alone and who appear to be unable to recognize their degree of sleepiness. Sleep-related accidents occur particularly between 2 a.m. and 6 a.m. and between 2 p.m. and 4 p.m., when the circadian rhythms most strongly promote sleepiness. Pre-accident behaviour includes fluctuating vehicle speed due to intermittent loss of muscle activity in the leg controlling the accelerator at the transition into sleep, shunting accidents at traffic lights and roundabouts, and weaving from lane to lane. At the time of the accident, there is often no evidence for braking or taking avoiding action.

Causes of excessive daytime sleepiness

Insufficient duration of sleep (sleep restriction)
This is the most common cause of sleepiness and is usually the result of social or work pressures or shift work, which also reduces the quality of sleep through altering its timing and regularity. A careful history should detect sleep restriction. It is important to discuss with the patient how other competing priorities can be managed so that adequate sleep is obtained.

Impaired quality of sleep (sleep fragmentation)
Poor quality of sleep may be due to an adverse sleep environment, which may be noisy, light, too hot or too cold, or uncomfortable. It may also be due to medical disorders that disrupt sleep, such as pain and discomfort, drugs such as caffeine or excessive alcohol, and conditions appearing during sleep, particularly obstructive sleep apnoeas and periodic limb movements as part of restless legs syndrome.

Hypersonnias
In these conditions, although sleep may be of normal duration, it is unrefreshing and the subject remains sleepy or naps during the day. Narcolepsy is usually regarded as a hypersonmia, but the total sleep time during the day and night is increased only slightly. In idiopathic hypersonmia, however, there is prolonged nocturnal sleep, with difficulty in waking in the morning associated with prolonged unrefreshing naps during the day. Sedative drugs may produce a similar clinical picture.

Individual disorders causing excessive daytime sleepiness

Narcolepsy
Narcolepsy is a disorder of REM sleep in which fragments of this intrude into wakefulness. Sleep itself is destabilized, with frequent nocturnal awakenings. Its prevalence is around 1 in 2000–3000. It usually arises in adolescents or young adults. Insomnia at night is combined with severe sleepiness during the day. The physiological loss of muscle tone in REM sleep is manifested as sleep paralysis, often at the onset of sleep, and cataplexy, which is a loss of muscle tone in response to sudden or intense emotion, usually laughter. The intensity of dream mentation is increased, leading to hypnagogic and hypnopompic hallucinations and vivid dreams at night.

Narcolepsy may be triggered by environmental factors, but it also has a genetic component. Lack of functioning of orexin-producing neurons in the perifornical hypothalamus appears to be a common factor in classical narcolepsy.

The presence of cataplexy is virtually specific to narcolepsy, but if there is diagnostic doubt polysomnography with multiple sleep latency tests are usually helpful (Box 53.1). Sleep-onset REM sleep during the overnight study with a short sleep latency and two or more episodes of sleep-onset REM sleep during the MSLTs are characteristic of narcolepsy. HLA DQB*01602 is present in over 90 per

</table>
cent of white people with narcolepsy. It is also present in around 25 per cent of the normal population, but its absence makes narcolepsy unlikely. Estimation of cerebrospinal fluid orexin concentration is currently a research procedure, but low values are typical of narcolepsy.

Explanation of the nature and prognosis of the symptoms and advice about lifestyle factors to manage their impact is important. The first-line medication for excessive daytime sleepiness is modafinil, but if this is poorly tolerated or ineffective dexamphetamine and methylphenidate are alternatives. Cataplexy is usually treated with an antidepressant such as venlafaxine, but if this or daytime sleepiness remain troublesome sodium oxybate is usually effective.

Obstructive sleep apnoeas
These are characterized by transient obstruction of the upper airway, usually at pharyngeal level. They may occur up to 500 times each night, and each is associated with a micro- arousal from sleep. These fragment sleep and lead to daytime sleepiness. The condition is most common in middle-aged males, particularly if they are obese, but it can occur at any age in both sexes.

The characteristic clinical features are a combination of snoring with apnoeas witnessed by the partner and excessive daytime sleepiness. Diagnosis can be confirmed by sleep studies, including domiciliary oximetry studies. Attention to lifestyle factors, particularly weight loss, is important; particularly in children, tonsillectomy may be effective. Mandibular advancement devices that protrude the lower jaw and tongue and thereby increase the dimensions of the pharyngeal airway are often effective in mild sleep apnoeas, but they may be tolerated poorly. The most effective treatment is a nasal continuous-positive airway pressure (CPAP) system, which inflates the airway. This prevents the airway obstructing and relieves both the symptoms and the consequences of sleep apnoeas, including the increased risk of myocardial infarction, stroke, hypertension and road traffic accidents.

Idiopathic hypersomnia
This condition usually affects young adults and is characterized by prolonged unrefreshing sleep, difficulty in waking in the mornings, and prolonged unrefreshing naps. None of the other features of narcolepsy are present. No cause is found, although a similar condition may appear after brain injury. Treatment with modafinil, or if necessary dexamphetamine, is usually effective.

Psychiatric disorders
Excessive daytime sleepiness is caused only occasionally by psychiatric problems, although it is a feature of depression, particularly in adolescents and young adults. It can develop as a protective psychological reaction to circumstances that are difficult to cope with. This may be difficult to distinguish from idiopathic hypersomnia. Daytime sleepiness in schizophrenia is usually due to sedative medication or sleep apnoeas associated with obesity rather than the disorder itself.

INSOMNIA

Insomnia is the most common sleep disorder, and at any one time 10–15 per cent of the population has this problem. It is more common in females and in older people. Insomnia is not a diagnosis but a symptom complex of the perception of insufficient or poor-quality sleep, despite an adequate opportunity to sleep, together with a feeling of being unrefreshed or fatigued on waking and during the day. Insomnia may be transient (adjustment sleep disorder), when it is usually a response to a stressful event. The pattern of insomnia may be primarily a difficulty in initiating sleep (DIS; sleep-onset insomnia), difficulty in maintaining sleep (DMS; sleep-maintenance insomnia) or early-morning wakening (EMW).

Effects of insomnia
Insomnia is associated with a lower delta power on the EEG during sleep and intrusion of alpha waves, suggesting a lower threshold for arousal to stimuli such as pain or noise. The heart rate is faster in all stages of sleep, as in wakefulness, and hypertension is more common in people with insomnia than in the normal population.

The psychological consequences of insomnia are loss of concentration and deterioration of memory, irritability, mood disturbance, loss of motivation, and increased risk of anxiety and depression. There is also a sensation of physical weariness, fatigue and muscle aches, which are usually worst in the limbs but may be associated with headaches.

Causes of insomnia
Primary insomnia (hyperarousal states)
The hyperarousal state that underlies primary insomnia is also present during wakefulness. There may be a genetic predisposition, exacerbated by, for instance, shift work or age. Precipitating factors can be detected in 75 per cent of people with chronic insomnia and include a wide range of stressful situations, which lead to an increase in both physiological and psychological arousal. Once insomnia has been established, it is often perpetuated by maladaptive attitudes, beliefs and behaviours that lead to poor sleep hygiene.

There are several clinical types of primary insomnia, including the following:
- Sleep state misperception: in this condition, the duration of sleep may be normal, but it is perceived to be short despite the absence of any physiological abnormalities during sleep. The risks of hypertension and depression appear to be similar to those in people with true primary insomnia.
• **Psychophysiological (conditioned) insomnia:** this is an apprehensive concern about difficulties in sleeping, which perpetuates insomnia. It is in effect a focal anxiety state centered on the inability to sleep adequately. The sleep difficulty may become a major concern during wakefulness.42

• **Anxiety states:** these are often associated with poor sleep at night and waking with panic attacks.

• **Chronic fatigue syndrome:** there is often hypersomnia initially, followed by a prolonged period of insomnia, which is usually related to poor sleep hygiene secondary to the fatigue, associated with anxiety about obtaining sufficient sleep.

• **Fibromyalgia:** sleep is usually considered to be unrefreshing and light. Polysomnography often shows alpha intrusion. The sleep problems of fibromyalgia overlap with those of chronic fatigue syndrome.

### Co-morbid (secondary) insomnia

It is now recognized that insomnia associated with a wide variety of psychiatric and physical disorders is not simply the result of these disorders but one of their causes. It often requires treatment in addition to the treatment of the associated co-morbidity.

#### Depression

Insomnia is a common and often initial symptom of depression. There is difficulty maintaining sleep and early-morning awakening rather than difficulty initiating sleep. Excessive sleepiness during the day is a feature of depression in younger patients.43

There appears to be an increase in drive to enter REM sleep combined with a weakened drive for NREM sleep (Figure 53.1). As a result, there is characteristically a short total sleep time, with short latency until the first REM sleep episode, and an increase in the duration of REM sleep, with reduction in stages 3 and 4 of NREM sleep. There is an increase in sleep stages 1 and 2 and frequent awakenings. These features are seen particularly during an episode of depression, but they may persist after treatment; in particular, the REM sleep latency often remains short. There is also a tendency towards an advanced sleep phase, which probably contributes to early-morning wakening.

Sleep deprivation may elevate the mood in depression and even lead to mania in bipolar disorders.44 Sleep deprivation increases the drive to NREM sleep and, particularly if sleep is lost during the latter part of the night, the duration of REM sleep will be curtailed. Reduction in duration of REM sleep is also a feature of most antidepressant drugs and of electroconvulsive treatment. Sedative antidepressants such as tricyclics and mirtazapine are usually effective in relieving insomnia due to depression, but an alternative is a selective serotonin reuptake inhibitor (SSRI) antidepressant with a short course of a hypnotic.45

#### Bipolar disorder

The manic phase of bipolar disorder is usually associated with around 3–4 h sleep each night. There may also be abnormalities in circadian rhythms, including cortisol secretion.

#### Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) may follow a military or civilian traumatic event and is characterized by insomnia, intrusive thoughts, flashbacks, nightmares and avoidance behavior. The nightmares occur especially between midnight and 3 a.m. They may arise from stages 1 and 2 of NREM sleep as well as from REM sleep, in contrast to the usual type of nightmare. Their content relates to the precipitating event, although it may be generalized and hardly recognizable.

PTSD leads to a hyperarousal state both while awake while and asleep. As a result, there is insomnia, with difficulty in initiating and maintaining sleep. Panic attacks may occur, both during the day and at night, and insomnia may be exacerbated by depression.

Antidepressants, particularly SSRIs or venlafaxine, combined with behavioural therapy and psychotherapy may help to relieve the sleep-related symptoms. The nightmares and associated motor abnormalities often respond to prazosin.

#### Schizophrenia

Schizophrenia characteristically causes difficulty in initiating and maintaining sleep.46 These are particularly problems during and before acute exacerbations. The dreams of people with schizophrenia often feature strangers in an environment that is hostile to the patient. These dreams should be distinguished from hallucinations during wakefulness. Daytime sleepiness in schizophrenia is usually related to psychotropic drugs rather than to the schizophrenia itself.

#### Dementia

Insomnia is a common problem in dementia, particularly Alzheimer’s disease and multi-infarct dementia.47 The

---

**Figure 53.1 Abnormalities of sleep control in depression**

ASPS: advanced sleep phase syndrome; EMW, early-morning awakening; NREM, non-rapid eye movement; REM, rapid eye movement; TST, total sleep time.
normal sleep architecture disintegrates, with loss of the sleep cycles of NREM and REM sleep. Daytime naps are taken frequently, and an advanced sleep phase with an early sleep onset and early waking time is common. ‘Sundowning’ is a problem particularly with Alzheimer’s disease and is characterized by agitation, particularly in the afternoon and early evening, associated with wandering and confused behaviour. It improves with light therapy and is more common in the winter, when there is less light exposure.

The duration of stages 3 and 4 of NREM sleep is shortened, and there is an increase in REM sleep latency and a shorter duration of REM sleep.

The sleep-related symptoms may improve with sleep hygiene advice, particularly regular sleep–wake patterns, increased exposure to light in the day, more physical activity during the day, and the avoidance of stimulants such as caffeine and disturbance from attendants at night. Long-acting hypnotics that induce daytime sedation are best avoided.

**Treatment of insomnia**

The most important aspect of the treatment of insomnia is attention to sleep hygiene. Any underlying cause should be recognized and treated, whether this is physical or psychiatric. Attention to drugs that may contribute to insomnia, such as caffeine and nicotine, is important. Advice should be given about shift work.

Hypnotics may be effective in the short term, but it is usually recommended that their use is restricted to less than 1 month. Cognitive-behavioural therapy (CBT) may have long-term benefits, but its availability is limited.

**PARASOMNIAS**

This unsatisfactory term is conventionally used to describe unusual, undesirable and episodic events in sleep that are not due primarily to another sleep disorder. It is, however, difficult, to separate sleep disorders from the motor behaviours during sleep. Including the undesirable component also leads to a subjective assessment of what is a parasomnia. The range of unusual events during sleep is so broad that the term ‘parasomnia’ includes a very heterogeneous collection of conditions. In addition, some of these conditions are so common that they merge into normality.

Abnormal behaviour during sleep falls into three main categories.

**NREM sleep disorders**

These include sleeptalking, sleepwalking, sleep terrors, sleep-eating and sexual activity in sleep. The first three are most common in childhood, have a familial, probably genetic background, and can be precipitated by factors that increase the depth or duration of stages 3 and 4 of NREM sleep. These factors include sleep deprivation, hypnotics, alcohol, and factors that tend to cause arousal from sleep, such as a noisy environment, stress, and sleep fragmentation due to sleep apnoeas or restless legs syndrome. A primary psychiatric cause is unusual. Polysomnography is not diagnostic but excludes other causes for the episodes. Explanation and reassurance may be sufficient, but advice about safety issues, avoidance of precipitating factors, and occasionally drug treatment, including hypnotics and antidepressants, may be of help.

Sleep-eating and sexual activity during sleep tend to occur in young adults with a previous history of sleepwalking or sleep terrors. They should be distinguished from these activities occurring during wakefulness at night that are not recognized or are denied by the patient.

**REM sleep abnormalities**

The most important condition is the REM sleep behaviour disorder (RBD). This occurs in elderly males and is often the first feature of degenerative neurological conditions, particularly parkinsonism, but also multiple system atrophy and Lewy body disease. It is characterized by dreams with an aggressive content in which the patient is attacked or chased by strangers. The normal inhibition of motor activity (‘atonia’) in REM sleep is lost, so that these dreams are physically enacted, often with resulting injuries to the patient or their partner. Polysomnography shows retention of muscle tone during REM sleep and the nature of the physical activity. Clonazepam, zopiclone and melatonin are usually effective.

**Restless legs syndrome (Ekblom’s syndrome)**

This condition may affect up to 10 per cent of the adult population mildly and is troublesome in around 2 per cent of people. It is often familial, but it may be secondary to factors such as iron deficiency, renal failure and drugs, including antidepressants, antihistamines, antipsychotics and lithium. It is also a feature of normal pregnancy. It is characterized by an unpleasant sensation inside the legs occurring in the evenings, an urge to move the legs, and relief by movement (Box 53.2). During sleep it leads to repetitive movements of the legs, which fragment sleep. The main complaints are difficulty in initiating sleep and daytime fatigue. The most effective treatment is a dopaminergic agent such as ropinirole or pramipexole, but benzodiazepines, opiates and anti-epileptic drugs such as gabapentin may also be useful.

**DREAMS AND NIGHTMARES**

Dreams that include a complex narrative with visual and other images are usually associated with REM sleep. They
appear to be initiated by the pontine centres responsible for this. The bizarre nature of dreams is related to partial loss of frontal lobe function in REM sleep and to the loose mental associations that are characteristic of REM sleep.60

In pure NREM sleep there may be dreams with a simple content and that typically involve problem-solving,61 whereas REM sleep dreams have more narrative and emotional content.62 Similar processes can occur before the onset of sleep (hypnagogic hallucinations) and after waking (hypnopompic hallucinations); they are particularly characteristic of narcolepsy. The content of dreams differs according to age, culture and gender, and they vary considerably in their emotional content, vividness, timing during the night, and the extent of recall afterwards.

Nightmares are most common between the ages of 6 years and 10 years, but they occur occasionally in 40–50 per cent of adults. Nightmares are dreams that are terrifying and lead to an intense anxiety or fear on arousal from sleep, although there is little physical or autonomic overactivity.63 There is no confusion on waking, and they occur particularly during the last third of the night, when REM sleep is most prolonged. Polysomnography is rarely required, but nightmares should be distinguished from REM sleep behaviour disorder, nocturnal panic attacks and sleep terrors, which have little dream imagery and occur early in the night, and epilepsy. They may respond to antidepressants, which reduce the duration of REM sleep, and CBT, including imagery rehearsal therapy, in which the content of the nightmares can be modified into a non-frightening narrative.

Suicide has been common throughout human history. The Romans regarded suicide as permissible, provided one was not a soldier or a slave (i.e. of economic value to the State). Socrates regarded suicide as against God’s will but permissible if God sent ‘necessity’ on a man. Christian clerics condemned suicide at the Council of Arles in AD452, and Islamic texts specifically proscribe suicide. At times, suicide has been considered either appropriate or noble; death by seppuku was preferred to dishonour by Samurai, and insur- gent Jews, rather than face enslavement by the Romans, died in a mass suicide at Masada in AD74.

Any account of suicide is influenced by a society’s prevailing philosophical values. Emile Durkheim viewed suicide as a social phenomenon occurring under four conditions: (i) anomic (anomie – a social environment lacking norms), (ii) egoistic (an individual detached from society), (iii) altruistic (suicide for the greater social good) and (iv) fatalistic (to die rather than to endure oppression). The prevailing ideological account in Western society regards suicide as the pathological outcome of a diseased state of mind and successful suicidants as victims rather than perpetrators.

Statutory considerations
Suicides are regarded in English law as a mode of death that is unnatural, self-inflicted, deliberate and intended. A verdict of suicide is returned by the Coroner’s court only if suicide intent can be demonstrated beyond reasonable doubt; if not, then an open or other verdict will be returned (Box 54.1).

Two-thirds of open verdicts would be considered probable suicides when judged by clinical standards. Of clinically probable suicides, half of men and a quarter of women receive Coroners’ verdicts other than suicide. Thus, the legal determination of suicide is not a reliable indicator of its true incidence. Furthermore, the threshold at which a suicide verdict is returned varies between Coroners. Apparent variations in the suicide rates between countries are attributable partly to differences in legal criteria and socio-cultural factors affecting reporting.

Suicide researchers use either an exclusive or an inclusive framework for case ascertainment. The exclusive framework includes only cases that have received a Coroner’s verdict of suicide. The inclusive framework includes cases where a Coroner returned a verdict of suicide and cases where the intent to die is undetermined. The, usually preferred, inclusive method estimates the incidence of suicide as one-third higher than the exclusive method.

The Suicide Act abrogated the previous law whereby it was a crime for a person to commit suicide. However, complicity in the suicide of another person by having ‘aided, abetted, counseled or procured the suicide’ became a criminal offence punishable by imprisonment. The Suicide Act is therefore relevant to the continuing moral debate about end-of-life decisions and assisted dying.

Incidence and method of suicide
The current suicide rate in England is 10.5/10^5 population/year and is declining (Figure 54.1). This is in contrast to the worldwide picture of a 50 per cent increase in the incidence of suicide over the past five decades and projections that this will continue to rise. The current global
suicide rate is estimated to be $17/10^5$/year, and suicide accounts for 1 per cent of female deaths and 2 per cent of male deaths.\(^6\)

The highest suicide rates are found in Russia, Belarus and Lithuania ($36–42/10^5$/year) (Table 54.1).\(^7\) In the USA, the suicide rate varies by state; for example, in Washington, DC, it is $7/10^5$/year but in Nevada it is $23/10^5$/year (the national average is $11/10^5$/year).\(^8\) The differences in the suicide rates across European countries cannot be explained solely by sociocultural differences, and population genetics may be a relevant factor; for example, Hungary and Finland have populations with a common genetic origin and a high rate of suicide, but they differ greatly in their economic, cultural and political histories.\(^9\)

In England, the most common methods of suicide are hanging for men and drug poisoning for women (Table 54.2).\(^10\) The preferred methods of suicide appear to be influenced by the available means. There are four notable examples:

- **Coal gas**: until 1965, poisoning with domestic coal gas accounted for half of all suicides. Natural gas was introduced in 1965 and in the following years the suicide rate declined without any evidence of method substitution.\(^11\)
- **Firearms**: in North America, firearms are involved in 60 per cent of male suicides and 30 per cent of female suicides. States with the most restrictive gun laws have the fewest suicides involving firearms and lower suicide rates overall.\(^12\)
- **Vehicle exhaust**: in England, from 1993 onwards, it was required that new cars should be fitted with catalytic converters, which oxidize carbon monoxide (CO) to carbon dioxide (CO\(_2\)). Suicide by exhaust inhalation, once the most popular male method, declined by 90 per cent over the following decade.\(^13\) However, over the same period, there was an increase in male suicide by hanging, suggesting method substitution.\(^14\)
- **Analgesics**: from 1998, the size of packets of analgesics that could be sold over the counter at retail outlets was restricted by English law to 32 tablets. Subsequently, suicide deaths from paracetamol and salicylates reduced by 22 per cent.\(^15,16\)

The choice of method is influenced by sociodemographic factors. Jumping from high places is preferred by youths, compared with drowning, which is a choice of older people. In Asia, ingestion of pesticides in rural areas is common and self-immolation is commonly observed in Asian women.

### Sociodemographic factors associating with suicide

#### Gender

Annual suicide rates are higher for men than for women in all countries, except China, where the converse applies. In England, the male/female ratio is 3 : 1 (see Figure 54.1).
Womity ratios (PMR) show minimal class differences. An association between suicide rate and age. For example, in people has been lower (Figure 54.2). In elderly, but from 1998 the suicide rate in elderly is four times higher for men from social class V compared with those in social class I. However, proportional mortality ratios (PMR) show minimal class differences. An unemployed man has a two to three times greater probability of suicide than his employed counterparts (Figure 54.3).

Suicide rates are higher in certain professionals, such as veterinarians, dentists, pharmacists, doctors, salespeople, farmers, publicans, drivers and nurses. Access to means may be a relevant factor – for example, drugs for healthcare practitioners and pesticides and guns for farmers. Students are not at special risk of suicide.

Marital status and sexuality
Marital status shows a weak or inconsistent association with suicide. Among women, there are no statistically significant differentials in the risk of suicide by marital status categories. The relative risk (RR) of suicide is about 2 in divorced or separated men, but the association with bachelor or widower status is variable between studies. Young homosexual men and women are two to three times more likely to attempt suicide than other young people.

Ethnicity
The data on ethnic or racial group and suicide are inconsistent and hard to interpret. For example, the rate of suicide in minority ethnic groups is higher where such groups are in a small minority, but lower where they form a large minority of the population.

Temporal patterns
In both hemispheres, the rate of suicide in winter months is half that of the rest of the year, but such seasonal variations are now diminishing. Data from the UK and Japan indicate that 15 per cent more suicides occur on Mondays than on other days of the week. The cause or significance of these temporal associations is not known.

Criminality
A history of criminal or violent behaviour is associated with suicide. The SMR for suicide in prison inmates is 5, with a particular excess in boys aged 15–17 years (SMR 18). Ninety per cent of prisoner suicides are by hanging. A third of cases have a past psychiatric history and half have a history of parasuicide.

Intelligence
Gunnell and colleagues found that the level of performance on a logic test was inversely correlated with the suicide rate (Figure 54.4). In these Swedish male conscripts, the risk of suicide was three times higher in those with low, rather than high, logic test performance.

Psychobiology of suicide
Inheritance
A seminal study of the Old Order Amish community found that 26 suicides over a century occurred predominantly in four families in which mood disorder was also common. Other families with a similarly high prevalence of mood disorder did not contain any cases of suicide.
Roy and Segal examined the surviving twin of 28 twin pairs who had died by suicide. Four of 13 monozygotic (MZ) twins had attempted suicide compared with 0 of 15 dizygotic (DZ) twins.32 This finding is consistent with a previous study of 176 twin pairs in each of which at least 1 twin had committed suicide: in 9 of these twin pairs, both had committed suicide; of these 9, 7 were among 62 MZ pairs and 2 among 114 DZ pairs (P<0.01).33

After adjustment for psychological, psychiatric and social factors, the heritability of suicidal behaviours is estimated to be 30–50 per cent.34–36 However, many human behavioural traits have similar levels of heritability, for example extroversion.37,38

A number of genes have been proposed as candidates for transmission of suicidal propensities, but these associations are not replicated consistently (Table 54.3).39

### Neurobiology

Elevated plasma and urinary levels of cortisol, and decreased output of urinary homovanillic acid (HVA), have been found in patients who attempt suicide in comparison with non-suicidal patient controls.40–42

Many studies of 5-hydroxyindoleacetic acid (5-HIAA; a major metabolite of serotonin) in the cerebrospinal fluid (CSF) have produced convergent results, including:

- lower 5-HIAA levels in suicide attempters and completers than in controls;
- levels of CSF 5-HIAA are significantly lower in high-lethality compared with low-lethality attempters;
- low 5-HIAA also associates with greater impulsivity and likelihood of repetition;
- studies of the association between CSF 5-HIAA levels and the tryptophan hydroxylase (TPH) gene reveal that carriers of the 779C allele for the TPH gene are more likely to have low CSF 5-HIAA concentrations.44 Impulsive offenders with a suicidal history are also more likely to carry the 779C allele, suggesting a common link between low 5-HIAA, impulsivity and suicidality.45 The A218C polymorphism in intron 7 of the TPH gene does not show any association with suicidal behaviours.46

Other data implicating brain serotonin function in suicide include evidence of a blunted prolactin response to fenfluramine in suicide attempters, and reduced 5-hydroxytryptamine (5-HT) uptake, fewer serotonin transporter (5-HTT) sites, and increased density of 5-HT2A receptors in the platelets of suicide attempters.47–49

Findings from postmortem brain studies of suicide cases include:

- reduced binding sites for corticotropin-releasing hormone (CRH);50
- decreased presynaptic serotonergic binding sites;

• increased gene expression of 5-HT2A receptors;51
• an association between completed suicide and alter-
ations in both the phosphoinositide and adenyllyl
  cyclase/cyclic adenosine monophosphate (cAMP) sig-
  nalling systems;22,53
• decreased binding of [3H]phorbol dibutyrate to protein
  kinase C.54

Abnormalities have also been described in noradrenaline
function, for example fewer noradrenergic neurons in the
locus coerules of suicide cases, increased brainstem levels
of tyrosine hydroxylase and lower levels of postsynaptic
adrenergic receptors in the cortex.20

Notwithstanding the interesting nature of many of the
neurobiological findings, considerable caution must be
applied in interpreting them. A complete theory of how the
neurobiological associations might relate to psychological
functions and to the ultimate choice to kill oneself has yet
to emerge.

### Suicide and mental disorders

#### Overview
In Barralouhe and colleagues’ historic study of 100 cases
of suicide, the antemortem psychiatric state was considered
to be depression in 70 per cent of cases, alcoholism in 15
per cent, schizophrenia in 3 per cent, anxiety disorder in 3
per cent, other diagnoses in 2 per cent and ‘not mentally ill’
in 7 per cent.51 This study was pivotal in portraying suicide
as consequent on mental illness, and subsequent studies have produced convergent findings (Table 54.4).56–59

**Table 54.4** Diagnoses in cases of completed suicide

Bipolar disorder

The annual incidence of suicide in people with bipolar dis-
order is about 0.15 per cent, with a case fatality index (CFI;
the percentage of patients who end life by suicide) of 3 per
cent over 20 years.60 Suicide attempts occur at a rate of 1
per cent per year. The lifetime rate for suicide attempts is 52
per cent versus 26 per cent, respectively, for patients with
and without a family history of suicide.61

#### Schizophrenia

Estimates of the CFI in schizophrenia based upon individual
studies of up to 22 years’ follow-up range from 2 per cent to
30 per cent. A meta-analysis found a CFI of 5.6 per cent,
with a preponderance of suicide occurring early in the
course of the disorder.62 The SMR for suicide in schizophre-
nia is about 12.53 The associations of suicide within schizo-
phrenia (i.e. comparing living people with schizophrenia
versus people with schizophrenia who died by suicide) are
summarized in Table 54.5.64 The associations of suicide
within schizophrenia are different from those that apply in
the general population. For example, family history of
suicide, alcohol misuse, gender and living alone show a
weak or absent association in schizophrenia in contrast to
suicides generally.

Source: Hawton et al. (2009).64

Depression

In an epidemiological study of depressed cases, Simon and
VonKorff found that the standardized incidence rate for sui-
cide in depression was related to greater severity and mor-
bidity: 224 suicides/10^5 person-years in ever-hospitalized
patients, 43/10^5 person-years in general practice (GP) cases,
and 0/10^5 person-years in cases not judged to be in need of
antidepressants. Thus, alarmist assertions that ‘up to 15 per cent of patients with unipolar depression eventually commit suicide’ apply only to an extremely ill minority of patients with depression.

**Alcohol use**

Suicide occurs in 2–3 per cent of patients with hospital-treated alcoholism. This represents an SMR of 60–120 times the risk of suicide compared with those without psychiatric illness in the general population. Co-morbid alcohol misuse is found in 20 per cent of all suicides. Heavier drinking (≥414 g/week = 52 units/week) is associated with a RR of 2.3 for suicide compared with occasional drinkers. Alcohol abstainers also have a RR of 2.3 for suicide compared with occasional drinkers. This may be because former alcoholics are a part of the group of current abstainers.

**Cannabis**

Beautrais and colleagues concluded that much of the association between cannabis misuse and suicide attempts arises because cannabis misusers tend to come from disadvantaged backgrounds and have co-morbid mental disorders. Nevertheless, cannabis misuse may make an independent contribution to risk of suicide attempts.

**Personality disorders**

There is an unequivocal association between personality and suicidal behaviour, most evident in young people and in people with cluster B personality disorders. Seventeen per cent of adolescent suicides meet criteria for conduct disorder or antisocial personality disorder (APD). People with borderline personality disorder represent 9–33 per cent of all suicides, and the CFI is 3–10 per cent. The RR of suicide in APD is about 9 and the CFI is 5 per cent.

There is a strong association between an adult’s suicidal propensities and having experienced brutality, humiliation and abuse in childhood. A person’s upbringing shapes their adult personality, and Harlow’s experiments on primates remain an easily understood analogue for the effects of abuse and deprivation on human personality adjustment.

**Other clinical groups**

The suicide rate in admitted psychiatric patients is 13 per 10 000 admissions, equal in males and females. This implies a RR of 100–200 compared with the population base rate. Three-quarters of these suicides occur while the patient is on leave from hospital. The most common method is drowning (30%). Hanging, being hit by a train, jumping and self-poisoning each account for 10–15 per cent of cases. The peaks of suicide in relation to hospitalization are in the first week after admission and the first week after discharge. Seven in 10 000 patients kill themselves within 28 days of discharge from psychiatric hospital.

The RR of suicide in the postnatal period is low (SMR 1.14), and suicide is a leading cause of maternal deaths in this period only because other causes of death are even rarer. However, suicide occurs in 1 in 500 cases of postnatal psychosis, and in these cases the utmost clinical vigilance is required.

**Treatment factors**

Some medicines may be pro-suicidal and others anti-suicidal.

**Antidepressants**

The current balance of evidence regarding the pro-suicidal effects of selective serotonin reuptake inhibitors (SSRIs) is as follows:

- In adults aged 19–64 years, SSRI use is not associated with suicide attempts or suicide deaths (odds ratio (OR) about 0.85).
- In children and young people aged 6–18 years, SSRI use is associated with suicide attempts (OR = 1.52) and suicide deaths (OR = 15.62; 95% confidence interval (CI) 1.65 to infinity).
- In elderly people, there is an association between violent suicide and SSRIs (OR = 4.8), but not with other antidepressants.

**Atomoxetine**

Six suicide-related events, but no actual suicides, were identified in 1357 paediatric patients with attention deficit hyperactivity disorder (ADHD) receiving atomoxetine, while no events were seen in the 851 patients taking placebo.

**Anti-epileptics**

In clinical trials of anti-epileptics, the rate of suicide was 4/28 000 in subjects receiving anti-epileptics and 0/16 000 on placebo. Emergent suicidal ideation occurred in 105 and 35 subjects, respectively. Epilepsy itself confers a three-fold increase in the probability for suicide over the population base rate.

**Other agents**

The British National Formulary (BNF) lists suicide attempts as a side effect of interferon-beta and systemic corticosteroids, suicide risk as a contraindication to disulfiram, and suicidal ideation as a caution in the use of the CB1 inverse agonist rimonabant. A supposed association between isotretinoin and suicide is not supported by the available data.

**Lithium**

The current data support the view that lithium is specifically anti-suicidal in comparison with placebo and other mood stabilizers in bipolar disorder, and its use would be associated with 50 per cent fewer suicides than might otherwise be the case.
**Clozapine**

Clozapine may be anti-suicidal in schizophrenia. Over 2 years, 7 per cent of clozapine-treated patients attempted suicide compared with 11 per cent of patients taking olanzapine. There was no significant difference in the frequency of completed suicide (5 clozapine-treated patients vs. 3 olanzapine-treated patients; \( P = 0.73 \)).

**Suicide prevention**

Approaches to suicide prevention can be grouped as follows:

- **Whole-population strategies:** at a whole-population level, suicide rates are probably amenable to influence. Proposed approaches include improving social welfare (e.g. employment, housing), school and workplace mental-health promotion, public education, action on alcohol and drugs, and controlling access to means of suicide (e.g. plastic-bag design, firearms).

- **High-risk subgroups strategies:** approaches to high-risk subgroups include providing counselling services for socially dislocated young males, offering assistance for children leaving care, improving the assessment of parasuicide cases in accident and emergency departments, and improving the recognition of depression in GP populations. The Gotland Study demonstrated that educating GPs in the treatment of depression reduced that island’s suicide rate, although some authors have disputed the generalizability of the findings.

- **Mental health services:** substantial investment in National Health Service (NHS) mental health services in England has been accompanied by changes in service delivery aimed in part at reducing suicide rates. Initiatives include crisis intervention teams, 24-h access to services, and removing ligature points from in-patient environments. The unifying theme is that by effecting overall improvements in mental health services, fewer suicides will occur.

- **Case-by-case intervention:** the optimistic account of suicide prevention at a policy level appears discordant with the views of many clinical practitioners that suicide is hardly preventable in an individual patient. Such latter views are not irrational. Obtaining even minimal sensitivity (i.e. true positives) in predicting suicide is at the expense of an overwhelming number of false-positive predictions, for example a ratio of about 1:50 reported by Powell and colleagues. Nonetheless, clinicians will reasonably strive to minimize the potential for suicide in their patients. A conventional account is to view the relevant risk factors as (i) static, (ii) stable, (iii) dynamic and (iv) future. Although the format provides no calculus of risk (e.g. if a person got married but lost their job, would there be a net increase or net decrease in their suicide potential?), it is nevertheless a suitable one for articulating the evaluation of a patient. However, whether any specific clinical action with any individual patient at any particular point in time alters the overall trajectory of that patient towards, or away from, suicide, is very hard to test empirically (Table 54.6).

An aim of the National Suicide Prevention Strategy for England was to achieve a 15 per cent reduction in the rate of suicide by 2010. Key points from this strategy and other related documents are summarized in Box 54.2.

**PARASUICIDE**

**Definition and terminology**

There is no completely satisfactory terminology covering the behaviours of people who injure or poison themselves

with a non-fatal outcome. Various terms that are commonly used to describe these are set out in Box 54.3. Kreitman and colleagues rejected the term ‘attempted suicide’ on the grounds that the great majority of patients so designated were not, in fact, attempting suicide. Instead, the term ‘parasuicide’ was proposed to represent ‘an act which is like suicide, yet is something other than suicide’. The definition adopted by the World Health Organization (WHO)/EURO Multicentre Study on Parasuicide was:

An act with non-fatal outcome in which an individual deliberately initiates a non-habitual behavior, that without intervention from others will cause self-harm, or deliberately ingests a substance in excess of the prescribed or generally recognized dosage, and which is aimed at realizing changes that the person desires via the actual or expected physical consequences.

It may be that standardization of the terminology can never be achieved because the cases being referred to are diverse with respect to both the intention behind the act and the degree of medical seriousness that results. Thus, clinically, the preferred term will be the one that best describes the patient under consideration at the time.

### Epidemiology

#### Incidence

The person-based incidence of parasuicide is approximately 170/10^5 population/year in Europe, with regional averages concealing local variations, for example Cergy-Pontoise (France) – 440/10^5/year, Guipuzcoa (Spain) – 60/10^5/year. In the USA and Canada, the figures are 225/10^5/year and 304/10^5/year, respectively.

---

**Box 54.2 Governmental recommendations for suicide prevention**

**STRATEGIES FOR SUICIDE PREVENTION (1999–2002)**

- Staff training in the management of risk
- Highest level of care programme approach (CPA) for in-patients with severe mental illness and self-harm
- Care plans to specify to deal with non-compliance with pharmacotherapy
- Prompt access to services for people in crisis and their families
- Assertive outreach teams
- Promote use of atypical antipsychotic drugs
- Special services for co-morbid substance misuse with mental illness
- In-patient wards to remove or cover all likely ligature points
- 7-day follow-up of discharged in-patients
- Prescribe only small quantities of medication to patients who self-harm
- Post-incident case reviews.

**NATIONAL INSTITUTE FOR HEALTH AND CLINICAL EXCELLENCE (2004)**

- Assessment of needs and risks
- Sharing the written assessment with the service user
- Including social, psychological and motivational factors specific to the act in the assessment of self-harm
- Using a standardized risk assessment scale to identify patients at high risk of repetition of self-harm or suicide but not to use it to identify patients at low risk who are not then offered services
- Providing the service user with relevant written information about treatments and services.

**MEASURES TO REDUCE SUICIDES (2006)**

- Improved observation and physical environment in psychiatric wards
- Strengthen the transition from ward to community.

---

**Box 54.3 Commonly applied terms to describe the behaviours of people who injure or poison themselves with a non-fatal outcome**

- Self-harm
- Deliberate self-harm
- Intentional self-harm
- Parasuicide
- Attempted suicide
- Failed suicide
- Non-fatal suicidal behaviour
- Self-inflicted violence
- Self-poisoning
- Self-injury
- Self-mutilation.
England, in the uppermost quartile for Europe, has a presentation rate of parasuicide of above 300/10^5/year and an admission rate of about 130/10^5/year. Within England, adjacent postal districts show up to a seven-fold difference in the rate of parasuicide. In England, as elsewhere, there is an association with social deprivation and average income; the rate of parasuicide in the most disadvantaged quintile of the population is three to four times that of the least disadvantaged quintile.\(^{104,105}\)

### Changes over time

In England, rates of parasuicide increased in the 1960s and 1970s and have thereafter fluctuated in the range 250–350/10^5/year (Figure 54.5). Data from both Belgian and English studies found an increasing rate of parasuicide among young males (aged 15–42 years) in the 1980s to 1990s, but this increase has not been sustained.\(^{106}\)

### Age and gender

People aged 15–24 years account for 40 per cent of cases, 25- to 34-year-olds for 25 per cent of cases, 35- to 44-year-olds for 15 per cent of cases, 45- to 54-year-olds for 10 per cent of cases, and people aged 55 years and older for 10 per cent of cases.\(^{107,108}\) Some 60 per cent of parasuicide cases are females.

### Method

Self-poisoning accounts for 80–90 per cent of presentations. Paracetamol is employed in some 40 per cent of overdoses, antidepressants (mainly SSRIs) in 30 per cent, minor tranquillizers in 20 per cent, non-opiate analgesics other than paracetamol in 10 per cent, and other diverse substances in 30 per cent; overdoses commonly involve more than one substance, and hence the sum is greater than 100 per cent. Self-injury accounts for 10–15 per cent of presentations; of these, three-quarters involve cutting to the arm or wrist.\(^{109}\)

### Non-clinical populations

Klonsky and colleagues found that 4 per cent of young male and female air force recruits engaged in recurrent self-harm.\(^{110}\) In this population, a history of self-harm was correlated with features of nearly all the Diagnostic and Statistical Manual, 4th edition (DSM-IV) personality types, schizotypal, borderline, dependent and avoidant in particular. In the general population, 3–5 per cent of people have had some degree of suicidal thinking in the past year and 1 per cent in the past week.\(^{111,112}\)

### Psychosocial factors

#### Diagnostic associations

Some 30–70 per cent of people who present with parasuicide are depressed at the point of presentation. Around the time of parasuicide, the average score on the Montgomery Åsberg Depression Rating Scale is 25 points.\(^{108,113–115}\) However, using the Personality Assessment Schedule,\(^{116}\) Haw and colleagues found that 46 per cent of cases have personality disorder and an additional 33 per cent have ‘accentuated personality traits’.\(^{108}\) This observation, and the fact that a quarter of cases exhibit harmful use of alcohol, suggests that the concept of ‘depression’ in this group is a broad one. Diagnoses of distinct and severe mental illness (e.g. bipolar disorder, schizophrenia) are found in no more than 5 per cent of parasuicide cases.\(^{108,113}\) Anxiety, stress-related and somatoform disorders are found in approximately 25 per cent of cases and eating disorders in 10 per cent. A single-term diagnosis is an inadequate characterization of most parasuicide cases who commonly exhibit multiple and overlapping psychopathologies.

#### Personality genetics

Many studies have described strong associations between personality traits and parasuicide. These traits include aggression, anxiety, neuroticism, impulsivity, hostility and psychoticism.\(^{117}\) Personality traits are influenced by genetics and polymorphisms coding for the serotonin transporter, 5-HT1A, 5-HT2A, 5-HT1B and 5-HT3B receptors, have been variously associated with traits such as neuroticism, anger and impulsivity. These same polymorphisms have also shown an association with suicidal thoughts and behaviour.\(^{117,118}\) It is plausible that the effect of ‘parasuicide genes’ is mediated through an intermediate effect on personality.

### Social problems

Common clinical experience is that there has usually been some emotional problem preceding parasuicide. Hawton and colleagues found these problems to be with partners (in 50% of cases), family members (40%), employment (30%) and finances (20%).\(^{109}\) Alcohol had been consumed in the 6 h preceding parasuicide by 45 per cent of women and 56 per cent of men.
Problem-solving
One tenable psychological model of parasuicide proposes that what such cases have in common are deficient strategies for problem-solving; for example, having a passive rather than an active response to problems and perceiving the negative outcomes as more likely than possible positive outcomes. Thus, ‘hopelessness’, historically given great emphasis as a mediating variable in suicidal behaviour, may have a complex relationship with other variables such as deficient problem-solving, cognitive rigidity and dichotomous thinking.101

Assessment
Repetition or progression
In clinical populations, 16 per cent of parasuicide cases repeat self-harm within 6 months and 25 per cent over 10 years.119–123 Completed suicide occurs in 1–2 per cent of cases in the first year after parasuicide and in 3–7 per cent over 10 years.119–123 In the most disturbed cases (e.g. people with schizophrenia or severe borderline personality disorder), completed suicide occurs in 10–15 per cent over 10–20 years.124

Assessment
In England it is NHS policy that all patients presenting with parasuicide should be subject to an assessment by a suitably skilled professional.98,125 The content of such an assessment has been described in various ways, but for the psychiatrist it amounts to obtaining a full psychiatric history and mental state examination, leading to a working diagnosis or formulation as a basis for further action.

It is conventional when assessing parasuicide cases to take account of risk factors for repetition and subsequent progression to completed suicide. The factors mentioned in the National Institute of Health and Clinical Excellence (NICE) Clinical guideline 16 (Table 54.7) are those most commonly cited.98

However, the limitations of the conventional account of risk factors are readily apparent. For example, the weight that should be accorded to particular features is undefined, many features are matters of degree rather than category, and co-linear relationships between certain items would be expected. Thus, although it is easy to say what factors should be taken into account, meaningful proposals about how they should be taken into account have yet to be made.

Screening
It might be that structured screening and assessment instruments would offer some assistance, but the findings are not encouraging. A meta-analysis of the Beck Hopelessness Scale (BHS) found a sensitivity of 80 per cent and a specificity of 40 per cent for detecting completed suicide.126,127 In a typical clinical environment, this would yield a positive predictive value (PPV) of little more than 1 per cent. Furthermore, with the Suicide Intent Scale (SIS),128 there have been counterintuitive findings; for example, among male patients, 12.4 per cent of those with high SIS scores harmed themselves again within 12 months compared with 22.3 per cent of those with low SIS scores ($\chi^2 = 18.26$, $P<0.0001$).129 Although the BHS, SIS or SAD PERSONS scales may aid the clinician in the process of assessment, they do not form a valid basis for clinical decisions.130

Mental capacity
It is common for people presenting with parasuicide to be uncooperative with assessment and to discharge themselves prematurely from accident and emergency (A&E)

Management following parasuicide

Where a presentation with parasuicide reveals a distinct psychiatric diagnosis, then the management will be that of the condition in question. It is more difficult to decide on the appropriate attention for the broader group of parasuicide cases characterized by marginal depressive symptoms, situational problems, aberrant personality features and an absence of distinct mental illness. Psychiatric admission is seldom productive, and compliance with out-patient or community follow-up is poor even when waiting times are minimal.132

Studies of psychosocial or psychotherapeutic interventions aimed at reducing the repetition rate for self-harm have produced inconclusive results.133 The POMPACT study compared brief, manual-assisted cognitive–behavioural therapy (CBT) with treatment-as-usual (TAU) in 400 people.114 The 12-month repetition rate did not differ between CBT and TAU (39% v. 46%, P = 0.20). Conversely, Guthrie and colleagues found that brief psychodynamic therapy was associated with a reduced recurrence of self-harm compared with TAU (9% v. 28%, n = 119, P = 0.015).134 Dialectical behaviour therapy (DBT) is commonly cited as being of special benefit for prevention of repeated parasuicide.115 The repetition rate at 1 year was found to be 59 per cent for DBT versus 95 per cent for usual psychotherapy (n = 50, P < 0.01). Tarrier and colleagues concluded that, although many studies produce favourable results, optimism is tempered by evidence of publication bias.136

Providing patients with contact cards permitting on-demand access to care has not been shown to have an effect on repetition rate (3 studies; n = 1144, RR = 0.79, 95% CI 0.39 to 1.57).137–139

It is doubtful whether pharmacotherapy has a role in the management of repeated parasuicide. Montgomery and colleagues demonstrated a clinically significant effect of low-dose (20 mg) depot flupentixol in reducing repetition of self-harm.140 A study versus placebo showed equivocal benefit for paroxetine on the repetition of self-harm over 1 year (n = 91, 47% v. 33%, P = 0.12).141 Studies specifically in borderline personality disorder (taking these to be likely cases for parasuicide) have shown benefits for patients taking olanzapine but not ziprasidone on psychopathology.141–143

On balance, although there are sufficient data to support the use of pharmacotherapy where a clinician feels so inclined, general recommendations cannot be made.

Ultimately, there is no management of parasuicide per se because parasuicide is a behaviour rather than a disease or disorder and marks the presence of many social, psychological, personality and psychiatric dysfunctions. Until such time as there are major research advances, management remains a matter of clinical judgement on a case-by-case basis.

CONCLUSION

The biomedical literature on suicide emphasizes the search for deterministic causes of suicide, but the most that can be said at present is that it is multifactorial. There are many philosophical and ethical questions that could be raised. For example, can suicide be considered a choice that people make? If so, is it rational or irrational, and what standard of rationality would apply? How is it that deaths by suicide become referred to as ‘tragedies’ but deaths by motor vehicle as ‘accidents’? Such questions, although beyond the scope of this text, invite considerable reflection.

KEY POINTS

- In England, the current annual suicide rate is about 10.5/10^5 population and the parasuicide rate is about 300/10^5/year.
- Although many social, clinical and biological associations have been identified, a satisfactory explanatory model of suicide has yet to be proposed.
- Population-based or public health measures to reduce suicide can be effective.
- The ability of clinicians to predict suicide in individual clinical cases is minimal.
- Suicide and parasuicide cases differ substantially in their clinical and sociodemographic characteristics.
- Mental illness is common in cases of suicide but uncommon in cases of parasuicide.
- The essence of assessing a parasuicide case is to take the psychiatric history and examine the mental state, from which formulation and management will follow.
- The evidence that psychotherapies reduce the repetition rates for parasuicide is inconclusive.

INTRODUCTION

In this chapter we primarily discuss emergencies in psychiatry that fall into the following areas: acute behavioural disturbances; acute alcohol withdrawal; and medication-induced psychiatric emergencies. Other psychiatric emergencies are dealt with elsewhere in this book. A comprehensive account of practical details on cardiopulmonary resuscitation is to be found in Puri and Treasaden.¹

GENERAL POINTS

It is useful to bear in mind the following general points when dealing with emergencies in psychiatry:¹

● Ensure your own safety as well as that of the staff and, indeed, the patient.
● Always consider an organic cause and manage this.
● Patient confidentiality is not absolute. (For example, in the UK, the General Medical Council (GMC) accepts that doctors can reveal information if there is an immediate grave risk to the patient or others.)
● Always seek corroborative information, e.g. previous medical records, third-party information.
● Consult senior colleagues and other members of a multi-disciplinary team, with whom you can also share responsibility for difficult decisions.
● Maintain good contemporaneous records of assessment and management decisions.
● ‘If it’s not recorded, it didn’t happen’ is a good precautionary principle.
● At the least, records are evidence of what may have happened, but in reviews, enquiries and, indeed, courts, doctors will always have the opportunity to expand on their records.

ACUTE BEHAVIOURAL DISTURBANCES

It is important to ensure that adequate numbers of appropriate staff are present to manage the situation. If necessary, police assistance should be sought, including helping to disarm the patient. Rocca and colleagues have suggested that the initial behavioural and environmental interventions shown in Box 55.1 should be considered.²

Before physical interventions are considered, an attempt to verbally talk down an aggressive or otherwise behaviourally disturbed patient should be made. Approaches on how to do this are detailed in Box 55.2, while Box 55.3 describes guidance on how to manage the patient–therapist interaction.³ Sufficient time should be given to allow the patient to be verbally talked down in spite of the fact that in an acute situation there is often staff pressure to resolve the situation by restraint and medication.

Box 55.1 Behavioural and environmental interventions

- Use a room or an area big and calm enough, and not isolated, to allow others to come quickly if help is needed.
- You and the patient should be in such a position to allow both of you to easily reach the door, which must be open.
- Choose an environment as calm as possible and without intense stimulations or triggers.
- The environment must be safe, without objects that can be potentially dangerous.
- If a suitable room is not available choose an open space.
- Keep distance: do not be too close. The violent patient needs more room than others. Never approach the patient from behind or in a rough manner.
- Never turn your back to the patient.
- Do not be confrontational, and do not look the patient in the eyes. Try to assume a neutral facial expression and voice tone, and a relaxed body posture. Try to avoid positions with crossed arms or hands behind the back.
- The patient should not be left alone.
- If others represent a trigger for the patient’s violence, ask them to leave the area.
- Give information and support to relatives and significant others.
- Perform a debriefing with the staff and, if possible, also with the patient.

Reproduced from Rocca et al²
Acute behavioural disturbances

Ryan and colleagues, for the Royal College of Psychiatrists, have put forward practical guidelines for the use of sedative medication in emergency situations. Guidelines for non-elderly adults are shown in Figure 55.1, while Figure 55.2 gives guidelines for elderly people. These guidelines also give an example of a monitoring schedule to be used after administering an injection (Box 55.4). One should always be familiar with the local policies and

---

**Box 55.2 Verbal approach**

- Introduce yourself and explain what you are going to do.
- Use easy words, short and clear sentences, and a calm manner.
- Use a confidential but formal tone.
- Help the patient to understand what is happening and reassure him or her about the diagnostic and therapeutic procedures to be undertaken.
- Help the patient to restore their orientation.
- Use, at least at the beginning, alliance-oriented questions and wait before querying delicate issues.
- When possible, try to talk about the real motivations of the violence.
- Set limits of acceptable behavior and tell the patient that violations will not be allowed.
- Encourage the verbal expression of feelings, states of mind and fantasies.
- Discourage acting out. Make it clear that the patient will be held responsible for his or her actions.
- When you have to communicate your decision, do it in a clear and simple way.

Reproduced from Rocca et al.²

**Box 55.3 Patient–therapist relationship variables**

- Try to make procedures as flexible as possible.
- If possible, prioritize the patient’s requests.
- Show empathy and talk about the negative aspects of the present situation (‘I understand that this is not a good period for you; it seems to me that you feel bad — you look afraid of something’).
- Engage a therapeutic alliance (‘in such a difficult situation you need help; allow me to help you’).
- Don’t lie or betray the patient’s trust.
- Do not challenge the patient; do not be confrontational; do not look the patient in the eyes.
- Offer your help to discuss therapeutic aspects of mental disorder.
- Give help for problem-solving, especially with low copers. Give alternatives to violent behaviour.
- Evaluate the presence of acute and chronic stressors, especially if active, as violence triggers are related to past violence and victimization.
- Give reassurance for present or past paranoid features.
- Be careful with gender issues.
- If needed, give the patient an opportunity for time out, offer food and drinks, and if desired and possible allow the patient to smoke a cigarette or to make a phone call.

Reproduced from Rocca et al.²

---

**Figure 55.1** Royal College of Psychiatrists’ sedation guidelines for non-elderly adults

BNF, British National Formulary; IM, intramuscular; IV, intravenous; PRN, when required.
These guidelines apply where a frail patient over 65 years of age is behaving in a disturbed or violent manner that is unusual for him or her and that cannot be modified by interventions already in their care-plan. For physically fit patients and those currently or previously treated with higher doses of antipsychotics, the protocol for younger adults may be more appropriate. Details of the clinical situation and all interventions must be recorded in the patient's medical notes.

**Emergency resuscitation equipment, procyclidine injection and flumazenil injection must be available before treatment**

Medication should be the last resort in older people. If required, medication must be used cautiously and only by the oral route (except in very extreme emergencies – see lower panel). (Note the Mental Health Act 1983 status of the patient.)

Monitoring of the patient must be performed and recorded according to the further guidelines provided after any injection is given.

Procyclidine injection 2.5–5 mg can be given IV or IM for acute dystonic or parkinsonian reactions.

Flumazenil (a benzodiazepine antagonist) must be given if the respiratory rate falls to <10 breaths/min after lorazepam has been used (see panel below).

Give flumazenil 200 µg IV over 15 s. If desired level of consciousness is not obtained within 60 s, a further 100 µg can be injected and repeated at 60-s intervals to a maximum total dose of 1 mg (1000 µg) in 24 h (initial + 8 additional doses). Monitor respiration rate continuously until it returns to baseline level. N.B. The effect of flumazenil may wear off and respiratory depression return – monitoring must continue beyond initial recovery of respiration.

**Box 55.4 Example of a monitoring schedule from the Royal College of Psychiatrists**

After injections, this monitoring schedule must be followed, unless there are compelling reasons for doing otherwise, and must be recorded in all cases:

- Pulse and respiration as soon as possible after injection, then every 5 min for 1 hr.
- Temperature (using Tempadots) as soon as possible after injection as a baseline then at 5, 10, 15 and 60 min.
- Blood pressure at 30 and 60 min after injection.
- Monitor for signs of neurological reactions (e.g. acute dystonia, acute parkinsonism).

Reproduced from Ryan et al.3

**ACUTE ALCOHOL WITHDRAWAL**

Alcohol withdrawal can be considered not to be a psychiatric emergency in the sense that its primary management requires close liaison with a general medical team, who nowadays often undertake such treatment. Detoxification is the medical management of withdrawal symptomatology in individuals who have psychoactive substance dependence. It involves medication to reduce withdrawal symptomatology, close monitoring and nutritional supplementation. Alcohol withdrawal can arise as an emergency in general medical or surgical wards, for instance, or in police custody or prisons. Planned detoxification may be carried out on an in- or out-patient basis. The latter depends on the availability of adequate support. In-patient detoxification will be required if there is evidence of acute organic mental disorder, including delirium, significant co-morbid physical illness, seizures, and lack of available support in the community.

Benzodiazepines are used to ameliorate withdrawal symptomatology and to reduce the risk of seizures.
Chlordiazepoxide is often preferred in out-patient detoxification for its lower abuse potential, while diazepam is favoured for in-patient detoxification as it is faster-acting, allows for better dose titration and can be administered gradually. A benzodiazepine withdrawal regime is indicated where there are current symptoms or signs of withdrawal, a diagnosis of alcohol-dependent syndrome or a consumption of at least 10 units of alcohol daily over the previous fortnight. A possible out-patient reducing regime with chlordiazepoxide for a male adult is to commence with 90 mg (divided into three or four doses) on day 1, reducing to a total of 80 mg on day 2 (in four divided doses), a total of 50 mg on day 3, a total of 40 mg on day 4, and finally a total of 20 mg on day 5.

Benzodiazepines are usually sufficient as anticonvulsants in the above dosages, especially as other anticonvulsants do not reach therapeutic levels within this period of risk. Similarly, a benzodiazepine will usually control hallucinations or delusions that develop, but antipsychotic medication can be used if the benzodiazepine is insufficient. However, one should bear in mind that antipsychotics reduce the seizure threshold.

High-potency parenteral thiamine (vitamin B1) should be given if there is evidence of developing Wernicke-Korsakoff syndrome; in the UK, injections of Pabrinex® are generally used, which contain ascorbic acid, nicotinamide, pyridoxine, riboflavin and thiamine. In view of the fact that anaphylaxis has been reported with such treatment, facilities should be available for resuscitation. The parenteral treatment can be followed by a course of oral thiamine. Other psychotropic medications, such as those for associated anxiety or depression, should generally be avoided until such symptoms can be assessed in the absence of the effects of alcohol or its withdrawal.

MEDICATION-INDUCED EMERGENCIES

Acute dystonic reactions

Dystonic reactions can be painful and frightening and can occur on starting, increasing or withdrawing antipsychotic medication, particularly older typical drugs. They are more common in young men and are seen in approximately 10 per cent of patients exposed to older typical drugs (phenothiazines, butyrophenones).4

The most common features are torticollis, oculogyric crisis, tongue protrusion, grimacing and opisthotonos. Other features include retrocollis, dysarthria and dysphagia. Affected individuals may be unable to swallow or speak clearly and, in severe cases, the back may arch or the jaw dislocate.

The immediate treatment is parenteral antimuscarinic (anticholinergic) medication, such as procyclidine 5 mg intravenously or intramuscularly, or benztropine (benztpoine) 2 mg intravenously, which can be effective in minutes.

Subsequent management may include reduction in dose or changes in antipsychotic medication or oral antimuscarinic medication, for example procyclidine 5 mg every 8 h; note, however, that procyclidine, particularly at high doses, may produce euphoria and mydriasis and is associated with an abuse potential. Diazepam may also help but is less specific.

Oculogyric crisis

This acute dystonic reaction has become less common where newer atypical antipsychotics are used in preference to the older typical antipsychotics. After an initial phase of restlessness or agitation, during which the patient might develop a fixed stare, the full-blown oculogyric crisis characteristically manifests with arching of the neck and ocular involuntary movement superiorly and possibly laterally, although ocular convergence and downward movement may occur. The tongue may be protruded and the mouth opened widely. Rapid blinking, lacrimation, mutism or palilalia, and tachycardia may also occur.

Antipsychotic-induced oculogyric crises have been found to occur late in the day and at regular intervals, and to be associated with autonomic symptoms such as profuse sweating, facial flushing, transitory hypertension and difficulty in micturition; they have also been reported to be associated with transient psychiatric symptoms.5

Other medical causes of oculogyric crisis include:1

- post-encephalitic Parkinson’s disease;
- herpes encephalitis;
- juvenile Parkinson’s disease;
- non-antipsychotic psychotropic drugs, e.g. benzodiazepines, lithium salts, carbamazepine, tricyclic antidepressants, reserpine;
- other drugs, e.g. metoclopramide (a substituted benzamide), cisplatin, levodopa, nifedipine, chloroquine;
- influenza immunization;
- head injury;
- neurosyphilis;
- multiple sclerosis;
- Tourette’s (Gilles de la Tourette’s) syndrome;
- bilateral thalamic infarction;
- cystic glioma of the third ventricle;
- fourth-ventricle lesions.

In terms of management, it is important to review the current medication regime, particularly as it relates to the past 24 h. If the cause appears to be antipsychotic medication, then the patient should be reassured and an antimuscarinic drug administered parenterally. Regular oral antimuscarinic treatment may be needed in the short term.
Consideration may need to be given to changing the antipsychotic drug that caused the reaction.

In the absence of the patient receiving antipsychotic medication, a full history, careful perusal of the case notes, a physical examination and appropriate investigations may be required in order to detect other medical causes.

**Neuroleptic malignant syndrome**

This life-threatening medical emergency requires immediate treatment. Although neuroleptic malignant syndrome usually occurs with drugs that directly act on central dopaminergic systems, such as antipsychotic medication, it has also been reported with other drugs, including tricyclic antidepressants. Neuroleptic malignant syndrome is likely to be an idiosyncratic reaction; some patients have been cautiously re-challenged with the same agent without recurrence. High-potency typical antipsychotics such as haloperidol are more likely to cause the reaction.

The clinical features include the following:

- Autonomic dysfunction:
  - Hyperthermia
  - Labile blood pressure
  - Pallor
  - Sweating
  - Tachycardia
- Fluctuating level of consciousness (stupor)
- Muscular rigidity
- Urinary incontinence.

The condition may last for longer than a week after stopping the antipsychotic drug.

Characteristically, the serum creatine kinase is raised and there is a leucocytosis. Raised urinary myoglobin may also be detected.

Antipsychotic medication should be stopped immediately. The patient should be admitted as an in-patient to a medical ward, where maximal supportive care should be instituted. Sometimes dantrolene or bromocriptine (a dopamine agonist) may be required.

After recovery, the issue of reintroduction of the antipsychotic drug is likely to arise. A period of at least 2 weeks should elapse in the case of oral medication and a period of at least 6 weeks in the case of parenteral medication. The patient should be monitored carefully at this time for any signs of re-emergence of the syndrome before an attempt is made to reintroduce antipsychotic medication. It may be sensible to use a different, low-potency antipsychotic instead of the drug that was associated with the occurrence of neuroleptic malignant syndrome.

Complications such as respiratory, cardiovascular and renal failure contribute to an overall mortality of higher than 10 per cent.

**Clozapine**

Pharmacotherapy with clozapine may be associated with fatal agranulocytosis, fatal myocarditis and cardiomyopathy, fatal pulmonary embolism and life-threatening constipation.

Agranulocytosis occurs in around 3 per cent of patients on clozapine. All patients must receive regular haematological investigations to check for the development of neutropenia.

Fatal myocarditis is most common during the first 2 months of treatment. The UK Committee on Safety of Medicines has recommended the following:

- Take a physical examination and medical history before starting clozapine.
- The patient should have a specialist examination if cardiac abnormalities or history of heart disease are found. Clozapine should be initiated only in the absence of severe heart disease and if benefit outweighs risk.
- Persistent tachycardia, especially in the first 2 months, should prompt observation for other indicators for myocarditis or cardiomyopathy.
- If myocarditis or cardiomyopathy is suspected, clozapine should be stopped and the patient evaluated urgently by a cardiologist.
- Clozapine should be discontinued permanently if there is clozapine-induced myocarditis or cardiomyopathy.

Sudden clozapine withdrawal may be associated with rebound psychosis.

**Serotonin syndrome**

Serotonin syndrome may follow the administration of selective serotonin reuptake inhibitors (SSRIs) and also lithium salts and is characterized by:

- confusion;
- pyrexia and shivering;
- sweating;
- hyperreflexia;
- ataxia;
- myoclonus;
- akathisia;
- tremor;
- diarrhoea;
- poor coordination.
Cyproheptadine, which is an antihistaminic, antiserotonin and anticholinergic medication, has been used as a treatment.

Others

Lithium toxicity, paradoxical reactions to benzodiazepines, hyponatraemia associated with antidepressants, monoamine oxidase inhibitor (MAOI) reactions with tyramine-rich foods (the ‘cheese reaction’) and poisoning with psychotropic medication are discussed in Chapter 57.

KEY POINTS

- Ensuring the safety of staff and patients in psychiatric emergencies is paramount.
- Always consider the possibility of organic aetiology.
- Before physical interventions are considered, an attempt verbally to talk down an aggressive or otherwise behaviourally disturbed patient should be made.
- One should be familiar with local policies and procedures for the use of, and monitoring following, sedative medication to control behavioural disturbance.
- Following any serious untoward incident, it is useful to have a staff debriefing meeting, including learning any lessons.
- Benzodiazepines are usually sufficient on their own to ameliorate alcohol-withdrawal symptomatology and to reduce the risk of seizures.
- High-potency parenteral thiamine (vitamin B1) is usually given if there is evidence of developing Wernicke–Korsakoff syndrome, but this carries the risk of anaphylaxis.
- Oculogyric crises are painful and frightening; if the cause appears to be antipsychotic medication, then the patient should be reassured and an antimuscarinic drug administered parenterally.
- Neuroleptic malignant syndrome is a life-threatening medical emergency requiring immediate treatment and carries a mortality rate of over 10 per cent.
- Pharmacotherapy with clozapine may be associated with fatal agranulocytosis, fatal myocarditis and cardiomyopathy, fatal pulmonary embolism and life-threatening constipation.
PALLIATIVE CARE

The World Health Organization (WHO) has defined palliative care as:

The active holistic care of patients with advanced progressive illness. Management of pain and other symptoms and provision of psychological, social and spiritual care is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with other treatments.¹

Core principles of palliative care are:

- affirming life and regarding death as a normal process;
- neither hastening nor postponing death;
- providing relief from pain and other symptoms;
- integrating the psychological and spiritual aspects of care;
- offering a support system to help patients live as actively as possible until death;
- offering a support system to help the family cope during the patient’s illness and in their own bereavement.

The principles of palliative care should not be restricted to patients with cancer or to the last few days of life. Figures released by the Office of National Statistics show that in 2005 malignant neoplasm was reported as the cause of a quarter of all deaths; at least another quarter of patients died from a chronic progressive disorder such as heart failure, renal failure, chronic obstructive pulmonary disease or Parkinson’s disease. Alzheimer’s disease, senility and vascular and unspecified dementia account for 5 per cent of all deaths.² The time course of non-malignant illnesses is typically longer and death less predictable, but disability and the range of symptoms endured, both physical and psychological, are remarkably similar. In their comparison of symptom prevalence in advanced disease, Solano and colleagues reviewed 64 original studies to find that 10% of patients with cancer, acquired immunodeficiency syndrome (AIDS), heart disease, chronic obstructive pulmonary disease and renal disease.³ Patients with chronic lung disease and lung cancer have a comparable number of symptoms in the last year of life, although patients with chronic lung disease may have symptoms for longer and, perhaps surprisingly, experience more breathlessness.⁴ Similarly, patients with advanced renal failure have impaired quality of life and symptom burden at least as severe as terminal cancer patients.⁵ More than half of the patients admitted to hospital with heart disease complain of pain and dyspnoea, although only around a third have adequate treatment.⁶

Patients with non-malignant disease often have a stormy course towards the end of their life, with frequent relapses that may require hospital admission. Identifying the terminal phase of an illness such as heart failure can be difficult. Palliative care should be considered on the basis of the individual’s holistically assessed needs rather than prognosis. When deciding whether palliative care is appropriate for the patient with a chronic progressive disease, a useful question to ask oneself is ‘Would I be surprised if this patient were to die in the next 6–12 months?’⁷

The perception and severity of symptoms experienced at the end of life depend not only on the impact of the physical illness itself but also on the emotional state of the patient.

Pain

Pain is a subjective experience and, although the physical insult may determine the site of the pain, social, psychological and spiritual factors also influence the severity of the pain and the disability caused. The concept of ‘total pain’ was proposed by Cecily Saunders to acknowledge the multidimensional aspect of pain (Figure 56.1).⁸

Patients with cancer frequently believe, and fear, that they will experience pain at some point in their illness, but the reality is that a quarter of patients with cancer will have no pain.⁹ Conversely, pain in non-malignant disease is often overlooked and treated poorly.⁹ Staff in nursing homes judged pain to be significantly less in cognitively impaired residents compared with in cognitively intact residents; consequently, cognitively impaired patients received less analgesia.¹⁰ In patients unable to communicate, changes in behaviour, such as becoming agitated or
The analgesic ladder advocates the initial use of simple analgesia such as paracetamol or an NSAID with an adjuvant drug, depending on the cause of the pain. If this pain relief is insufficient, then a weak opioid such as codeine is added to the regime, or a strong opioid replaces the weak and the dose is titrated upwards until adequate pain relief is achieved. (See Table 56.1 for strong and weak opioids.) Wherever possible, analgesia should be given by mouth. Alternative routes of administration need to be considered if the patient is too unwell to swallow or is unable to keep medication down due to vomiting. The strong opioid of choice in the UK is morphine, which is available in both immediate- and modified-release preparations.

Other strong opioids commonly used for pain control include diamorphine, fentanyl, oxycodone and methadone. Fentanyl can be absorbed both transdermally (as a patch applied to the skin) and transmucosally (as a lozenge rubbed against the buccal mucosa). A strong opioid may be needed at any stage of the illness if the pain is severe and should not be withheld or given in an inadequate dose for fear of dependence. Opiate addiction is seen rarely in the clinical management of pain in patients with cancer. Adjuvant drugs often provide additional analgesic relief in difficult pain conditions such as neuropathic pain, despite their primary indication being other than pain. Examples include antidepressants (e.g. amitriptyline, doxepin (dothiepin)), anticonvulsants (e.g. carbamazepine, gabapentin), anti-arrhythmics (e.g. mexiletine, flecainide) and dexamethasone.

**Adverse effects of opioids**

Side effects may be seen when the opioid is initially taken in opioid-naive patients or when the dose is escalated rapidly. They include the following:

- Sedation
- Confusion and hallucinations
- Nausea and vomiting

NSAIDs, non-steroidal anti-inflammatory drugs.
- Constipation
- Dry mouth
- Myoclonus.

These side effects are common to all opioids, although some patients may tolerate one opioid better than another. Sedation and nausea often resolve within a few days, and it is worth warning patients of the side effects in order to encourage compliance. Nausea and vomiting can be controlled with anti-emetics such as metoclopramide or haloperidol. Constipation should be pre-empted and laxatives prescribed.

Opiate toxicity occurs when the intake of opioid exceeds the body’s ability to excrete the active metabolites, for example accumulation of morphine metabolites in renal failure. In such circumstances, a previously pain-controlled patient on a stable dose of morphine may present as confused, agitated and hallucinating, or with reduced conscious state and myoclonic jerks. If appropriate, decreasing the dose of morphine and rehydrating the patient reduces the active metabolites and may improve the toxicity. Switching to an alternative opioid or another route of administration may also reduce the side effects. Low-dose haloperidol (1.5–3 mg orally or subcutaneously) may be used in the interim to settle the agitation and hallucinations.

It is a great concern to many patients that they may have to give up driving while taking opioids, but this is generally not the case. A review of the psychomotor skills of patients taking long-term opioids concluded that the evidence supported no impairment of driving-related skills and that patients taking opioids were no more likely to be involved in motor accidents. Patients may be advised not to drive or operate machinery when opioids are first initiated or the dose is increased due to the risk of increased sedation. Once the sedation has resolved and the patient feels back to their usual level of alertness, they may resume driving.

The fear of addiction to opioids is also exaggerated. Very few patients with cancer and with pain, without a previous history of addiction, become addicted. This fear restricts adequate opioid prescribing by some physicians and reduces patient compliance. Some physical tolerance to the opioid may develop, although this does not result in the escalating need for opioids. Withdrawal symptoms such as diarrhoea, abdominal cramps, anxiety, sweating, hypersalivation and rhinorrhoea may occur if the opioid is stopped suddenly or an opioid antagonist such as naloxone is administered. For this reason, opioids should be reduced gradually after a successful intervention to reduce pain such as radiotherapy.

Bisphosphonates, both orally and intravenously, have been shown to relieve metastatic bone pain. Zoledronate 4 mg is given intravenously in 100 ml 0.9% saline over 15 min and repeated at 4- to 6-week intervals. The dose is reduced according to creatinine clearance. Daily oral calcium supplements are given to prevent hypercalcaemia. Common side effects from intravenous bisphosphonates include flu-like symptoms; more rarely, intravenous bisphosphonates have been linked with osteonecrosis of the jaw.

Palliative chemotherapy and radiotherapy can provide significant symptom relief, the latter being particularly useful for metastatic bone pain. Orthopaedic procedures such as bone-pinning, kyphoplasty and spinal stabilization can provide pain relief and maintain function. Neurolytic blocks with local anaesthetic and corticosteroid may provide local and regional pain relief; such techniques include spinal blockade, intercostal blocks and coeliac plexus blocks.

Non-drug methods such as heat pads, transcutaneous electrical nerve stimulation (TENS) and acupuncture may be helpful to some patients, particularly those who shun tablets. There is no strong evidence base to support the use of complementary therapies for pain relief, but anecdotally patients frequently report benefit from treatments such as aromatherapy massage, reiki and reflexology. Relaxation can significantly improve treatment-related symptoms such as nausea and pain in patients with cancer.

Pain occasionally fails to respond to analgesia, and at times it may be appropriate to return to the total pain model and consider the other factors that may be affecting the patient’s perception of the pain.

**Nausea and vomiting**

Nausea and vomiting are common and distressing symptoms often associated with anorexia and weight loss. The causes are multiple and may often be multifactorial. Some of the common causes include the following:

- **Gastrointestinal:**
  - Carcinoma of the stomach or head of pancreas causing gastric outlet obstruction
  - Gastritis
  - Infection
  - Bowel obstruction
  - Constipation
  - Radiotherapy

- **Drugs:**
  - Chemotherapy
  - Opioids

- **Metabolic:**
  - Uraemia
  - Hypercalcaemia of malignancy
  - Raised intracranial pressure
  - Anxiety, fear, severe pain.

Numerous anti-emetics are available, but the choice of a specific drug depends on the presumed cause of the vomiting; for example, nausea caused by constipation or hypercalcaemia would be best dealt with by treating the constipation with laxatives and the hypercalcaemia with a bisphosphonate. A prokinetic drug such as metoclopramide
10–20 mg three times a day may relieve the nausea due to gastric outlet obstruction but may aggravate colicky abdominal pain in bowel obstruction, where cyclizine 50 mg three times a day may be a better anti-emetic. The 5-HT3 receptor agonists ondansetron and granisetron provide good relief for the nausea induced by chemotherapy, while dopamine antagonists may relieve biochemical or drug-induced nausea by blocking the dopamine receptors at the chemoreceptor trigger zone. High-dose dexamethasone up to 16 mg per day may be given to reduce raised intracranial pressure. Anti-emetics can be given by mouth, but if vomiting is severe absorption can be unpredictable. In such instances, medication can be given subcutaneously.

**Breathlessness**

The unpleasant awareness of struggling to breathe is a symptom common to the advanced stage of many illnesses and occurs in up to 75 per cent of patients. Like pain and nausea, breathlessness can have many origins:

- **Lung disease:**
  - Chronic, e.g. chronic obstructive pulmonary disease (COPD)
  - Infection, e.g. pneumonia, pleurisy
  - Pulmonary embolus
  - Malignant, e.g. lung cancer, pulmonary metastases and mesothelioma, all of which may cause a malignant effusion
- **Cardiac:**
  - Acute left ventricular failure with lung congestion
  - Chronic heart failure
- **Anaemia**
- **Ascites:**
  - Splinting the diaphragm
- **Neuromuscular degeneration:**
  - Motor neuron disease
- **Treatment-induced:**
  - Pneumonectomy
  - Radiation- or chemotherapy-induced pneumonitis
- **Anxiety, panic and severe pain.**

Wherever possible, the underlying cause of breathlessness should be treated, namely antibiotics for pneumonia, furosemide for acute left ventricular failure, blood transfusion to correct anaemia, and paracentesis to drain ascites. If this is not possible or if breathlessness persists despite attempts to correct the cause, then the following drug and non-drug measures should be tried.

**Drug measures**

- Low-dose immediate-release opioids have been demonstrated to be beneficial for breathlessness associated with both malignant and non-malignant disease. A typical regime may initially start with oral morphine 2.5–5 mg as required, up to every 4 h, and titrating upwards until the desired effect is achieved. Sustained release preparations of morphine given to patients with COPD improved breathlessness and sleep.
- Low-dose benzodiazepines may be helpful for the anxious dyspnoeic patient. Benzodiazepines may enhance the benefit of opiates in relieving breathlessness. Benzodiazepines alone in the non-anxious patient may not improve the sensation of dyspnoea or improve exercise tolerance. For the anxious breathless patient, low-dose diazepam may be taken on a regular basis. Lorazepam 1 mg can be used sublingually for panic attacks and any remaining medication may be removed when the attack has subsided.
- Oxygen therapy via cylinders or concentrators may be helpful for a few patients, although care needs to be taken in patients with COPD, who rely on their hypoxia to drive ventilation. Appropriate assessment is important. For patients with mild hypoxia, non-drug measures may be more beneficial. In a small group of patients with COPD, Liss and Grant found no improvement in reported breathlessness with increasing inspired nasal oxygen concentration, but they did demonstrate an increase in breathlessness after anaesthetizing the nasal passages with topical lidocaine, which suggests that oxygen had a placebo effect.

**Non-drug measures**

- Reassurance
- For some patients, fans can be as effective as oxygen for symptom relief
- Breathing exercises and relaxation
- Repositioning.

**Psychological problems**

Much of the evidence for psychiatric disorders at the end of life comes from the adult cancer population. The prevalence of psychiatric morbidity in patients with cancer is high. Derogatis and colleagues assessed 215 patients with cancer and found that 44 per cent had a psychiatric diagnosis, of which 68 per cent had an adjustment disorder, 13 per cent a major affective disorder and 4 per cent anxiety disorders. In a systematic review of patients with advanced disease in a palliative care setting, a prevalence of definite depression ranged from 19 per cent to 34 per cent, with a prevalence of major depression ranging from 5 per cent to 26 per cent. Psychiatric disorder is poorly detected in patients with cancer, and only a minority of patients receive adequate treatment. Diagnosis of an affective disorder can be difficult due to the overlap of symptoms encountered in terminal illness and depression, such as pain, poor appetite, fatigue and poor concentration; the symptom ‘loss of interest’ may help to identify the depressed patient with cancer. Depressed patients with cancer exhibit more symptoms, particularly pain, insomni
and fatigue, than non-depressed patients and tend to rate their symptoms as more severe.\textsuperscript{14,15} Patients’ concerns about their illness are an indicator of psychological distress: those with four or more concerns (particularly concerns about sexuality, feeling upset or feeling different) had significantly more anxiety or depression.\textsuperscript{16,17}

After a diagnosis of a life-threatening illness, a patient will experience a range of emotions. Massie and Holland proposed a model of phases of normal adjustment.\textsuperscript{18} Phase 1, or the initial response, is characterized by disbelief and denial, which they suggest allows a ‘temporary emotional distancing’ from the crisis, for some the response may be one of despair. After a few days, the patient may enter second phase of dysphoria, where they may exhibit anxiety, depression and poor concentration. This phase may last a couple of weeks, before the third phase of adaptation is reached.

Elizabeth Kübler-Ross interviewed patients with cancer during the 1960s and identified five common stages through which patients may pass from diagnosis to death.\textsuperscript{39}

1 \textit{Denial}: a transient stage while the bad news sinks in. Some patients may use denial during later stages of their illness, for example when diagnosed with metastases. Denial is rarely maintained throughout the course of the illness but is a defence mechanism for some patients protecting them from distress.

2 \textit{Anger}: feelings of resentment and frustration may be directed in all directions, towards family and friends, healthcare professionals, God or the patient themselves. Family members may find these emotions difficult to cope with and require support themselves.

3 \textit{Bargaining}: patients may make promises with themselves, their doctors or God in order to maintain hope and extend life.

4 \textit{Depression}: when the impact of the diagnosis has subsided, the patient then has to face the losses, whether real or imaginary, ahead. It may be the loss of health and independence or the loss of role in society and among peers and family. There may also be the fear of disfigurement, abandonment and uncontrolled symptoms such as pain leading to despair and depression.

5 \textit{Acceptance}: patients may accept their impending death at varying stages in their illness. Some put their affairs in order, make peace with estranged family and friends, and arrange their funeral while still active; others, however, may appear to accept their fate only when fatigue increases and they are too weak to resist.

Some patients may not pass through Kübler-Ross’s five stages neatly, and instead may skip stages or oscillate back and forth; some patients may exhibit several stages at the same time. The five-stage model has been adapted by other authors acknowledging that the patient may have a mixture of reactions characteristic of the age and personality of the patient and the social context in which they find themselves, rather than the stage of dying.\textsuperscript{40}

Clinical staff may lack the skills and knowledge to recognize a normal reaction to a cancer diagnosis and to distinguish this from a psychiatric disorder, some even believing that the latter is inevitable in cancer.\textsuperscript{41} For staff with no specialist psychiatry training, screening tools for detecting psychiatric disorder may be valuable. The single question ‘Are you depressed?’ asked of a group of terminally ill North Americans correctly identified depressed patients,\textsuperscript{42} but the results were not repeated when the same question was asked of British patients.\textsuperscript{43} The Hospital Anxiety and Depression Scale (HADS) and Edinburgh Post–Natal Depression Scale (EPDS) have both been shown to be effective in screening for depression in a palliative population and acceptable to the patients.\textsuperscript{44} There has been little research into the use of antidepressants at the end of life, although review of the few studies available does suggest that antidepressants are effective.\textsuperscript{45,46} For some patients with a prognosis of a few weeks, the time for a therapeutic response to standard antidepressants may be unacceptable.

**Delirium**

Delirium is an acute confusional state associated with clouding of consciousness, in contrast to dementia where there is no drowsiness unless compounded by delirium. Delirium is often encountered at the end of life and frequently seen in patients with cancer. The patient may present as agitated, aggressive, confused and hallucinating, with a disrupted sleep–wake cycle (hyperactive), or they may be withdrawn, drowsy and confused (hypotactive). Hypoactive delirium can frequently be missed in patients and undertreated. There are many possible causes of delirium; the more common ones at the end of life include the following:

- Infection
- **Drugs:**
  - Opiates
  - Anticholinergics
  - Steroids
- **Metabolic:**
  - Encephalopathy secondary to liver or kidney failure
  - Hypercalcaemia
  - Hyponatraemia
- **Withdrawal states:**
  - Alcohol
  - Nicotine

Delirium is very distressing for both the patient and their family, and early identification is important. Reversible causes should be corrected if possible, and the patient should be nursed in a calm, non-confrontational environment. The patient should be communicated with clearly, using and often repeating simple explanations. Low lighting at night can help to reduce misinterpretation of objects or people around the patient. Centrally acting drugs thought to be causing delirium should be reduced or
stopped. Low-dose haloperidol 1.5–3 mg at night may be effective for the distressed, agitated or withdrawn patient.

Delirium at the end of life is frequently referred to as ‘terminal agitation’. It is irreversible and often multifactorial, although due to the inappropriateness of investigations at the end of life specific causes are commonly not identified. Speculated factors include biochemical derangement and dehydration, multi-organ failure with accumulation of metabolites and drugs, direct metastatic or paraneoplastic effects, hypoxia and possibly spiritual distress.

**Dying**

The dying phase is all too commonly unrecognized in the acute hospital, especially by junior staff. As end-of-life care becomes increasing medicalized, there is a danger that death too is becoming medicalized, with patients being subjected to futile treatments. There is considerable debate as to what makes a ‘good death’, although there are some consistent themes.  

- Maintaining dignity
- Physical comfort and without emotional distress
- Being with family and loved ones
- Dying in one’s place of choice
- Awareness of death and acceptance of death.

In order to help a patient achieve a ‘good death’, the recognition of impending death is important. Functional decline at the end of life is very variable and may depend on age and the disease. Patients dying of a sudden, unexpected death may have been very active and independent in the previous months. Patients with cancer have a gradual deterioration in functional status in the last 3 months of life. Patients with chronic disease such as lung or heart failure have a fluctuating course with acute exacerbations, but they may have frequent hospital admissions and become more dependent in their final 3 months. As death approaches and the patient becomes more fatigued, there are several features that indicate that death may be only days away:

- Poor oral intake and struggling to take more than sips of fluid
- Difficulty swallowing tablets
- Profound weakness
- Bed-bound
- Semi-comatose.

Ellershaw and colleagues recognized that a majority of patients were dying in the acute hospital setting and developed a multidisciplinary care pathway to help identify the dying patient and promote a good death. The Liverpool Care Pathway (LCP) aims to improve dying by promoting review of symptoms, psychological and spiritual issues, and prompting good communication between professionals and family members. It reminds staff to review existing medication and discontinue unnecessary medical interventions while prescribing anticipatory drugs for the patient’s comfort. Anticipatory drugs are prescribed subcutaneously for ease of administration and may include the following:

- Morphine or diamorphine for pain
- Anti-emetics such as cyclizine or haloperidol
- Hyoscine butylbromide for noisy respiratory tract secretions
- Midazolam for agitation.

The dose of opiates or benzodiazepines will often depend on whether the patient has been on regular doses before. Advice can be obtained from the local specialist palliative care team. If the patient requires frequent doses of medication, it can be given by continuous subcutaneous infusion via a syringe driver over a 24-h period.

Personal experience of the death of a loved one can have a profound and lasting effect on the individual. A ‘good death’ does not diminish the pain of the loss but may help that individual through their own bereavement period and when facing their own mortality.

**BEREAVEMENT**

Grief is a normal response to loss and will be experienced by most people at some point in their lives. It has a recognized aetiology and phases, but in any individual its course is very personal and influenced by age, social and cultural factors.

Bereavement is well known to be a causal factor in a number of psychiatric conditions. Grief may also coexist with anxiety states or depression, and differentiation is important if unnecessary suffering is to be prevented. Psychiatrists may be asked to supervise bereavement counsellors when knowledge of complicated grief and its management may be needed. Bereavement, however, is not always a negative experience, and it can sometimes be a time of personal growth.

**Definitions**

- **Bereavement**: the objective situation of having lost someone significant.
- **Grief**: the primarily emotional (affective) reaction to the loss of a loved one through death.
- **Mourning**: the social expressions or acts expressive of grief that are shaped by the practices of a given society or culture group.

The concept of anticipatory grief is described by Parkes as the psychological and emotional reaction to anticipation of bereavement.

**Theoretical models of loss and bereavement**

Theoretical models can be helpful in understanding the phenomena and course of normal bereavement and can
assist our clinical work with bereaved people. There is no single explanatory model of loss and bereavement, and many different models and theories are described in the literature. Parkes considers that it is helpful to view the theories as complementary rather than conflicting with each other in their approaches.60

Freud pioneered early work on bereavement and in his classic text Mourning and Melancholia recorded both the similarities and the differences between grief and depression and normal and pathological grief.61

Bowlby’s early work, in association with James Robertson and Mary Ainsworth, focused on the behaviour and attachments of children separated from their mothers under traumatic conditions.62 He identified a constant sequence of behaviours in these children, namely protest, despair, yearning and detachment. He adopted attachment theory as a way of understanding the emotional response to the severing of a close bond. John Bowlby was joined by Colin Murray Parkes in 1962 at the Tavistock Clinic, and they collaborated closely until Bowlby’s death in 1992. Their work continues to remain central to our understanding of the grief process.

Bowlby and Parkes noticed similarities in the grief of adults and young children following the loss of close and significant individuals. They conceptualized grief following bereavement to be a form of separation anxiety, originally in a three-phase model.63 They later jointly developed this into a four-phase model (see below). Phase theory originally required the bond to the deceased to be broken in order for resolution of grief to have occurred, but more recently this idea has been challenged.

Parkes developed a theory of bereavement as a psychosocial transition (PST). Such an event is relatively sudden, has lasting implications and invalidates a person’s set of expectations and assumptions about their world. This necessitates adjustment and revision of the person’s ‘assumptive world’.64

Worden, in the 1980s, proposed a model of grieving with some different features.65 He considers that the grieving person must accomplish four tasks before mourning can be completed and a healthy adjustment made. These tasks are to accept the reality of the loss; to work through the pain of grief; to adjust to an environment in which the deceased is missing; and emotionally to relocate the deceased and move on with life.

A newer model is that of the dual-process model of coping with bereavement, described by Stroebe and Schut.66 They propose that, in grieving, people undertake, in varying proportions, what could be called loss- and restoration-oriented coping activities. Both categories of stressor require coping effort during bereavement, although this coping is of necessity a part of everyday life. The loss-orientation refers to dealing with part of the loss experience (and has some similarities to the grief work process), whereas the restoration-orientation component refers to coping with the stressors that arise as a consequence of the bereavement. The central component of the model is that oscillation occurs between these two states and that this is necessary for optimal adjustment. In addition, they also argue the need for ‘dosage’ of grieving when respite is taken from either loss- or restoration-oriented coping activities as an adaptive means of coping.

Klass and colleagues have proposed a ‘continuing bonds model of grief’.67 They propose that bereaved people remain involved and connected to the deceased and that they actively construct an inner representation of the deceased that is part of the grieving.67 They suggest that, although the intensity of the relationship may diminish with time, the relationship does not disappear and can help to inform their future. Their model is supported by some eastern cultures and the grief process of children.

Rubin has described the Two-Track Model of Bereavement, in which the loss is conceptualized as two interactive axes or tracks.68 Track I is concerned with biopsychosocial functioning, whereas track II relates to the bereaved person’s ongoing emotional attachment and relationship to the deceased.

The nature of normal grief

The first systematic study of acute grief was carried out by Lindemann in 1944.69 He studied the bereaved survivors of a nightclub fire, along with other groups, and established grief as a distinct syndrome with recognizable symptoms and a defined course. The following were common to all people in acute grief:

- Waves of somatic distress, for example sighing respiration, lack of strength
- Intense preoccupation with the image of the deceased
- Guilt
- Irritability and anger
- Restlessness and aimlessness.

The phases or stages of grief

Parkes and Bowlby have described phases of grief or bereavement.60 They describe grief as a process and not a state.60 It involves a succession of clinical symptoms that blend into and replace one another. They emphasize that these phases or stages are guidelines only and are not intended to dictate where a bereaved individual ought to be at a particular time in the course of their grief. It is well recognized that an individual may pass back and forth in a fluid way between phases.

The following phases are described:65

- Phase of numbnss: this is the immediate reaction to the shock of death. There is numbness or a feeling of unreality: ‘I can’t take it in – it doesn’t seem real.’ This may last for hours or weeks.
- Phase of pining: as the death is acknowledged, there may be periods of intense pining and yearning for the
lost person. There is a tendency to weep, interspersed with quiet periods of anxiety and tension. Preoccupation with images of the deceased occurs. There may be anger and somatic distress, and anxiety may escalate to hyperventilation and panic attacks. Short-term memory is poor, and there may be irritability and depression.

- **Phase of disorganization and despair**: the pangs of grief reduce in intensity, interspersed with longer periods of apathy and despair. Ruminations over events leading up to the death may persist. A sense of the presence of the dead person, illusions, misinterpretations and hypnogogic hallucinations may occur.

- **Phase of reorganization and recovery**: Most people are aware of recovery in the second year after loss and can engage in activities directed to the future. Anniversaries, however, are often times of renewed grieving, following which energy usually returns.

It is difficult to demarcate a normal end point of grief, as studies have shown significant distress at 13 months and longer after bereavement.70

Although the stage theory of grief is widely accepted, the first empirical study of the sequence was carried out in 2007 by Maciejewski and colleagues.71 They carried out a longitudinal cohort study, the Yale Bereavement Study, assessing five grief indicators (disbelief, yearning, anger, depression, and acceptance) from 1 month to 24 months after loss. Contrary to the traditional stage theory of grief in which disbelief predominates first and acceptance is reached slowly, they found acceptance and yearning for the deceased the most frequently endorsed items. However, each negative grief indicator peaked in the sequence proposed by the stage theory, within 6 months after loss.

Shuchter and Zisook have described a multidimensional approach to the grief experiences of newly bereaved spouses.72 The following dimensions are involved:

- Emotional and cognitive states
- Coping strategies
- Continuing relationship with the deceased
- Health and social functioning
- Changes in relationships
- Changes in identity.

Although many of the bereavement studies involve white, English-speaking groups, cultural rituals and practices strongly influence grief in different cultures and different parts of the world.73

**Functional neuroanatomy of grief**

Gundel and colleagues carried out the first functional magnetic resonance imaging (fMRI) study of grief.74 Symptoms of grief were elicited in eight bereaved women by means of photographs of their deceased relative and words specific to the death event. They were also asked to view photographs of a stranger and ’neutral words’. These were put together as 60 composites in total, such as ‘deceased and grief word’ and ‘stranger and grief word’, and were presented to the study subjects during scanning. Three brain regions were activated independently by the picture and word factors: posterior cingulate cortex, medial/superior frontal gyrus and cerebellum. When the picture of the deceased was shown, distinct activity was also seen in the cuneus, superior lingual gyrus, insula, dorsal anterior cingulate cortex, inferior temporal gyrus and fusiform gyrus. When the death-related words were shown, distinct activity was seen in the precuneus, precentral gyrus, midbrain and vermis. The authors concluded that grief is mediated by a distributed neural network that subserves affect processing, memory retrieval, processing of familiar faces, visual imagery, autonomic regulation and modulation/coordination of these functions.

O’Connor, one of the authors of the study above, provides further background to this area and describes how neuroimaging may contribute to current debates in the bereavement literature.75

**Assessing the risk of bereavement**

Grief affects some people more adversely than others, and in most cases several factors may contribute. The factors that research has shown to contribute to a poor bereavement outcome are summarized in Table 56.2.76,77

Stroebe and colleagues have also described factors that promote ‘resilience’ and are protective, such as a secure attachment style in relations with others and perceived control over daily activities.77

Although many risk factors have been described, little is known about the way in which individual factors interact to cause a particular outcome. Stroebe and colleagues have developed an integrative risk factor framework for predicting bereavement outcome, which they hope will stimulate research in this area. Their framework includes five variables: the nature of the stressor; interpersonal resources; intrapersonal resources; appraisal; and coping processes and outcomes.78

**The complications of bereavement**

**Mortality**

Bereavement can be associated with increased mortality. The evidence for this comes predominantly from longitudinal studies in which bereaved people are matched with non-bereaved subjects for age, sex and other variables. An early study in 1963 by Young and colleagues followed a cohort of 4486 widowers aged 55 years and older over 5 years.79 They found that, during the first 6 months of bereavement, widowers had an increased mortality rate of 40 per cent greater than for married men of the same age. After the first 6 months of bereavement, the mortality fell back to that of married men. A longer follow-up period of 9 years by Parkes and colleagues provided additional information on cause of death. Cardiovascular disorders
Care of the dying and bereaved

('coronary thrombosis and other arteriosclerotic and degenerative heart diseases') accounted for two-thirds of the excess mortality, 67 per cent greater than the expected number.80

Helsing and colleagues carried out a sizeable retrospective cohort study between 1963 and 1974 of 4032 bereaved men and women.81 The group was followed until 1975. They added a range of control factors, including race, education, church attendance, number in a household, and smoking, making their study highly comprehensive and controlled. In contrast to previous studies, they did not find an increased risk immediately after bereavement. Their results indicated a significantly higher mortality rate (based on person-years at risk) for widowers than for married males. Such a difference was not observed between widows and married females. Younger people were at higher risk than older people after death of a spouse. Mortality rates among widowed males who remarried were very much lower than in those who did not remarry, although no effect on mortality was noted for females who remarried. After 3 years’ follow-up, however, those who had not remarried had a higher mortality than the remarried or married people.

Martikainen and Valkonen examined excess mortality and its cause in a large Finnish study of 1 580 000 married people.82 They found that excess mortality among bereaved people was high for accidental, violent and alcohol-related causes (50–150%), moderate for chronic ischaemic heart disease and lung cancer (20–35%) and low for other causes (5–15%). The excess mortality was greater in the first 6 months for all causes and among younger men.

A large number of studies predominantly of spousal bereavement have been reviewed by Stroebe and colleagues.77 The majority have shown an early excess risk of mortality among bereaved people. This extends to non-conjugal relationships and across cultures and countries. The relative risk of mortality is higher for widowers than for widows and higher in younger age groups than older age groups.

The mortality associated with bereavement must, however, be assessed in terms of the absolute number of people who die. Stroebe and colleagues suggest that the figure is low, with approximately 5 per cent of widowers versus 3 per cent of married men aged 55 years and older dying in the first 6 months after bereavement.77

Physical ill-health

People who have been bereaved are more likely to have physical health problems, especially if the bereavement is recent.

In an early study, Parkes studied the medical records of 44 unselected widows before and after bereavement.83 The consultation rate for physical symptoms was increased by 50 per cent in both older and younger widows. The change was most pronounced for the subgroup diagnosed ‘osteoarthritis’. In a subsequent study by Parkes and Brown in Boston, MA, USA, 68 widows and widowers under age 45
years, who had been bereaved 14 months previously, were compared with 68 matched controls by questionnaire interviews on health matters. They found that the hospitalization rate was higher in the bereaved group than in matched married controls. They also reported more changes in sleep, appetite and weight. Increased psychological and somatic symptoms commonly associated with anxiety were found in the bereaved group. Autonomic symptoms such as chest pains, dizziness and headaches were also more common in the bereaved people.

Other studies have also found more disability and higher use of medications. Thompson and colleagues found older bereaved spouses to be at greater risk of a new or worsened illness, and their self-reported use of medication was higher.

Various mechanisms have been proposed to explain why some individuals are more vulnerable following bereavement.  

- **Behavioural changes:**  
  - In social ties and living arrangements  
  - For widowers, increased alcohol consumption and the loss of the sole confidante  

- **Neuroendocrine and immunological changes.**
  - Increased urinary free cortisol excretion  
  - Raised plasma cortisol levels  
  - Positive dexamethasone suppression test  
  - Elevated serum growth hormone in response to stress  
  - Increase in growth hormone secretion  
  - Reduced lymphocyte response to mitogens in widows and widowers 2 months after the loss, and reduced T-cell subpopulation and natural killer cell activity.

**Psychiatric disorders**

The most frequently reported psychiatric complications of bereavement are major depression, anxiety disorders and post-traumatic stress disorder (PTSD). Pre-existing conditions such as alcohol and substance misuse may be exacerbated. Importantly, any psychiatric condition may coexist with complicated grief. Treatment of any psychiatric disorder must run in parallel with facilitation of the grief process.

A study of depressive syndromes in the first year after the death of a spouse found that 24 per cent of 350 widows and widowers met criteria for depressive episodes at 2 months, 23 per cent did so at 7 months and 16 per cent did so at 13 months. The rate was 4 per cent in a group whose spouses were still living. At 13 months, those at particular risk were younger widows and widowers and people with a past history of depression. Sub-syndromal symptomatic depression is also prevalent through the first 2 years of widowhood and is responsible for significant morbidity. According to the *Diagnostic and Statistical Manual, 4th edition* (DSM-IV), the diagnosis of a major depressive episode should not be made if a recent bereavement could account for the symptoms and the symptoms do not persist beyond 2 months. This is currently the subject of considerable debate. Recent investigators, however, have found that by 2 months after bereavement, depression may already be chronic and a cause of considerable morbidity. Evaluation of all major depressive syndromes 2 months after bereavement should be performed and appropriate treatment considered.

The suicide risk of widows and widowers is increased particularly in the first week after bereavement but falls in the first month.

Anxiety disorders can occur in bereavement. Jacobs and colleagues found a large overlap between anxiety disorders and major depression.

PTSD and bereavement phenomena may become closely mixed together, particularly when the death has been very traumatic, such as suicide or murder. The PTSD-type symptoms may interfere with the capacity to grieve and often require treatment first before the grief can be facilitated.

**Complicated grief disorder**

A number of researchers have moved to the position that complicated grief represents a distinct syndrome. Many different terms have been used to describe this disorder in the literature, including pathological grief, abnormal grief, atypical grief, traumatic grief and chronic grief. Parkes and Weiss developed a classification of pathological grief based on a study of American widowers and widows. They identified delayed or repressed grief, often in response to an unexpected loss; conflicted grief, occurring when the survivor has ambivalent feelings toward the deceased; and chronic grief, often occurring in a relationship where one partner was dependent on the other.

However, some researchers now feel that complicated grief disorder (CGD) is a single disorder that may display features of the original subtypes in varying amounts. Bereaved people with CGD typically appear stuck in a state of chronic mourning. Studies have shown complicated grief to be distinct from normal grief, major depression and PTSD.

Complicated grief disorder has been proposed as a syndrome for inclusion in the next edition of the DSM. A diagnosis of CGD requires that the bereaved person must have persistent and disruptive yearning, pining and longing for the deceased. Diagnostic criteria specify that the person must also experience four of the following eight symptoms as marked, overwhelming or extreme:

- Trouble accepting the death
- Inability to trust others since the death
- Excessive bitterness related to the death
- Feeling uneasy about moving on
- Detachment from formerly close others
- Feeling life is meaningless without the deceased
- Feeling that the future holds no prospect for fulfilment without the deceased
- Feeling agitated since the death.
The symptoms must have been present for at least 6 months and must cause marked dysfunction in social, occupational or other important domains of functioning.

It is important to note that CGD is diagnosed only at a minimum of 6 months after loss. This is because many of the symptoms are present in normal grief early on but can be expected to have declined by 6 months and not be a cause of significant functional impairment. The disorder may often occur alongside major depressive disorder and PTSD.

Bereaved people with CGD symptoms have been shown to have an increased risk of cancer, hypertension, cardiac events and suicidal ideation. They have also been associated with functional impairments, adverse health behaviours and depressive disorders.

Particular risk factors for CGD include the following:

- Sudden unexpected deaths
- A dependent relationship with the deceased person
- Childhood abuse and serious neglect
- Childhood separation anxiety
- Lack of preparation before the death and lack of support after it.

**Primary preventive interventions**

Schut and colleagues reviewed the studies of primary prevention. They found a range of studies, some with methodological flaws, and others with interventions that did not show positive effects or benefits that were only short-lived and not sustained. They concluded that none of the primary intervention studies could be described as ‘evidence-based’. However, the studies aimed at helping bereaved children to cope with the loss of a parent or sibling appeared to show positive results.

**Secondary preventive interventions**

The effects of secondary preventive interventions are more promising. The first study to show the benefit of offering intervention to high risk bereaved individuals was carried out by Raphael. She assessed a group at high risk of complicated grief selected with particular risk factors: the traumatic sudden death of their partner, low social support, an ambivalent relationship with the deceased, and multiple concurrent stressful life events. The treatment group received specific support for grief in the first 3 months of bereavement, whereas the control group received no intervention. A significant benefit as seen by reduction in symptoms was seen in the intervention group compared with the control group.

Schut and colleagues have reviewed other studies and concluded that the effects of intervention were modest and not always long-lasting.

Bereavement by suicide, although not necessarily more severe, can present specific difficulties for the surviving relatives. One case–control study found that inquest procedures and media reporting were a frequent source of distress for bereaved relatives, and feelings of stigma, shame and rejection were more common than in other bereavements. These problems make coping more difficult and many people will require specialist help.

Most specialist palliative care units and hospices in the UK have well-developed bereavement services available to any grieving relatives known to the service. They are proactive in screening for individuals at high risk of poor bereavement outcomes and offering appropriate support.

**Tertiary preventive interventions**

Most studies conclude that tertiary preventive interventions for people with complicated grief are generally helpful. This includes interventions for bereavement-related major depressive disorder and PTSD. Complicated grief can be differentiated from major depression and PTSD, and this is important, because studies so far show that treatment of the depressive disorder has little effect on the complicated grief symptoms, which require a different approach.

A variety of therapies have been tried for complicated grief, which may be individual-, group- or family-oriented and include guided mourning, interpersonal or psychodynamic therapy, cognitive-behaviour therapy and family-focused grief therapy. Two factors considered important to...
the outcome of treatment whether the bereaved person asks for help directly and the timing of the intervention.

Shear and colleagues were the first to target the symptoms of complicated grief directly. They developed a targeted complicated grief treatment involving interpersonal psychotherapy (IPT) for grief-related depression to address the depressive symptoms and IPT techniques modified to include cognitive-behavioural therapy for addressing PTSD symptoms, for example intrusive images. Patients were randomized to receive IPT (n = 46) or complicated grief treatment (n = 49). The response rate was greater for complicated grief treatment (51%) than for IPT (28%), and the time to response was faster for complicated grief treatment.

Other studies have also shown interesting results. One controlled trial of brief psychotherapy and mutual-help group treatment for widows with unresolved grief reactions found that both treatments were equally efficacious at the end of treatment. Another, Internet-based cognitive-behavioural therapy programme targeted at bereaved people suffering from complicated grief found that the treatment group showed significant improvement compared with the control group.

Kissane and Bloch have described in detail the use of family-focused grief therapy in palliative care and bereavement. They carried out a randomized trial with 81 families participating. Significant improvements were seen in distress and depression in certain groups and in ‘intermediate’ and ‘sullen’ families, and the authors concluded that the therapy had the potential to prevent pathological grief.

However, although there are many different types of intervention for bereavement-related difficulties described in the literature, it is apparent that more research is needed to establish which types are effective and for whom.

### KEY POINTS

- Patients with malignant and non-malignant disease have a similar symptom burden at the end of life. Palliative care is available to all, depending on the need rather than the diagnosis.
- Symptoms such as pain, nausea and breathlessness may be multifactorial in cause and have a psychological, social, spiritual and physical basis.
- The prevalence of psychiatric disorder in patients with cancer is high, although depression is frequentlyundiagnosed and untreated.
- A ‘good death’ can be achieved by early recognition of the dying phase, good communication with all involved, anticipation of symptoms and their timely management.
- Models of bereavement can assist in our clinical work with the bereaved.
- Bereavement can be associated with significant morbidity and mortality.
- Identifiable risk factors may be associated with a poor bereavement outcome.

HISTORICAL OVERVIEW

Psychopharmacology – the study of medicines with effects on brain functions – is both an old subject and a new topic. Humans have exploited mind-altering substances for thousands of years, and ancient texts have numerous references to these drugs. But in the past 50 years, dating from the discovery and introduction of the antipsychotics, antidepressants, lithium and anxiolytics, psychiatry has benefited from the discovery of numerous psychotropic substances. Continuity has been maintained between the old and the new as many of these substances date back thousands of years but are still in use, alcohol and opium derivates being prime examples.

The history of psychopharmacology and psychopharmacologists has been reviewed extensively. For the current observer, the intriguing paradox is the general acceptance of numerous therapeutic agents by practising psychiatrists but the reluctance, if not downright opposition, by both a minority of practitioners and numerous patient and client groups to use these agents. Polemical arguments persist over whether the risks of various medications outweigh their benefits. The recent hardening of lay attitudes against psychotropic medication and medication in general can be set against a scepticism regarding scientific claims and a concern that scientists are insufficiently critical and inadequately aware of moral and ethical issues concerning therapeutic drug use. For these reasons, it is important that the prescriber sets their usage into the context of historical background and current mores.

The earlier psychotropic substances included alcohol and opioid compounds, but a large number of names are cited in recorded texts and an extensive oral tradition. Some of these medications such as ‘soma’ have not been identified fully. Use of such psychoactive drugs could occur in a religious context, some of which survive. Examples include mescaline and toxic mushrooms.

For centuries, very few psychotropic drugs were available. Psychotropic treatment remained inchoate, with restraints and punishments substituting for any humane measures. By the Age of Enlightenment in the eighteenth century, more sympathetic methods of management were adopted and psychiatric patients were less frequently regarded as objects of derision, as in the well-documented Bethlem visits. But right into the nineteenth century, pharmacological treatments were restricted to crude sedatives such as the opioids and then bromide, chloral hydrate and paraldehyde.

By the beginning of the twentieth century, other agents, particularly the barbiturates, were being introduced as powerful sedatives. The 1930s saw the start of usage of amphetamines, but their antidepressant effects were unimpressive. Two other physical treatments were tried: first, the induction of fits, first chemically and then electrically, and electroconvulsive therapy (ECT) still survives; second, brain surgery – lobotomy – which was the subject of a horrendous, indiscriminate overuse, echoes of which persist.

The modern revolution in psychopharmacology dates from the 1950s. By that time, the numbers of occupants of mental hospitals had peaked, but there was little if anything in the way of specific remedies. The discovery of the powerful sedative and antipsychotic effects of chlorpromazine, an antihistamine derivative, was greeted with enthusiasm by some, but by no means all, psychiatrists. Those working in mental hospitals – the ‘alienists’ – regarded chlorpromazine as a wonder drug that would empty their overcrowded wards. Others relied on social measures to reintegrate their patients into the community. Slowly the two sides came together, and combined measures were adopted.

Following soon after, imipramine was tried as an antipsychotic but was found rather serendipitously to have undoubted antidepressant properties, particularly in the more severe patients with biological features such as sleep and appetite impairment. About the same time, another serendipitous discovery, that iproniazid raised the mood of patients with tuberculosis, led to the introduction of the less popular monoamine oxidase inhibitors (MAOIs). Lithium’s effects on regulating mood were also described, but its exploitation proved more contentious.

Sedatives used to lessen anxiety and induce sleep were also refined with the discovery and enormous popularity of the benzodiazepines. Unfortunately, unwanted effects such as oversedation, paradoxical excitement and withdrawal problems caused a reaction, both within the medical profession and among lay people, that still reverberates.
The problem of dementia had always been neglected, but demographic trends with ageing populations in Western countries led to the development of various drugs to help manage cognitive deficits.

Over the intervening years, numerous developments have refined our psychotropic substances. The most noticeable examples have been the introduction of a heterogeneous assortment of atypical antipsychotic drugs and of more selective antidepressants, the selective serotonin reuptake inhibitors (SSRIs) and the serotonin and noradrenaline reuptake inhibitors (SNRIs).

Throughout all this time, the mechanisms of action of psychotropic agents have been elucidated only slowly. This is not surprising. Classical neurotransmitters such as serotonin in the brain were discovered only at about the time the drugs were introduced. Perusal of texts from the 1950s shows how primitive our neuropharmacological knowledge was then. The revolution in our understanding of the anatomy, physiology and biochemistry of the brain has proceeded apace, facilitated by major developments in our chemical and behavioural techniques. But we still have gaps in our understanding: for example, why is clozapine, originally developed in the 1960s and 1970s, still the only atypical antipsychotic drug with enhanced efficacy? The advances in neuropharmacology have also led to the evaluation of novel agents acting selectively on subgroups of receptors. Psychopharmacology has got its second wind, and real advances rather than molecular refinements may be in the offing.

On the clinical level, our techniques have become more refined and sensitive. Clinical trial methodology has been revolutionized, partly at the behest of the regulatory authorities. Clinical trials involve vastly greater numbers of subjects, and statistical analyses are substantially more sophisticated. Data are scrutinized and ranked in quality. This has culminated in the Cochrane initiative, with standardized reviews and meta-analyses of an exhaustive range of topics. Other useful sources of information include comprehensive reviews in refereed journals. These can be compendious (e.g. Thornley and Adams). The need for evidence-based decisions has been voiced repeatedly (e.g. Geddes et al.).

The classification of psychotropic drugs still reflects our classification of psychiatric symptoms, together with some use of putative biochemical mechanisms. Thus, the British National Formulary (BNF) contains Section 4, headed ‘Central nervous system’ (Table 57.1).

Subsections 4.1–4.4 and 4.10–4.11 would be regarded as ‘core’ psychotropic drugs. Nevertheless, the remainder have central nervous system (CNS) effects, and drugs used primarily for non-CNS indications can also have CNS effects, usually unwanted (e.g. sedation with the older antihistamines, stimulation with bronchodilators). Most of the headings are symptomatic or syndromal, for example ‘antipsychotic’; a few are biochemical, for example ‘monoamine-oxidase inhibitors’. Sometimes the rubric has become too limited; for example, the SSRIs are classified as antidepressants but are widely licensed and prescribed for the anxiety disorders.

PHARMACOKINETICS

The study of pharmacokinetics involves observations of what happens to drugs once administered. As such, it involves the study of what the body does to drugs, as opposed to pharmacodynamics, the study of what drugs do to the body.

All pharmacokinetic processes can be expressed mathematically, and this is of considerable value in determining and predicting the pharmacokinetic properties of drugs. Clinically, however, mathematical modelling of pharmacokinetic processes is of very limited utility. Much more important is an understanding of the basic principles of what happens to drugs when administered by different routes, and how single and multiple dosing of different formulations affect plasma concentration–time relationships (Figure 57.1).

Pharmacokinetics is traditionally divided into absorption, distribution, metabolism and elimination. Although this is a useful division, not all processes occur with all drugs, and additional processes occur with some formulations of drugs. Note also that, although these processes do take place in this sequence, it is usual for two, three or even all four processes to overlap.

Absorption

Absorption describes the process of the passage of a drug from the gut or the drug’s site of administration into the bloodstream.

Oral administration

The most commonly used formulation for oral administration is the tablet, a ubiquitous but surprisingly complicated dosage form. Tablets contain not only drug but also a variety of other substances incorporated for various functions. These include lubricants (to allow passage through tabletting machines), fillers (to bulk tablets of minute drug dosage), binding agents and so-called bursters (to allow water to penetrate the tablet once exposed to an aqueous environment). Once taken, tablets cannot be absorbed as a whole but first need to disintegrate in order to allow dissolution in the stomach and bowel fluids. Only dissolved substances can be absorbed, usually by passive diffusion along the concentration gradient but occasionally by active transport mechanisms.

The necessity for disintegration and dissolution delays absorption and therefore delays drug action – tablets do not have a rapid therapeutic effect. The disintegration process can be manipulated to produce modified-release or controlled-release tablets. Here, disintegration is slowed by physical means (e.g. incorporating drug into a wax matrix) and becomes the rate-limiting step in absorption. The rate of absorption is slowed and the duration of drug action usually prolonged. Many tablets are film- or sugar-coated to improve taste or appearance. These coatings may delay absorption to a small extent.

Capsules incorporate powdered or liquid drug into a gelatine sheath. There is no need for disintegration, but absorption is slowed by the dissolution of the gelatine capsules and by wetting of the drug powder (clumps of dry powder often resist water entry). Absorption from capsules is generally similar to that of tablets, although liquid-filled capsules allow fairly prompt absorption.

Liquid oral formulations show slightly different absorption characteristics. Suspensions contain undissolved drug particles suspended in a vehicle, usually water or syrup. When the liquid is taken, absorption is fairly brisk because disintegration need not take place, although dissolution is still necessary. With solutions (dissolved drug in a vehicle), absorption is very prompt as the drug is actually given in an absorbable form.

Once absorbed, orally administered drug is carried in the hepatic portal vein to the liver. The liver is presented with the entire drug absorbed often at high concentration and so substantial hepatic metabolism may take place. This is the well-known first-pass effect. The amount of drug reaching the general circulation after oral administration is known as the oral bioavailability. This quality is expressed as a percentage or fraction and incorporates in its value the extent of absorption and the effect of first-pass hepatic metabolism.

Sublingual, buccal and rectal administration

Some drugs (buprenorphine, midazolam, lorazepam) may be given sublingually or via the buccal route. Sublingual tablets usually disintegrate within seconds, allowing dissolution and absorption. Liquid drugs given in this way are absorbed within a few minutes. First-pass metabolism is avoided and so bioavailability is often very much higher than when given orally. Rectal administration also allows very prompt absorption and mostly avoids first-pass metabolism. None of these routes allows release of drug to be modified in any meaningful way, and so administration by these routes is usually reserved for drugs with poor oral
availability (buprenorphine) or where a rapid effect is required (midazolam).

**Parenteral administration**

Subcutaneous administration of drugs or drugs in solution usually provides a rapid onset of action. Injected drug diffuses fairly rapidly into local blood vessels and is carried into the general circulation. Intramuscular (IM) injection is usually more rapidly effective because of the relatively greater blood flow in muscles. IM injections are usually of drugs in aqueous solution, but drug release can be controlled by the use of injectable suspensions (e.g. some corticosteroids) or by the use of drug dissolved in vegetable oil (e.g. antipsychotic depot injections). Both methods provide slow release of drug over days or weeks. Intravenous (IV) injections are usually effective within a few seconds – the drug is injected directly into the general circulation.

**Distribution**

Once a drug reaches the general circulation, it is said to undergo the process of distribution. That is, the drug equilibrates between the blood and the tissues according to various factors. These include plasma protein binding, water and lipid solubility, molecular size, pH partition and tissue binding. The apparent volume of distribution \( V_d \) is a measure used to indicate the extent to which a drug equilibrates outside the blood compartment. Small values indicate that the drug is held in the blood compartment, larger values (some several hundred litres – hence ‘apparent’) indicate that much of the drug is held in the tissues. The volume of distribution is easy to calculate. Say we give 200 mg of a drug that shows 50 per cent bioavailability, and we find that the resultant plasma level is 20 mg/L. The volume of distribution is the volume that is required to account for the entire drug reaching the circulation – in this case, 100 mg/20 mg = 5 L (i.e. most or all of the drug is in the blood compartment).

Psychoactive drugs are usually highly lipid-soluble and show a large or very large volume of distribution. Lipid solubility is required to allow the drug to pass the blood–brain barrier (the barrier presented to chemical entities by endothelial cells of cerebral capillaries). The absence of fenestrations (gaps or windows) between endothelial cells in brain capillaries means that chemicals must pass through the cells to enter the brain. This factor limits transit to lipid-soluble chemicals and chemicals subject to active transport mechanism (some simple sugars and amino acids). This high lipid solubility shown by most psychoactive drugs also means that they are subject to extensive metabolism (water-soluble drugs can be excreted unchanged).

**Metabolism**

Drug metabolism involves chemical modification of the drug, usually to render it less toxic or active (sometimes more toxic or active – a ‘pro-drug’) and more polar and water-soluble to facilitate urinary excretion. Phase I metabolism generally involves minor chemical reactions (hydroxylation, demethylation) catalysed by cytochrome p450 (CYP) and other enzymes in the liver and sometimes in the gut and elsewhere. Phase II reactions are those that involve the combination (conjugation) of the drug or primary metabolite with another molecule to form a complex such as a glucuronide. These compounds are polar and invariably inactive and are readily removed by the kidney (morphine-6-glucuronide is a rare active glucuronide).

**Metabolic enzymes**

Phase I drug metabolism is performed by a range of hepatic and extra-hepatic enzymes. These include the cytochrome enzymes (CYP), flavin-containing mono-oxygenases (FMO), monoamine oxidase and alcohol dehydrogenase. The CYP enzymes are most important in respect to drug metabolism.

CYP enzymes catalyse oxidative reactions and are sub-categorized according to their encoding genes. Drug metabolism is catalysed mainly by CYP1A2, CYP3A4, CYP2C9/19 and CYP2D6 (CYP2E1 has a role in alcohol metabolism). There are a great many other CYP enzymes involved in the metabolism of endogenous steroids, fatty acids, cholesterol and certain vitamins.

CYP enzymes show some genetic variations, and their function can be suppressed (enzyme inhibition) or increased (enzyme induction) by other substances (drugs, foodstuffs, polyaromatic hydrocarbons contained in cigarette smoke). Table 57.2 shows the CYP enzymes commonly involved in psychoactive drug metabolism.

**Excretion**

Drugs are eliminated from the body either unchanged or as metabolites. Lipid-soluble drugs are usually metabolized to polar conjugates to allow excretion. Typically, most drugs are excreted by the kidney, although biliary, faecal and pulmonary excretion occurs with some drugs.

Renal excretion may involve glomerular filtration, active tubular secretion and passive tubular re-absorption. All three processes are dependent on glomerular filtration rate. Only free (i.e. unbound) drug can be excreted. Hepatocytes also excrete drugs, even lipid-soluble parent drugs and metabolites. Active transport mechanisms are usually involved. Drug passes into the bile and then may be re-absorbed (enterohepatic recycling) or eliminated in the faeces. Pulmonary excretion is seen only with volatile anaesthetic gases and vapours and, to a small extent, with compounds such as ethanol.

Because of their lipophilicity, psychoactive drugs are usually metabolized, often extensively and by a variety of pathways, before being eliminated. A very few psychotropics are excreted unchanged; these include lithium, sulpiride and amisulpride. The clinical doses of these drugs (up to
and over 1 g a day) are an indirect indication of the poor lipid solubility: high doses are needed to ensure that sufficient quantities enter the brain.

**Clearance**

Clearance (CL) is the term used to define the rate of elimination of a drug. Mathematically, it is a product of the elimination rate constant (Ke) and the volume of distribution (Vd).

\[
CL = Ke \times Vd
\]

Clearance is expressed in litres/hour, and so rate of drug removal from the body can be seen as a function of drug concentration, assuming clearance remains constant. For example, if clearance of drug X is 5 L/h, then when the concentration of X is 100 mg/L the amount eliminated per hour will be 5 × 100 mg = 500 mg. When the plasma concentration is 10 mg/L, then the amount removed will be 5 × 10 mg = 50 mg/h. This aptly demonstrates the nature of so-called first-order kinetics of drug elimination – the rate of drug elimination is dependent on plasma concentration (the higher the concentration, the faster the elimination).

The nature of first-order kinetics can also be seen in the measure of drug persistence in the body – the plasma half-life (t1/2). This measure gives the time for plasma concentration to fall by a half. The time taken for plasma concentration to fall from 100 mg/L to 50 mg/L will be the same as the time for the concentration to fall from 10 mg/L to 5 mg/L. This exponential decay can be seen in plasma concentration–time graphs, particularly those following IV administration.

**Multiple dosing and steady state**

Most psychoactive drugs are given in repeated, regular dosing to treat enduring conditions. In multiple dosing, absorbed drug is added to drug already in the system. The plasma level obtained after the second dose will therefore be higher than that seen after the first dose. Plasma levels continue to rise until a steady state is achieved, when rate of drug availability equals rate of drug removal (another result of first-order kinetic processes). Attainment of steady state usually takes four to five half-lives to achieve in regular dosing (the frequency of dosing does not affect the time to attainment of steady state, unless the intervals are so long that all previously administered drug has been removed).

Knowledge of steady-state kinetics has two important implications. First, it should be understood that plasma levels are usually much higher at steady state than after the first or second dose (Figure 57.2) and so assessment of drug effect or tolerability should be delayed until steady state is achieved. Second, the use of plasma levels to ensure response or safety will usually be appropriate only once steady-state levels are achieved.

**Plasma drug levels and therapeutic response**

The action of all drugs is dependent on their concentration at the site of action. This, in turn, is proportional to drug plasma level. Plasma level is related directly to dose and
frequency of dosing. However, because of individual and genetic variation in absorption, metabolism and excretion, drug plasma level is sometimes difficult to predict from dose alone. So, for some drugs, plasma level monitoring (or therapeutic drug monitoring, TDM) is essential to ensure their safe and effective use. In psychiatry, TDM is mandatory for lithium, very useful for clozapine, carbamazepine and valproate, and sometimes beneficial for olanzapine, risperidone and tricyclic antidepressants (TCAs).

A prerequisite for the use of TDM with a particular drug is that its plasma levels should be related clearly to its therapeutic or adverse effects. In fact, plasma level is always related to these outcomes – a plasma level of zero produces no effect, certain concentrations slightly above zero will also produce no effect, higher levels will give rise to therapeutic and/or adverse effects, and higher levels still will probably produce no further therapeutic effect but more severe or frequent adverse effects. For most psychotropics, the precise relationship between dose or plasma level and therapeutics has not been defined clearly. The main reason for this is that not all patients show a response, and so in some individuals no therapeutic effect will be seen, no matter what dose or plasma level is attained. This makes difficult the process of establishing exact dose– (or plasma level–) response relationships.

For TDM to be clinically useful, the measured drug plasma level must have some inherent meaning – it should indicate the likelihood of therapeutic or adverse effects. For the psychotropics listed above, a target range (sometimes misleadingly termed ‘therapeutic’ or even ‘normal’ range) has been defined. This is a range of plasma levels where clinical effectiveness can be expected while adverse effects are minimized. The lower limit is usually the lowest plasma level at which effect might be seen, and the upper limit is that at which adverse effects become unacceptable. The target range is inevitably something of an approximation, and so it should not be taken as holy writ. Moreover, where therapeutic or adverse effects are obvious, plasma level becomes immaterial. This is a frequent occurrence in practice: some patients will respond at apparently subtherapeutic plasma levels, while others will suffer severe adverse effects with plasma levels in the target range. In such cases, it always pays to treat the patient (i.e. what you see before you) rather than to be concerned obsessively about achieving the ‘right’ plasma level.

**Sampling**

Appropriate blood sampling is crucial to effective TDM. Plasma levels vary over time, sometimes showing substantial peak-to-trough variation within the dosing interval. Target ranges are generally set for plasma samples taken at a particular time in respect to the previous dose and may be less useful or even meaningless for samples taken at other times. It is essential, therefore, to make the effort to sample at the appropriate time, and it is imperative that the times of sampling and of the previous dose are recorded on the pathology request slip. Changes in reported plasma levels in individual patients may well be a result of changes in sampling times rather than, say, a change in compliance.

**Lithium**

TDM is essential when prescribing lithium because it has a narrow therapeutic index (toxic levels are only slightly above therapeutic levels), because plasma level is difficult to predict from the dose alone, and because its prophylactic effect in bipolar disorder is difficult to discern clinically. Various studies have suggested a target range of around 0.8–1.2 mmol/L (12-h post-dose sampling) for bipolar prophylaxis. However, possibly the most reliable predictor of effect is the reduction in plasma level: abrupt changes seem to provoke increased frequency of relapse. In acute mania, there is some evidence that plasma levels of 1.0–1.2 mmol/L are necessary for an adequate effect.

**Clozapine**

With clozapine, TDM is useful principally because plasma level attained varies considerably in individuals given the same dose (gender and smoking status have a profound influence on clozapine metabolism). The threshold for therapeutic effect is around 0.35 mg/L, and important adverse effects such as seizures tend to occur at plasma levels above 1.0 mg/L. The recommended target range is 0.35–0.6 mg/L. Blood samples are usually drawn at the end of the dosing interval (i.e. trough sample).

**Carbamazepine**

The target range for carbamazepine in bipolar disorder has not been established clearly, but TDM is useful nonetheless because of the drug’s ability to induce its own metabolism and the variation in plasma levels that results from this. Trough plasma levels above 7 mg/L seem to be associated with response. Adverse effects such as diplopia and dizziness usually become intolerable at plasma levels of around 10 mg/L. Modified-release carbamazepine tablets are gen-
generally tolerated better because they result in lower peak plasma levels than conventional tablets.22

Valproate
In epilepsy, the target range for valproate is 50–100 mg/L. Most trials establishing valproate’s utility in mania and bipolar prophylaxis have utilized this range as a guide to dosing. In mania, response seems to improve as trough plasma levels increase from 50 mg/L to 125 mg/L,23 so TDM is probably useful. At the very least, TDM should prevent underdosing of valproate.

Olanzapine
Dose–response relationships for olanzapine are not defined clearly, largely because of the absence of fixed-dose studies in the literature. Plasma level–response relationships are better understood, and a threshold for response has been discerned at around 20 μg/L (12-h post-dose).24,25 Levels above 40 μg/L seem to offer no additional benefit.26 A target range of 20–40 μg/L has been suggested.27 In practice, olanzapine TDM is helpful only where response is not seen at the highest licensed dose or where compliance is in doubt.

Risperidone
Few UK laboratories measure risperidone plasma levels. A target range of 20–60 μg/L has been suggested.19 Dose–response relationships for oral risperidone are well understood,28 and so risperidone TDM is perhaps only of value with risperidone long-acting injection where appropriate dosing is difficult because of its delayed release characteristics and uncertainty over appropriate dosing.29

Tricyclic antidepressants
TDM of tricyclics is now undertaken rarely, but it is occasionally helpful. Therapeutic plasma levels are usually around 100 μg/L (target ranges vary according to drug).10 Plasma levels are useful in cases of non-response or suspected non-compliance. Tricyclic toxicity is best assessed by electrocardiogram (ECG) rather than drug plasma level.

Other drugs
In the UK, TDM practices leave a lot to be desired. Often, a prescriber will send off a blood sample for drug plasma level determination with little knowledge of its likely value. The analyst assumes that the prescriber would not request a drug assay without good reason, determines the plasma level, and reports this to the prescriber. The prescriber assumes that if the laboratory undertakes the assay, then it must be of some use, and so it goes on. In fact, TDM is entirely inappropriate for the large majority of psychotropic drugs (SSRIs, most antipsychotics, benzodiazepines), either because the effect or plasma level is predicted readily from the dose given or because no reliable target range has been defined. Even plasma level requests aimed at ruling out non-compliance have limited utility: a plasma level of zero or close to zero indicates recent non-compliance, but any other value is impossible to interpret.

PHarmacodynamics

The background to this section is set out in detail in Chapters 23 and 24. See also Leonard.31

The term ‘pharmacodynamics’ refers to the effect of a drug on biological mechanisms – in psychopharmacology, specifically in the brain. The key structure is the synapse, which is the gap between one neuron (presynaptic) and the next (postsynaptic). The key substance is the neurotransmitter that is released from the presynaptic axon and diffuses to the postsynaptic dendrites of the next neuron. Thus, an electrical signal is converted into a chemical one and then back into another electrical signal (excitation), or prevents the electrical signal (inhibition). Several neurotransmitters can act in the same synapse, allowing for subtle multiple influences, in contrast to the axonal transmission, which is all-or-none. The mammalian CNS contains over 50 neurotransmitters, of which the most relevant to psychopharmacology are acetylcholine, dopamine, noradrenaline (norepinephrine), serotonin (5-hydroxytryptamine, 5-HT), glutamate, histamine, the encephalins, γ-aminobutyric acid (GABA) and glycine. The release of the small molecule transmitter is often accompanied by the release of larger molecule peptides as co-transmitters. The effect of the neurotransmitter will also depend on the characteristics of the receptor to which it binds, and can stimulate or inhibit neuronal activity.

The schema of axonal impulse → neurotransmitter → neuron is now known to be oversimplified, and dendritic release can also occur. Axons can be branched, which increases the complexity. Further, neurons can be plastic and alter their properties with use and disuse. The anatomical organization of the 10¹² neurons in the brain is exceedingly complex, and drug actions are accordingly complicated.

Neurotransmitter function

The elucidation of neurotransmitter and drug functions has been two-way traffic – the discovery of a putative transmitter led to examination of psychotropic drug effects on that transmitter’s mechanisms, and the drug could be used in the search to establish the physiological function of that transmitter. For example, serotonin was found in the brain and then lysergic acid diethylamide (LSD) was found to exert its hallucinogenic properties by interacting with it. Criteria have been generally adopted as necessary requirements to establish a substance as a transmitter (Box 57.1).

Receptors

Receptors are complex protein structures, often with different types of subunit. They surround and control an ion
channel across the nerve membrane that governs the entry of various ions into the neuron, altering its excitability. Sodium, potassium and calcium are the most common cations involved. The effects of the transmitter can be fast (inotropic) or slow (metabotropic); both are important in psychopharmacology. The latter receptors are linked to intracellular second messengers.

Presynaptic activity can be altered by auto-inhibition, thus providing a negative feedback system. The neurotransmitters are typically stored in vesicles, which can be altered by drugs; for example, reserpine depletes neurons of dopamine.

Postsynaptic mechanisms can involve an increase (up-regulation) or decrease (down-regulation) of receptor numbers, according to activity across the synapse, another feedback mechanism. Long-term use may be associated with a change in the receptor itself; for example, it has been suggested that benzodiazepine tolerance and dependence involve the synthesis of a different balance of receptor subunits.

A drug may change the balance postsynaptically, but its effects will then be opposed by a change in the receptor numbers in an attempt to overcome its effects. SSRIs prevent the reuptake of serotonin back into the presynaptic neurons, increasing the drug’s availability and action on the postsynaptic receptors. These and other receptors further down the neuronal cascade then become reduced in number (‘down-regulated’) to overcome the stimulation.

Complex mechanisms exist to terminate the actions of the neurotransmitter. Enzymes can be found in the synapse and its vicinity. Some transmitters are re-absorbed back into the presynaptic neurons, where they may re-enter the storage vesicles or be metabolized intracellularly. These disposal mechanisms are a prime target for psychotropic drug action, such as MAOIs and SSRIs. Most other psychotropics act on the receptors themselves, both pre- and postsynaptic. Although neurotransmitters can be widespread in the brain (e.g. GABA, glutamate), others are found in fairly well-defined systems, such as the dopaminergic system. However, although the cell bodies may be found in circumscribed areas, their projections may be very diffuse in the brain, particularly the cortex.

### Individual neurotransmitters

The large number of neurotransmitters precludes any detailed discussion. The main features of those most relevant to psychopharmacology are listed in Table 57.3.

Electroconvulsive therapy
This treatment has established efficacy in severe depression, but it may induce cognitive defects. Numerous changes occur in the brain. Those most likely to be associated with the therapeutic response include increases in serotonin and noradrenaline, enhanced postsynaptic 5-HT_2_ activity and decreased postsynaptic beta-adrenergic activity. The memory deficit may be an expression of decreased function of central muscarinic receptors.

FACTORS INFLUENCING TREATMENT

Initial level effects
The response of an individual to a drug treatment will often be partly dependent on the initial level of activity. For example, very depressed patients tend to be more responsive than mildly depressed individuals to antidepressants. Indeed, it has been asserted that SSRIs have no demonstrable efficacy in mildly ill patients, so that antidepressants are not indicated. In patients with dementia, some cognitive enhancers are not recommended in the early stages of the condition but are reserved for later stages (Mini Mental State Examination (MMSE) 10–20).

Dose effects
The effect of a drug varies with dose. The classic dose–effect curve is sigmoid, with a slow increase in effect at the lowest doses, a steady increase in effect, and then a flattening off at higher levels. The maximum effect can vary greatly from drug to drug. A good example concerns the analgesics. Non-opioid agents, no matter how high the dose, cannot achieve the degree of effective analgesia of an opioid.

The dose–effect relationship is important in influencing the way a drug is administered in practice. Some drugs have unwanted effects at dose levels close to those needed for a therapeutic effect. For example, extrapyramidal side effects (EPSes) occur at doses of typical antipsychotics only just above those inducing a worthwhile therapeutic effect. Lithium has such a narrow therapeutic margin between risk and benefit doses that routine serum drug estimations are used to optimize dosages.

Doses of drugs are often recommended as a range. Generally speaking, treatment is initiated at the lower end of the range and the dose is increased if no response is forthcoming after a reasonable trial period. However, there have been very few studies in which this strategy has been tested adequately. The appropriate trial design is to select a group of predefined non-responders and randomize them to continue double-blind on their dose plus placebo or the extra dose. There are few trials of this nature. Fixed-dose studies of antipsychotics suggest a fixed threshold for therapeuic effect above which dose increases show no benefit, and the National Institute for Health and Clinical Excellence (NICE) suggests that lowest licensed doses of SSRI antidepressants are sufficient for most people. Nevertheless, dosage increase is usually routine.

Time effects
Drug effects change over time. Repeated doses may induce effects not discernible with single-dose administration. Two main processes are relevant. With long-acting compounds, accumulation must occur in order for a therapeutic level to be attained. An opposing process is that of tolerance, wherein repeated doses result in tolerance, so that effects wane or the dose has to be increased to maintain the effect. Some drugs of misuse, such as the stimulants and sedative hypnotics, are prone to show tolerance with marked escalation of dosage.

One phenomenon that has prompted much debate is the delay of onset of detectable response to the antidepressants and the antipsychotics. The conventional view is that the initial week or two of administration is characterized by unwanted effects such as sedation and nausea, without any clear signs of improvement. Then the side effects wane and remission begins. This time sequence has been challenged by others, who point out that controlled trial data with both classes of medication show some improvement from early on but that this does not reach statistical let alone clinical significance until 2 weeks or more.

Individual variation
As with almost all biological responses, much individual variation can be discerned. Factors such as ethnicity and genetic heterogeneity have been elucidated, but much of this patient-to-patient variation remains unexplained. Pharmacokinetic differences between people are also important, and many studies have investigated this. Despite all this endeavour, lithium and some other mood-regulators remain the only psychotropic medications in which estimation of bodily concentrations is routine.

Variation in response can also occur in the same individual at different times or even within the 24-h diurnal cycle. The severity of the illness may also govern the response, with higher doses needed when a patient relapses than when on maintenance treatment. Some patients can be taught to self-monitor their psychiatric symptoms with a view to increasing the dose if they sense that relapse is imminent.

Milieu effects
Drugs are given to individuals in specific social situations, such as the home or a ward in the hospital. Drug responses may be modified accordingly. The classic example was the introduction of chlorpromazine in the 1960s. Some sceptics
regarded the undoubted subsequent benefits, including enhanced discharge rates, as reflecting the greater confidence and optimism of the nursing staff, rather than a specific pharmacological effect. In turn, this facilitated a more liberal mental health policy, which increased the beneficial effects, thus setting up a ‘virtuous cycle’.

Another interpretation was that the drug and non-drug effects were not interacting positively but that either could be effective on their own, and there was no gain in combining them. The most extreme view was that one treatment could interfere with the other, a negative interaction. Over time, it has become accepted that a positive interaction occurs even when both components of treatment are already optimal.

Therapist effects are also operating. A prescriber with a positive but still critical attitude to drug therapy tends to have better results than the sceptic.

**Placebo effects**

Placebo effects have become a large topic in pharmacology. They are often particularly noticeable with respect to psychotropic medication and psychiatric patients. In trial after trial, in a range of disorders, 30–50 per cent of patients show a clinically useful improvement on placebo. Many factors are involved. One is the panoply of attention and optimism that surrounds the participant in a clinical trial. This response occurs even though the patient is aware that he or she is taking an inert substance. The hopes, fears and expectancies of the individual operate to good effect.

Another feature that may masquerade as a placebo effect is natural remission. A proportion of patients will improve because that is the natural progression of that type of illness. But even in chronic non-remitting disorders, the placebo effect may be appreciable.

**Controlled trials**

The methodology involved in the evaluation of a treatment has proceeded apace over the past few decades. No longer is it acceptable to give a few specialists a new drug to try out and to take their opinions as worthwhile. Under pressure from drug regulatory authorities and academic experts, strict guidelines have evolved for the controlled assessment of medications, new and old. This type of trial is the accepted gold standard to evaluate both efficacy and risk. The following are the main components:

- Careful selection of the target population using standard diagnostic criteria, usually from the *Diagnostic and Statistical Manual*, version 4 (DSM-IV) or the *International Classification of Diseases*, version 10 (ICD-10). A screening instrument may be used.
- Exclusion of patients who are inappropriate or may be at particular risk of adverse effects, e.g. women of childbearing potential not using effective contraception, or patients taking other medications or illicit drugs.
- Use of appropriate, sensitive and validated outcome criteria, usually employing a rating scale or an objective measure like the polysomnogram. Investigators should be trained in their use.
- Allocation using a randomization procedure to the test drug and a placebo, often with a standard medication as a comparator. The comparator allows a post-hoc estimate of the sensitivity of the trial because it should separate from placebo. If it does not, then no conclusions can be drawn, as the study seems insensitive. The placebo should match the test drug in every way possible.
- Neither the patients nor the investigators should be aware of which medication any individual patient is taking (double-blind). Ideally, one investigator should question the patient about adverse effects, and the efficacy should be assessed by a separate observer. This was a particular problem with older medications, which were very likely to induce unwanted effects that the patient would report, thus invalidating the double-blind procedures.
- The design of the study should be rigorous and the proposed statistical analyses set out unequivocally in the protocol. An experienced statistician should be involved from the start.
- The outcome variables should be predesignated as ‘primary’, upon which the outcome of the trial depends, and ‘secondary’. This prevents cherry-picking of significant variables post hoc. More general measures such as quality of life may be helpful.
- A clear distinction should be maintained conceptually between statistical significance with a preset level, usually 0.05, and clinical significance, which is the investigator’s clinical judgement as to whether the statistical difference has any real meaning in practice. Variables such as response and remission rates are often more apposite than changes on the rating scale.
- Careful records are kept of adverse effects. These can be objective such as QT prolongation of the ECG, or subjective complaints volunteered spontaneously by the patient or elicited by the investigator, perhaps using a standard scale.
- Dosage schedules must be chosen carefully. Are patients going to be allocated to fixed doses throughout the duration of the study, or can the dose be varied according to the patients’ response and tolerability? Are several fixed doses to be used, thus providing a dose–effect curve? How are the doses chosen, and is the dose of the comparator a fair one? There are numerous quite complex considerations here.
- The duration of the trial must also be chosen judiciously. If the duration is too short, then the therapeutic effects may not be sufficiently evident to reach statistical significance. If the duration is too long, then in some conditions natural remission in both groups may obscure any effect. Longer-term assessment usually takes the form of relapse-prevention, whereby responders to a test
medication are allocated randomly to continue on the medication or to switch to placebo: relapse rates are then calculated.

- The number of patients entered into the trial should be sufficient to allow a conclusion to be obtained with a reasonable degree of probability. It is pointless and unethical to enter so few patients that significant differences are unlikely to accrue. The number can be computed in advance (power calculations).
- Compliance with medication can be monitored with tablet counts or random urine or blood tests. Best of all is to retain the patient’s confidence.
- The protocol for the study should be submitted to the appropriate ethical committee and the patient should give informed consent, preferably written. Serious adverse events should be referred immediately to the ethical committee and, where necessary, to the relevant regulatory authority.

**PRINCIPLES OF RATIONAL PRESCRIBING**

This is a huge topic that has been revolutionized by the advent of numerous guidelines for prescribing. Such guidelines can be promulgated by a variety of agencies, both national and international. In the UK, the British Association for Psychopharmacology and the Royal College of Psychiatrists have been active in setting out advice on treating various disorders and problems. Official bodies such as the Committee on Safety of Medicines have issued warnings on particular adverse effects. NICE has produced influential but sometimes contentious guidelines on a range of disorders; the guidelines tend to emphasize non-drug treatments, especially for less seriously ill patients.

The topic of severity of the presenting complaint has tended to dominate this area. Most conditions form a pyramid of frequency, with many mildly ill people only just attaining ‘caseness’, and some moderately ill individuals above them, and culminating in a peak of a few severely ill patients. The first decision is whether to treat at all or to resort to ‘watchful waiting’ and reassurance, non-drug methods such as sleep hygiene with insomnia, or lifestyle advice. More elaborate psychological techniques such as cognitive-behavioural therapy (CBT) may be recommended.

If a drug is deemed appropriate, a low dose should be tried initially, particularly in elderly patients and patients with physical illness. The patient should be informed fully about the medication, its effectiveness and its more common adverse effects. Appropriate tests should be carried out, such as renal function in patients being considered for lithium therapy and blood counts in candidates for clozapine.

An adequate time should elapse before an increase in dose is contemplated. The dose can be increased up to the recommended maximum in the BNF. Beyond that, any increases should be very circumspect and the reasons documented carefully and legibly in the notes. This is particularly necessary with antipsychotic medication, where dosage ranges tend to be wide.25

The duration of treatment is an important consideration. With some, such as the benzodiazepines, duration should be minimal; with others, such as the SSRIs, the treatment should not be curtailed prematurely.

The choice of medication will reflect the information contained in the reviews but also the individual prescriber’s experience and predilections. If the first treatment proves unsuccessful, then guidelines for resistant or refractory patients should be followed for the second and even third choices. Ancillary symptomatic treatment may be needed, for example hypnotic medication in the unresponsive depressive patient plagued by severe insomnia. Side effects of the primary medication may need symptomatic treatment, but the number of concomitant medications must be monitored and minimized. Too often, even now, some patients end up on multiple drugs with the high risk of drug interactions.

Prescribers should be very clear as to whether their prescription is for a licensed indication for that medication or whether it is unlicensed (‘ex-label’). The medicolegal implications are vastly different.26 If such a usage is resorted to, the notes should state very clearly why, and the reasons discussed with the patient and/or the carers.

**DRUG CLASSES**

**Antipsychotics**

The earliest true antipsychotic, chlorpromazine, is a derivative of phenothiazine compounds originally developed as commercial dyes in the 1880s. Chlorpromazine was found, by chance, to have antipsychotic activity in the early 1950s. Early developments involved minor modifications of the phenothiazine structure to produce compounds such as thioridazine (now withdrawn) and prochlorperazine (used as an anti-emetic). In the 1960s Paul Janssen developed haloperidol, a butyrophenone compound, from pethidine. Further phenothiazines (fluphenazine, trifluoperazine) were also developed, along with closely related thioxanthine compounds such as flupentixol. Also in the 1960s, antipsychotics were shown to share antagonist properties at dopamine receptors. For a while, development centred on producing drugs whose pharmacological activity was limited to dopamine antagonism. Examples include pimozide (a diphenylbutylpiperidine) and sulpiride (a substituted benzamide).

All of these drugs were effective antipsychotics, with little to choose between them in terms of efficacy, and all caused parkinsonian symptoms and tardive dyskinesia as a result of their dopamine antagonist effects. Clozapine, a drug first used in the 1960s, was seen to be effective without causing extrapyramidal symptoms. Clozapine...
became known as an atypical antipsychotic because it did not cause typical adverse effects. In the 1990s, clozapine was reintroduced as an atypical antipsychotic, having earlier been withdrawn because of its association with agranulocytosis. Other atypical antipsychotics followed: risperidone, olanzapine, sertindole, quetiapine and amisulpride. These drugs are classified by their atypical nature (although some are atypical only at low doses) and not by their chemistry. Clozapine, olanzapine and quetiapine share a similar chemical structure, but the others are more diverse. Aripiprazole is also atypical but, unlike other antipsychotics, both conventional and atypical, it is a dopamine partial agonist rather than an antagonist. Bifeprunox is similar.

There are thus two broad groups of antipsychotics, conventional (typical) or first-generation drugs, and atypical or second-generation drugs. Conventional drugs are subdivided according to their chemistry, and atypical drugs according to their pharmacology (Table 57.4).

All antipsychotics are active orally, and some are used parenterally (e.g. haloperidol) as simple IM or IV injections. Some phenothiazines and thioxanthines have a terminal –OH group, which allows reaction (esterification) with long-chain carboxylic acids to form oil soluble esters (e.g. decanoate, enanthate, palmitate). These drug esters are highly lipid-soluble and are given in vegetable oils as IM depot injections. Slow release from the oily depot affords stable plasma levels over several weeks. Examples include pipotiazine palmitate, fluphenazine decanoate and flupentixol decanoate. Some atypical drugs are also given as depot injections, although their formulations differ. Risperidone, for example, is given as a suspension of microcrystalline particles in which risperidone is incorporated. The drug is released slowly as the particle breaks down.

**Efficacy**

The efficacy of antipsychotics is usually assessed in randomized, placebo-controlled trials lasting 4, 6 or 8 weeks. Symptomatic change is evaluated using the Positive and Negative Symptom Scale (PANSS) or the Brief Psychiatric Rating Scale (BPRS). A reduction of 20 per cent in either scale is usually defined as a response. In first-episode schizophrenia, response is usually seen in more than 80 per cent of patients treated, depending on the trial conditions and drugs used. In so-called refractory schizophrenia, responders usually number less than 10 per cent when standard treatments are used.

Efficacy studies have largely revealed a wide range of antipsychotics to have very similar effects on psychotic symptoms in schizophrenia. In refractory schizophrenia, clozapine is substantially more effective than conventional and some atypical antipsychotics. High-dose olanzapine may have similar properties. A large meta-analysis of efficacy studies suggested that clozapine, olanzapine,

NB: potency is not related to efficacy. Low-potency drugs require higher doses to be effective (e.g. 100 mg/day); high-potency drugs are given in lower doses (e.g. < 20 mg/day).

*No longer used.

**Usually classified as atypical.

EPSE, extrapyramidal side effects; 5-HT, 5-hydroxytryptamine.
risperidone and amisulpride were significantly more efficacious than conventional antipsychotics. This perhaps reflects these drugs' reduced propensity to produce extrapyramidal effects and the resulting improvement in negative symptoms of schizophrenia.

Effectiveness studies, which study a more diverse range of patients under more naturalistic clinic conditions, have suggested differences between antipsychotics. Clozapine is clearly supremely effective in refractory schizophrenia, and olanzapine may have some useful effectiveness. Olanzapine and risperidone also appear to have advantages in patients intolerant of other drugs. Quetiapine appears to have relatively weak antipsychotic effectiveness.

Rational prescribing of antipsychotics involves the use of a single antipsychotic drug at a licensed dose. In the UK and elsewhere, antipsychotic polypharmacy and high-dose prescribing are very common. A major factor in both practices is the use of 'when necessary' (PRN) prescribing of antipsychotics. In such cases, antipsychotics are generally prescribed for their sedative effects; sedatives such as promethazine and benzo diazepines are thus better choices.

Antipsychotic polypharmacy offers no therapeutic benefits over single-dose treatment and may worsen outcome and increase mortality. Polypharmacy with clozapine is often recommended where clozapine alone has failed, but even this strategy has only a minimal evidence base to support it. Similarly, high-dose antipsychotics offer no advantages. In fact, most if not all antipsychotics show a threshold-type dose–response relationship, with optimal doses often shown to be at the lower end of the licensed dose range.

In organic psychosis, the same principles of rational prescribing apply. Choice of antipsychotic is based on individual characteristics, in the absence of a body of controlled trials of different agents. In psychosis of dementia, antipsychotics have only a limited effect, a fact not reflected in their widespread use in elderly patients.

**Anticonvulsants**

Anticonvulsant drugs show an extremely wide range of chemical structures and have an exceedingly wide range of actions and adverse effects. Their modes of action often involve either enhancing the activity of the inhibitory transmitter GABA or antagonizing the effects of the excitatory transmitter glutamate. Classification is usually by chemistry, but clinical use and pharmacological mechanisms are sometimes used. In this chapter, anticonvulsants are classified primarily according to their chemistry.

**Aldehydes**

Paraldehyde is still used occasionally, either by the IM route or rectally. It is usually reserved for refractory status epileptics. Glass syringes should be used, as paraldehyde dissolves some plastics. Its mode of action is unknown. Paraldehyde undergoes significant pulmonary excretion.

**Barbiturates**

These were once the mainstay of the treatment of epilepsy but they are now rarely used because of their adverse cognitive effects and increased risk of suicide. Phenobarbital and primidone (a pro-drug of phenobarbital) are the only products still licensed for epilepsy in the UK. TDM may be helpful for both products: the target range for plasma levels is 15–40 mg/L. Phenobarbital injection is still used occasionally in status epilepticus.

**Benzodiazepines**

Most benzo diazepines have anticonvulsant properties (they enhance GABA activity). Clobazam, clonazepam and clorazepate are used orally in the prophylaxis of seizures. Tolerance can develop. Diazepam (IV or rectally), lorazepam (IV or IM) and midazolam (IV, IM or via buccal mucosa) are used in status epilepticus.

**Carboxamides**

Carbamazepine is used extensively in a variety of seizure disorders and in trigeminal neuralgia and bipolar disorder. Oxcarbazepine is similar to carbamazepine (its structure has an additional oxygen atom) but seems to be tolerated better and less prone to drug interactions. Both drugs act by stabilizing voltage-gated sodium channels, thus suppressing repeated neuronal firing. TDM is useful with carbamazepine, both in epilepsy and in bipolar disorder. The target range is usually 8–12 mg/L.

**Fatty acids**

Valproate, vigabatrin and tiagabine are fatty acids. The mode of action of valproate is poorly understood. Vigabatrin inhibits GABA metabolism, and tiagabine is a GABA reuptake inhibitor. Valproate is the most widely used. TDM is helpful with valproate. The target range is 50–100 mg/L in epilepsy.

**Fructose derivatives**

Topiramate is a fructose derivative licensed for the treatment of a range of seizure disorders and for migraine prophylaxis. It has multiple actions, including enhancement of GABA and inhibition of glutamate. It is one of the few drugs used in psychiatry that reliably causes weight loss. Impairment of memory and concentration can be problematic.

**GABA analogues**

This group includes gabapentin, pregabalin and vigabatrin. The mode of action seems to include binding to voltage-gated calcium channels (gabapentin, pregabalin). Gabapentin was once used in mania. Pregabalin is effective in anxiety.

**Hydantoin**

Phenytoin and fosphenytoin (a phenytoin pro-drug used parenterally) are used widely in epilepsy. The mode of action is similar to that of carbamazepine. Phenytoin
famously shows capacity-limited or zero-order metabolism. Small changes in dose can give rise to extensive changes in plasma level. The target range is 10–20 mg/L.

**Pyrrolidines**
Levetiracetam is a relatively new anticonvulsant given orally and IV. Its mode of action is complex and poorly understood.

**Succinimides**
Ethosuximide was once in widespread use, but it is now used rarely. Its main use is in absence seizures, but blood dyscrasias can be problematic. Its mode of action is unknown.

**Sulfonamides**
Acetazolamide is no longer used in epilepsy, except in that associated with menstruation, but zonisamide is licensed for refractory partial seizures with or without secondary generalization. Zonisamide may act by binding to voltage-gated sodium and calcium channels.

**Triazines**
Lamotrigine is an effective anticonvulsant that also shows efficacy in bipolar depression and as a prophylaxis against bipolar depression. Lamotrigine inhibits glutamate release. Its use is made complicated by the need for slow titration (because of the risk of rash, which can be life-threatening) and by interaction with valproate (a common co-therapy). TDM is sometimes undertaken, but a target range has not been defined.

**Drugs for Alzheimer’s disease**
Alzheimer’s disease involves numerous structural and neurochemical changes that pharmacotherapy attempts to correct at least partly. The function of acetylcholine is known to be reduced in Alzheimer’s disease, and drugs that inhibit acetylcholine metabolism (acetylcholinesterase inhibitors, ACHIs) afford some symptomatic improvement. Three acetylcholinesterase inhibitors are in widespread use in the UK, as is a drug with multiple actions, memantine.

**Acetylcholinesterase inhibitors**
Donepezil was the first ACHI to be marketed in the UK for use in Alzheimer’s disease, although its use had been preceded by tacrine, a similar, but unlicensed drug with problematic hepatic adverse effects and a short plasma half-life. Donepezil is usually tolerated well (nausea and diarrhoea are the most common adverse effects) and can be given once daily. It is subject to hepatic metabolism catalysed by CYP2D6 and CYP3A4. It has a robust but small effect on cognitive symptoms of Alzheimer’s disease.

Rivastigmine has a similar mode of action to donepezil, except that its action on acetylcholinesterase is more prolonged (pseudo-irreversible inhibition). It is metabolized at the site of action, with a plasma half-life of around 2 h; there is no hepatic metabolism. Rivastigmine is usually given orally twice daily or via a once-daily transdermal patch. Efficacy and tolerability are similar to those of donepezil. Galantamine, the third ACHI, is derived from bulbs and flowers of snowdrops and related species. It may also possess nicotinic receptor agonist activity. Galantamine has a plasma half-life of around 7 h, but modified-release preparations allow once-daily dosing. It is metabolised by CYP2D6 and CYP3A4. Galantamine has similar efficacy and tolerability to donepezil.

**Memantine**
One theory for the loss of neurons in Alzheimer’s disease is that neurons are damaged by excitotoxic injury induced by excess glutamate and overstimulation of N-methyl-D-aspartate (NMDA) receptors. Memantine is an NMDA receptor antagonist thought to have neuroprotective activity. It has a measurable but small effect on change in symptom severity, either when used alone or when given with an ACHI. Adverse effects include dizziness, confusion and constipation. Memantine is metabolized in the liver to inactive compounds. Cytochrome p450 enzymes are not involved.

**Cognitive enhancers**
There are four licensed drugs that might be considered cognitive enhancers, all of which are licensed for the treatment of Alzheimer’s disease. The ACHIs donepezil, rivastigmine and galantamine have remarkably similar therapeutic effects, all delaying deterioration by around 9 months. Memantine has similar efficacy. Rational prescribing involves using the highest tolerated dose and avoiding the concomitant use of anticholinergic drugs.

**Delirium**
Delirium is a common event in hospitals and is a frequent cause of confusion in elderly patients. Effective treatments include benzodiazepines, conventional antipsychotics, and newer antipsychotics such as risperidone and olanzapine. The benzodiazepine lorazepam is probably the drug of choice owing to its rapid onset and relatively short duration of action.

**Antidepressants**
These are medications effective in the treatment of major depressive disorders of moderate and severe degree, including depressive syndromes associated with physical illnesses. Patients with dysthymic disorder may also respond. The main classes include the TCAs and related compounds, the SSRIs, the SNRIs and the MAOIs (both selective and non-selective). Stimulants such as the amphetamines are not antidepressants but can elevate mood in normal subjects. St
John’s wort (*Hypericum perforatum*) is a widely used herbal remedy, with some MAOI activity, with efficacy in mild depression.70

The antidepressant actions of the MAOIs were discovered when patients with tuberculosis treated with iproniazid (related to isoniazid) became euphoric. The MAOIs are used infrequently and currently comprise phenelzine, isocarboxazid and tranylcypromine. They act by irreversibly blocking the enzyme monoamine oxidase in the brain and elsewhere. Tranylcypromine is closely related to the amphetamines and shares their stimulant properties. The blockade of MAO raises amine-type neurotransmitter levels in the brain and underlies the antidepressant and anti-anxiety actions, especially against phobic symptoms. The blockade also raises amine levels in the bowel. The well-known interactions with other amines and similar substances result from the MAO inhibition that prevents the breakdown of tyramine in ingested food such as cheese, broad-bean pods, pickled herring, and soya and meat extracts.71 This results in tyramine passing into the bloodstream and causing dangerous hypertensive crises. The other problem is interaction with indirect-acting sympathomimetics in cough and decongestant preparations, and with pethidine. These hazards can persist for 2–3 weeks after the MAOI is discontinued, as the inhibition is irreversible and new enzyme has to be synthesized.

To overcome this problem, reversible MAOIs have been developed. The only one extant is moclobemide, which is selective on only one form of the enzyme, MAO type A. It is much less likely to be associated with pressor responses, but it is not regarded as efficacious as the classic MAOIs.

The TCAs were also discovered serendipitously, this time in the search for antipsychotics following the advent of chlorpromazine. Imipramine, chemically similar to chlorpromazine, had no appreciable antipsychotic action but helped patients with depression, particularly those with biological features. A whole range of similar compounds were then developed, including amitriptyline, amoxapine, clomipramine, dosulepin (dothiepin), doxepin, lofepramine, and trimipramine. Related but non-tricyclic compounds are maprotiline, mianserin and trazodone. Their usage differs substantially between countries, and each prescriber has her or his favourite among the TCAs.

The mechanism of action was elucidated after the empirical clinical demonstration of efficacy.72 The main action of TCAs is to inhibit the reuptake of serotonin and noradrenaline (and, to a lesser extent, dopamine) from the synaptic cleft, back into the presynaptic neurons. Most TCAs affect serotonin disposition either on its own or in conjunction with noradrenaline. Sometimes, as with amitriptyline and clomipramine, the demethylated metabolite primarily blocks noradrenaline reuptake. Others, such as maprotiline and clomipramine, affect noradrenaline uptake alone. Bupropion (amfebutamone), licensed as an antidepressant in the USA but not in the UK, affects mainly noradrenaline and dopamine.

The TCAs are ‘dirty drugs’:73 they also have actions on cholinergic, alpha-adrenergic and histaminergic receptors, believed to be unnecessary for the antidepressant response. This results in anticholinergic side effects such as dry mouth, blurred vision, constipation and urinary retention; alpha-blocking effects with hypotension and dizziness, particularly in elderly patients (and priapism, especially with trazodone); and antihistaminergic effects, with sedation, sometimes profound. Other unwanted effects include sweating, hypotension and ECG changes. TCAs are dangerous in overdose: lofepramine is probably the safest of the group.74

The SSRIs and the SNRIs are direct descendants of the TCAs. When it became apparent that only the reuptake blockades were associated with antidepressant activity, the race was on for pharmaceutical companies to develop more selective compounds, thereby reducing side effects. The first group were SSRIs, starting with zimeldine (withdrawn because of neurotoxicity), followed by (in alphabetical order) citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. They are less sedating, have fewer or no anticholinergic effects and are less cardiotoxic than the TCAs.75 They can induce side effects such as nausea and diarrhoea, anorexia with weight loss, and heightened anxiety and sexual problems. As with other antidepressants, hypomania can be induced in susceptible patients. Because of changes in serotonin peripherally, platelet adhesion is decreased and bleeding may occur. The more common side effects such as nausea are clearly dose-related but tend to wane with continued use.

The SNRIs were developed with a similar rationale to the SSRIs, but with an additional claim that, as they acted selectively on two neurotransmitters, they would prove more effective than the SSRIs. This claim is still debated. The first introduction was venlafaxine, followed more recently by duloxetine.76 The side-effect profiles are similar to those of SSRIs, but the noradrenaline reuptake inhibition is associated at higher doses with a clinically significant rise in blood pressure. Concerns about the arrhythmogenic properties led to a temporary restriction on prescribing venlafaxine.77 Blood pressure should be monitored in all patients receiving SNRIs.

Reboxetine is a selective noradrenaline reuptake inhibitor with some anticholinergic-type side effects78 and may also increase blood pressure. Mirtazapine acts in a complex way and resembles mianserin; it is sedative and associated with definite weight gain.

Finally, the amino acid L-tryptophan, the precursor of serotonin, appears to benefit a few patients when given adjunctively to patients with treatment-resistant severe depression.79

It can be seen that the pharmacology of the antidepressants focuses on their actions on serotonin, noradrenaline and, to a minor extent, dopamine. Nevertheless, despite the establishment of efficacy in a range of disorders, the mode of action of these compounds remains unclear. Add to that the demonstration of efficacy in other disorders such as
anxiety, and our limited understanding becomes apparent. It is hardly surprising that a range of other biochemical mechanisms are constantly being explored to seek targets for novel drug actions – so far, with only limited success. Too often, a promising compound with an unusual putative mechanism of action fails to fulfil its promise in the clinic.

**Therapeutic issues**

The treatment of depression and other mood disorders is discussed in other chapters. We have selected some aspects that have particular relevance to the psychopharmacology of the antidepressants.

**Basic principles**

It is important to discuss at some length with the patient the diagnosis of depression and its implications, and the need for medication. The reasons for the particular choice of antidepressant should be explained. The likely outcome of the treatment should be estimated, without exaggerating the probability of a rapid and complete response. The possibility and type of unwanted effects should be outlined carefully without unduly alarming the patient.

The initial dose of a TCA should be such as to minimize unwanted effects and will usually need increasing as side effects wane. The SSRI dosage is usually an efficacious one from the start but may need increasing if the response is unsatisfactory. For a single episode, continue treatment for at least 4–6 months after apparent remission. For repeated relapse, longer-term or maintenance treatment may need to be considered. The early stages of drug administration need careful monitoring, especially in patients under the age of 30 years. Restlessness, agitation (a form of akathisia) and suicidality may ensue or increase. Dosage adjustments are then necessary. Dosages, particularly of paroxetine and venlafaxine, should be tapered off carefully. Even so, some withdrawal symptoms may supervene, so the patient should be forewarned.

**Children and adolescents**

This is a complex topic dealt with elsewhere.

**Elderly people**

Depression is particularly common in elderly people. Suicide is an especial risk and is a danger in socially isolated or recently widowed people. Most physical illnesses are more common in elderly people and are associated with an increased risk of depression. Examples include Parkinson’s disease, cardiovascular and respiratory diseases, and chronic pain, particularly joint pain, with its association of restricted movement. Elderly people are likely to be taking medication for their physical illnesses, with the consequent risk of increased adverse reactions and complex drug interactions.

The TCAs are often poorly tolerated in elderly patients, who are prone to develop troublesome symptoms such as dry mouth, blurring of vision, constipation, urinary retention and postural hypotension. SSRIs are tolerated better.

Treatment should be initiated at half the dose, but full doses may be needed. The risk of gastrointestinal or cutaneous bleeding may be increased, particularly in very elderly people. Sedative antidepressants should be monitored carefully, as confusion may ensue. Response often seems slower in elderly patients than in younger adults. Patients who have suffered repeated episodes may need indefinite treatment. Because of the likelihood of drug interactions in patients with physical disorders and treatments, reference should be made to the BNF drug interaction tables in order to avoid any complications of combined treatments.

**Refractory depression**

Refractory depression is a common problem in secondary care. A fair proportion of patients referred by general practitioners (GPs) to psychiatrists have failed to respond to the antidepressant initially prescribed. The choice of an alternative is already limited. Various protocols have been drawn up, some based on clinical experience, and a few based on the scant data that are available. Either switch or augmentation regimens can be used.

The switch protocols are essentially trial-and-error. On theoretical grounds, it should be advantageous to move to a different class of drug. The most common stratagem has been to switch to venlafaxine from an SSRI, with the rationale that it is better to influence two neurotransmitters rather than one. The evidence is by no means consistent.

Direct comparisons of the SSRIs and the SNRIs show very few significant differences. A few studies suggest that escitalopram is superior to citalopram and venlafaxine. Even fewer studies establish the superior efficacy of venlafaxine to the SSRIs. Dosage considerations may affect such comparisons.

Augmentation procedures have been available for a long time. They are sometimes based on animal studies, and the results in the clinic are less impressive. The best established is the addition of lithium, aiming for a serum level of 0.4–1.0 mmol/L. This is recommended by NICE, which also advocates ECG monitoring. Lithium needs careful monitoring of renal and thyroid function. Other augmentation regimens with some evidence to support them include triiodothyronine, bupropion, buspirone and mirtazapine. Non-drug treatments such as CBT are also worth considering.

**Long-term prevention (prophylaxis)**

Depression is a recurrent, episodic disorder. Over half of patients having a first episode will have a second attack, and most of those will go on to have a third and subsequent attacks. The risk of recurrence is increased in people with marked social problems and a family history. Chronic medical illness also increases the risk of recurrence.

Continued treatment with an antidepressant reduces the risk of recurrence by up to two-thirds. NICE has recommended that patients who have suffered two or more episodes of depression in the recent past, accompanied by significant functional impairment, should be kept on antidepressants for at least 2 years. Re-assessment may then
lead to even longer maintenance. The dosage used should be the same as that effective in the acute episode, unless there are troublesome unwanted effects such as sexual dysfunction.

Lithium has proven efficacy in preventing episodes of depression in patients with bipolar disorder but apparently less efficacy in patients with unipolar disorder.

Patients should be reassured that antidepressants are not addictive and maintain their efficacy over time. When the antidepressant is discontinued, a slow taper is recommended, although withdrawal symptoms may still occur.

**Psychotic depression**

Response rates to antidepressants alone in psychotically depressed patients are poor.\(^8^7\) It is generally recommended that a combination of an antipsychotic and an antidepressant be used. An atypical antipsychotic such as olanzapine or quetiapine is often preferred. ECT may be needed.

Whatever combination is used, care must be taken to avoid hazardous drug interactions.

**Conclusions**

The treatment of the more severe forms of depressive illness is a major part of the responsibilities of the psychiatrist. Although numerous medications have been developed and introduced since the MAOIs and TCAs were discovered over 50 years ago, the choices available are variations on the theme of increasing brain availability of serotonin, noradrenaline and perhaps dopamine. Although the newer drugs are generally tolerated better, there is no evidence that any material improvement in the efficacy of the antidepressants has occurred.

**Mood stabilizers**

This name is given to a group of drugs that comprise lithium and several agents used primarily as anticonvulsants. Their main use in psychiatry is to prevent both up-swings and down-swings of mood in patients with bipolar disorder.

**Historical aspects**

Lithium was used as a panacea in the nineteenth century but was rediscovered in the 1940s by Cade for use in psychotic disorders. Because of difficulties in establishing its efficacy in long-term prophylaxis of mania and its undoubted toxicity, it was slow in being accepted by prescribers. Eventually schedules for its use were introduced, and it is now regarded as a useful but problematic drug.

A series of anticonvulsants were introduced into psychiatric practice, including carbamazepine, valproate compounds, lamotrigine and topiramate. Antipsychotic drugs are also used in acute mania.

**Lithium**

This simple cation is used to prevent and to treat mania and hypomania, recurrent depression and bipolar disorder in general. Its use in mania is limited by the slow onset of action\(^8^8\) and by the possibility of potentiating the EPSEs of antipsychotic medication. Lithium is also used to augment antidepressant medication in patients with depression who appear refractory.

The most firmly established indication for lithium is in the prophylaxis of bipolar affective disorder, where it reduces both the frequency and the severity of relapses, particularly into mania.\(^8^8,8^9\) The number needed to treat (NNT) in order to prevent relapse into mania has been estimated as 10 and into depression as 14.

A set of tests is essential before prescribing lithium – renal, thyroid and cardiac function. Reliable contraception is essential in women of childbearing potential. Patients should be prepared carefully for lithium therapy and should be told about the need for regular therapy, the signs and symptoms of incipient toxicity, the necessity of avoiding dehydration, and the need to keep constant the salt intake in the diet. Potential drug interactions should be outlined.

The efficacy of lithium has been the subject of numerous studies, including an appraisal by NICE.\(^9^0\) As well as reducing the risk of relapse into an affective episode, lithium reduces the likelihood of a hypomanic upsurge with antidepressant medication. In combination with valproate, it may reduce the frequency of rapid cycling, which is usually defined as a bipolar disorder in which four or more episodes of mania or hypomania occur in a year. It can be difficult to manage and may necessitate change of the antidepressant as well as a trial of mood stabilizers. NICE recommends that a mood stabilizer should be prescribed prophylactically:

- after a single severe manic episode;
- after two or more episodes of mania;
- in recurrent hypomania characterized by significant risk of suicide, functional impairment or high rate of relapse.

Lithium is generally recommended as a first-line measure. It is not possible to predict responders with any degree of accuracy, so trial of therapy with careful monitoring must be resorted to. Patients with mania rather than depression as the dominant feature tend to respond better than those with the reverse pattern.

Abrupt discontinuation of lithium may be followed by an increased rate of relapses during the ensuing few months.\(^8^1\) Tapering over a month has been clearly shown to help. Accordingly, instituting of lithium therapy should not be undertaken without careful consideration of the risk/benefit ratio right through to eventual discontinuation. Perhaps the main benefit in bipolar illness is the reduction of suicide risk to the general population level.\(^9^1\)

Lithium is the main psychotropic drug that is monitored routinely. Blood is taken 12 h after the last dose. After lithium is started, a plasma level should be estimated after 4–7 days and then weekly, until a stable level has been attained. It should then be checked every 3 months. If the dose has to be adjusted, more frequent estimations should be carried out. Plasma levels of 0.6–1.0 mmol/L are usually
recommended. The purpose of the monitoring is both to keep the level in the therapeutic range and to avoid toxicity. Adverse effects are related to bodily levels and increase rapidly above 1 mmol/L. The most common mild symptoms are thirst, polyuria day and night, and fine hand tremor. Psoriasis may be aggravated. In long-term use, thyroid function may be depressed. Hyperparathyroidism may also ensue, so that monitoring of calcium may be advisable. A subjective complaint in patients taking lithium is that they feel dulled: objective impairment of memory can be demonstrated.

The relationship of renal impairment to long-term lithium therapy remains controversial. A small number of such patients develop interstitial nephritis, with reduction in renal function of clinical significance. The nephrogenic diabetes insipidus with polyuria that develops early in treatment may later become irreversible.93

Lithium toxicity is often overlooked, as it can ensue insidiously. There is increasing anorexia and diarrhoea, muscle twitching, drowsiness and ataxia. If the level exceeds 2 mmol/L, seizures may occur and forced diuresis may be indicated. Neurotoxicity with memory disturbance may become irreversible.94

**Carbamazepine**

This compound is an anticonvulsant and is also used to treat trigeminal neuralgia. In psychiatry it is licensed as a second-line prophylactic in bipolar illness. It has also shown efficacy against the acute symptoms of mania. It is generally considered to be less effective than lithium, and NICE considers it to be a third-line treatment.90 If its use is imperative, women should be counselled before valproate is prescribed. Adequate contraception should be used and folate prescribed as a precaution. Unfortunately, if treatment of recurrent mania is ineffective, sexual disinhibition can be one of the first signs of relapse.

**Valproate**

Various forms are available – sodium valproate, valproic acid and semi-sodium valproate (Depakote™). The last is licensed for the treatment of acute mania but is widely used prophylactically in bipolar affective disorder, for which the evidence is less compelling.

Adverse effects are common. Gastric irritation and intense nausea can be a problem; higher doses may be associated with confusion and lassitude. Weight gain may be a nuisance. Women complain of hair loss, but the regrowth is curly! Children on complex regimens that include valproate are at remote risk of fulminating hepatic failure. Blood dyscrasias and pancreatitis have also been documented. Keeping plasma levels below 100 mg/L has been recommended to minimize side effects, and some formulations have smoother plasma level curves after ingestion than do others.

Valproate is regarded as a teratogen. NICE recommends that it should not be used routinely in women of childbearing age.90 If its use is imperative, women should be counselled before valproate is prescribed. Adequate contraception should be used and folate prescribed as a precaution. Unfortunately, if treatment of recurrent mania is ineffective, sexual disinhibition can be one of the first signs of relapse.

**Other treatments**

It seems that every new anticonvulsant sooner or later is tried in affective disorder. Lamotrigine is an example, but intriguingly it seems better in preventing relapse of bipolar depression than of mania.95

Topiramate96 and oxcarbazepine97 are also tried on occasion, usually as add-on therapy. There are limited trial data to support their efficacy.

Some patients are maintained long term on more than one mood stabilizer. Such a regimen can be established only empirically. Antipsychotic drugs are used routinely both to treat acute phases and in the long term. Clozapine is established as a treatment for refractory mania.98

**Anxiolytics and hypnotics**

These groups of drugs are discussed together as their use is dictated by custom rather than by their pharmacology. However, differences in pharmacokinetic properties do play some part.

The term ‘sedative’ originally meant allaying anxiety, but it now has the connotation of causing unwanted drowsiness. Instead, the terms ‘anxiolytic’ and ‘(minor) tranquillizer’ are now used to describe drugs that lessen anxiety, and the term ‘hypnotic’ is applied to medications taken at night to induce sleep. A range of substances, including alcohol, bromides, chloral hydrate and paraldehyde were used in the nineteenth century as both sedatives and hypnotics, but they were supplanted by a range of barbiturates in the twentieth century. These were effective but caused oversedation and confusion, were prone to be abused and were dangerous in overdosage. In turn, they were replaced by first meprobamate and then by numerous benzodiazepines from the 1960s onwards. Very popular at first, the benzodiazepines were found to be associated with cognitive and psychomotor impairment, particularly in elderly patients. Their use was curtailed, but they are still used extensively.
The mode of action of the benzodiazepines is to potentiate the inhibitory neurotransmitter GABA by binding to specific receptors. This can reduce the turnover of several neurotransmitters such as noradrenaline and serotonin. The main sites of action of the benzodiazepines are in the spinal cord, where they mediate muscle relaxation, the brainstem, the cerebellum, causing ataxia, and the limbic and cortical areas involved in emotional experience and behaviour. The benzodiazepines vary in their profile and activity; for example, clonazepam has more anticonvulsant properties than most.

A benzodiazepine antagonist, flumazenil, is available. It binds to benzodiazepine receptors and prevents the actions of benzodiazepines. It can be used to reverse benzodiazepine overdosage. Finally, benzodiazepine inverse agonists have been described that have the opposite effects from those seen in benzodiazepines, being pro-convulsant and anxiogenic.

In normal individuals, the depressant effects of single and repeated doses of benzodiazepines can be detected easily, as they cause dose- and time-related cognitive and psychomotor impairment. Saccadic eye movements are disrupted and short-term memory is disorganized.

It would seem logical to use long-acting benzodiazepines as anxiolytics, reserving shorter-acting ones for hypnotic use. For complex historical reasons, however, this is not so, and anxiolytic benzodiazepines vary greatly in their duration of action. In the clinic, benzodiazepines reduce generalized anxiety and muscle tension and induce sleep. They also cause detectible cognitive and psychomotor impairment and subjective sedation. Careful testing shows that, although the subjective sedation subsides as tolerance sets in after a few days, the objective impairments may persist into the longer term, showing that tolerance is system-specific. In parallel, the electroencephalogram (EEG) fast beta activity that is increased by benzodiazepines persists. An additional complexity is that anxious and insomniac patients tend to perform poorly anyway. Anxiolytic/hypnotic treatment will improve that performance, so the depressant effects of the benzodiazepines will tend to be obscured by their beneficial effects. As the benefit wanes when tolerance sets in, only the impairments remain.

Because of these changes over time, it is widely recommended that the use of benzodiazepines be restricted to 4 weeks as anxiolytics and 2 weeks as hypnotics. These injunctions are largely ignored by some prescribers, who advertently or inadvertently allow the usage to become chronic, with the risk of withdrawal and dependence problems. Benzodiazepines do not have antidepressant properties. Concern that they may even induce depression is probably misplaced; however, as they lessen anxious symptoms in patients with both anxiety and depression, the depressive symptoms come to the fore. Concerns that benzodiazepines interfere with psychological processes such as bereavement or impede CBT are not supported by evidence.

NICE recommends that the benzodiazepines should not be used in panic disorder and found no evidence for their short-term use as adjunctive treatment with antidepressants in managing depression. Benzodiazepines such as lorazepam are used in conjunction with antipsychotic medication to sedate acutely disturbed psychotic patients and appear to have a potentiating action. Longer-term usage in psychotic disorders is not established.

Unwanted effects
As well as the sedative effects outlined above, ataxia, dysarthria, blurred vision, headache and gastrointestinal upset can occur. Psychiatric side effects include memory disturbances, which are strongly dose-related. Elderly people are particularly at risk, and the effects can be so profound as to lead to the apparent worsening of cognitive decline. Withdrawal of the medication leads to resolution of the effects. One particular concern is impairment of driving performance, which can have legal implications. Another concern is that the risk of hip fractures in old people taking benzodiazepines is increased by at least 50 per cent.

Another unwanted effect with possible legal complications is paradoxical excitement. This disinhibitory effect of the benzodiazepines can cause increased anxiety, acute excitement and hyperactivity. Aggressive impulses may be released with hostility and rage; criminal acts such as assault and rape have been documented. Estimates of incidence range from less than 1 per cent to at least 20 per cent, depending on the patient sample. High-risk patients include those with borderline personality disorders, impulse control disorder and alcohol problems. The combination of a benzodiazepine and alcohol is particularly prone to lead to paradoxical reactions. The patient may have complete or partial amnesia for the event, such as an episode of ‘air-rage’. Intravenous administration of high doses of high-potency benzodiazepines poses an enhanced risk.

Dependence and withdrawal
Withdrawal symptoms from the benzodiazepines can ensue after 4–6 weeks of use, but only in about 20–30 per cent of patients. The reasons why some patients can withdraw with impunity after even years of continuous use while others undergo agonies remains unclear. Dosage reduction and complete withdrawal can result in withdrawal symptoms. These include physical symptoms such as muscle tension, spasm and weakness, ‘pins and needles’ and flu-like symptoms. Perceptual hypersensitivity and depersonalization are common. Anxiety and insomnia may increase, nightmares may wake the patient, memory and concentration may be impaired, and depressive symptoms may ensue. Occasionally, fits or a paranoid psychosis may occur. The symptoms come on within two to three half-lives of the particular benzodiazepine and subside within a few weeks. Some patients claim that their symptoms have persisted for months or indefinitely.
Simple advice given by the GP can be quite effective.\textsuperscript{107} Withdrawal schedules are available widely and involve tapering, usually after substituting diazepam.\textsuperscript{108} The rate of taper is based not on good evidence but on the clinical experience of the prescriber. Psychological therapies or support groups should be used during the period of withdrawal. Once the patient has experienced withdrawal problems, they should not be prescribed a benzodiazepine again.

Dependence and withdrawal should be distinguished from addiction and abuse, in which the individual ingests large amounts of benzodiazepines. This can be part of poly-drug abuse or an extension of prescribed sedative medication that has got out of hand.

Overdosage is common but not usually dangerous.

\textbf{Other anxiolytics}

Buspirone is the only available member of the azapirone compounds and is a partial 5-HT\textsubscript{A} agonist. It is a reasonably effective anxiolytic in general, but its onset of action is delayed.\textsuperscript{109} It is relatively ineffective in patients with extensive prior experience of benzodiazepine treatment. Side effects include headache, dizziness and nausea. It is not associated with sedation, tolerance or withdrawal problems.

Hydroxyzine is an antihistamine/anticholinergic drug with some anxiolytic properties.\textsuperscript{110} A recent introduction is pregabalin. This compound was already licensed to treat neuropathic pain and some forms of epilepsy. It binds to the alpha-2-lambda subunit of voltage-gated calcium channels in the CNS. It has proven efficacy in generalized anxiety disorder in clinical trials.\textsuperscript{53} It has a low incidence of side effects such as dizziness, somnolence and dry mouth. Tolerance, dependence and addiction potential are low. It reduces neurotransmitter release.

The drug treatment of choice in the anxiety disorders is the SSRI/SNRI group of drugs.\textsuperscript{100} Antipsychotic drugs are favoured by some, but no firm evidence backs their use. Beta-blockers are still used by some primary care practitioners, but this use is not evidence-based.

\textbf{Hypnotic treatments}

Before prescribing a hypnotic short-term, ‘sleep hygiene’ measures should be recommended to the patient. These include daily exercising (afternoon is optimal), avoiding napping during the day, reducing alcohol and caffeine intake, ensuring regular sleep habits, and instituting anxiety-management/relaxation techniques.

A range of hypnotic benzodiazepines are available. The ‘Z-drugs’ – zopiclone, zolpidem and zaleplon – are essentially short- or very short-acting benzodiazepine-like drugs.\textsuperscript{111} The short duration of action confers some advantages, such as lack of daytime sedation, but they are inappropriate for patients with early-morning awakening.\textsuperscript{112} They probably have less propensity to rebound and withdrawal problems than benzodiazepines of equivalent duration of action. Addiction has been documented on occasion.\textsuperscript{113}

Whatever hypnotic is chosen, it should be given at the lowest effective dose for no more than 2 weeks. Usage on an intermittent basis is desirable. Withdrawal should be slow. It is doubtful whether the risk/benefit ratio is favourable in elderly patients.\textsuperscript{114}

Melatonin has a long tradition of being used to induce sleep. A sustained-release preparation (Circadin\textsuperscript{109}) is available for use in insomniac people aged over 55 years.\textsuperscript{115}

Sedative antidepressants such as amitriptyline and trazodone are prescribed to help induce sleep.\textsuperscript{116} Sedative antihistamines are also available over the counter but can cause troublesome residual sedation the next morning. Other over-the-counter herbal remedies include valerian and hops.\textsuperscript{117}

Finally, as with treatment of anxiety, CBT has been adapted to treat insomnia but is not widely available.

\textbf{Stimulants}

These drugs have few recognized indications and should not be used to treat depression, obesity, debility or fatigue. The amphetamines such as dexamfetamine can cause dependence and psychoses and are widely abused. Some patients with narcolepsy may derive benefit. The amphetamines and methylphenidate can be used as first-line treatment in attention deficit hyperactivity disorder (ADHD). Atomoxetine is also recommended by NICE as part of a comprehensive treatment programme in children.\textsuperscript{116} Side effects include insomnia, restlessness and excitability. Anorexia and growth retardation can occur. Other side effects include dry mouth, sweating, tachycardia, palpitations and hypertension. Methylphenidate has been linked to allergic reactions and blood dyscrasias.

Adult ADHD remains a controversial diagnosis, but some children with ADHD continue to show symptoms into adulthood. The efficacy of stimulants has not been established in adults, so their use should be circumspect, especially in patients with a history of drug problems.

Modafinil is used to treat patients with narcolepsy, but its use in other indications such as depression remains experimental.\textsuperscript{119} Caffeine is a weak stimulant that is an ingredient of many analgesic preparations. Withdrawal can be followed by a headache, which can be severe.

\textbf{Drugs used in substance dependence}

Disulfiram is indicated as an adjunct in the treatment of chronic alcohol dependence.\textsuperscript{120} It inhibits aldehyde dehydrogenase, leading to interruption of alcohol metabolism at the acetaldehyde stage. This causes unpleasant symptoms such as facial flushing, throbbing headache, palpitations, nausea and vomiting. After large amounts of alcohol, the reaction can be severe, with collapse. Disulfiram reduces
the number of drinking days but does not increase total abstinence.

Acamprosate is a taurine derivative that interacts with GABA systems. It somewhat reduces relapse to alcohol use.\textsuperscript{121} It is contraindicated in renal and hepatic failure. Side effects mainly involve the gastrointestinal system, with diarrhoea, nausea and vomiting.

Alcohol withdrawal can be facilitated by substitution and then tapering of a benzodiazepine such as chlordiazepoxide or with clomethiazole.\textsuperscript{122}

Bupropion is licensed as an adjunct to smoking cessation. It is a tricyclic-type antidepressant primarily affecting the reuptake of dopamine. It approximately doubles the success rate in people trying to cease smoking and lessens significantly the severity of withdrawal symptoms.\textsuperscript{123} It is contraindicated in patients with a history of seizures. Insomnia, dry mouth and headache are common side effects.

Varenicline is a partial agonist at the nicotinic acetylcholine receptor. It is more effective than bupropion, but it also causes nausea.\textsuperscript{124} It has recently been licensed in Europe and introduced into the UK.

Nicotine-replacement therapy is available over the counter, and a range of preparations are available. It increases the rate of achieving smoking cessation by up to two-fold.\textsuperscript{125} Dosage is self-adjusted and varies according to the degree of dependence.

Opioid dependence

Treatment of this condition is usually initiated by specialist staff after a comprehensive assessment. Methadone (full agonist) or buprenorphine (partial agonist) can be substituted for the illicit opioid, usually diamorphine (heroin).\textsuperscript{126} Maintenance regimens need careful monitoring and may go on for long periods of time. Overdoses, deliberate or accidental, are frequent, and naloxone is indicated in short-term management. Monitoring should be continued for some time and doses repeated as necessary. Naltrexone has been advocated as an opioid antagonist for long-term use, but debate continues as to its effectiveness.\textsuperscript{127} It can cause severe withdrawal reactions in current opioid users, who must be detoxified first.

The problem common to management of these conditions is that patients inform doctors of their usage of alcohol and opioids, and their estimates are notoriously unreliable and misleading. The prescriber should always err on the side of caution in evaluating both the misuse of the drug involved and the patient’s report of the effectiveness of any treatment. For example, a misuser may exaggerate opioid usage when methadone is being substituted, which can lead the unwary prescriber into prescribing potentially harmful amounts.

PREScribing IN PREGNANCY

The prescribing of psychotropics in pregnancy presents numerous difficulties.\textsuperscript{128} Investigation of the teratogenic effects of drugs is limited to experiments in laboratory animals. For ethical reasons, trials are not conducted in humans. Thus, assessment of teratogenic potential is based on animal studies of dubious benefit and informal observations of pregnancy outcomes in women taking drugs in clinical practice. For many older drugs, teratogenic potential is reasonably well defined: valproate and carbamazepine are highly teratogenic, whereas older antipsychotics and antidepressants appear to have very limited or no effect on the developing fetus. Despite this knowledge, prescribers in the UK have been shown to take few precautions when prescribing potentially teratogenic drugs to women of childbearing age.\textsuperscript{129}

When prescribing in pregnancy, the balance of risks needs to be considered and discussed with the patient. On one side, there is the risk of harm to the fetus (often poorly quantified) caused by the use of effective drugs; on the other side, there is the risk of relapse presented by cessation of drug treatment by switching to alternative treatments. No general guidelines can be given, and each individual case should be treated as such. Always consult the latest information regarding pregnancy risk, as this changes very rapidly. It should be remembered that no drug is proven to be safe in pregnancy.

ADVERSE DRUG REACTIONS

Adverse drug reactions are classified as augmented or predictable (type A) or qualitatively bizarre or unpredictable (type B).

Type A reactions are predicted by a drug’s pharmacology and are usually the result of an exaggerated but otherwise normal pharmacological action. Examples in psychiatry include sedation seen with benzodiazepines and some antipsychotics, extrapyramidal reactions to conventional antipsychotics, and nausea and diarrhoea seen with cholinesterase inhibitors. Note that type A reactions can occur as a result of both the therapeutic pharmacological action and other pharmacodynamic actions (e.g. H\textsubscript{2} antagonism, antimuscarinic activity). Type A reactions are dose-dependent, their incidence is high (relative to type B reactions) and mortality is low.

Type B reactions cannot, at least initially, be predicted from a drug’s known pharmacological actions. These reactions are usually not dose-related and occur within the recommended dose range. Type B reactions may involve genetic causes (e.g. glucose-6-phosphate dehydrogenase (G6PD) deficiency) or immunological mechanisms and are said to be idiosyncratic. The frequency of type B reactions is usually so low that their possibility may not be detected during pre-marketing screening tests and trials. Morbidity and mortality are relatively high. Examples in psychiatry include agranulocytosis with clozapine, toxic epidermal necrolysis with carbamazepine, and neutropenia with mianserin.
Reporting adverse drug reactions

In the UK, the Medicines and Healthcare Products Regulatory Agency (MHRA) organizes the Yellow Card Reporting Scheme. The MHRA monitors the safety of licensed drugs by collecting and collating spontaneous reports of suspected adverse reactions submitted by health professionals and members of the public. Reporting may be completed online at http://yellowcard.mhra.gov.uk or by using yellow cards available in all editions of the BNF. For new drugs (signified in the BNF by the black triangle symbol ▼), all suspected adverse reactions should be reported. In this context, ‘serious’ is defined as reactions that are fatal, life-threatening, disabling, incapacitating, resulting in or prolonging hospitalization, or otherwise medically significant.

MEDICATION ERRORS

Medication errors occur in the prescribing, dispensing and administration of drugs. They are a source of considerable patient morbidity and mortality. Prescribing errors are broadly divided into two categories: errors in the decision-making process and errors in writing the prescription. Decision-making errors include prescribing a drug to which the patient is allergic, prescribing two drugs for the same indication, and prescribing too low or too high a dose. Prescription-writing errors are usually ‘slips of the pen’, such as mistranscribing from previous charts, prescribing without stating dose or frequency, and omitting other data such as start date or patient name. Both types of error are fairly common in psychiatry in the UK: one study found errors in almost 1 in 40 prescriptions written.130

Decision-making errors can be reduced by ensuring thorough knowledge of each prescribed drug’s dosage regimen, therapeutic indication, adverse effects and drug interactions. Many prescribing errors relate to drugs with which the prescriber is unfamiliar (e.g. general medical drugs prescribed by psychiatrists). Prescription-writing errors are avoided or reduced in number by careful checking for accuracy and completeness of the prescription. Both types of error can be made less likely by the use of electronic prescribing systems, which prevent the use of unlicensed doses and automatically ensure completion of the prescription.

POISONING WITH PSYCHOTROPIC DRUGS

Assessing the possibility that an individual has been poisoned, and identifying that poison, requires systematic detective work by the practitioner. Poisoning can be accidental or deliberate, either self-poisoning or with criminal intent. Clues include suicide notes and the circumstances in which the individual presents; clinical clues are often non-specific. The latter is quite important, as some psychotropic drugs have antidotes, such as naloxone for opioid poisoning and flumazenil for counteracting benzodiazepines. These can also be used as diagnostic tests.

All patients in which poisoning is suspected should be examined in hospital and usually admitted. This applies particularly to drugs with delayed action such as aspirin, paracetamol and TCAs. These are often resorted to by suicidal patients, as they are easily obtainable or at hand.

Most patients can be treated only symptomatically. Respiration may be depressed, for example with barbiturates, benzodiazepines and TCAs. Assisted ventilation may be necessary, but respiratory stimulants are potentially dangerous.

CNS depressants can lower blood pressure, so the patient should be given oxygen to correct any hypoxia and fluid replacement initiated. Some stimulants, such as amphetamines, cocaine and MAOI interactions, may induce a rise in blood pressure. Cardiac conduction defects may follow TCA or phenothiazine antipsychotic overdoses; specialist advice may be needed. These drugs can also induce hypothermia. Conversely, rises in temperature may follow stimulant overdose or occur in neuroleptic malignant syndrome. Appropriate vigorous remedial measures are required.

Convulsions may occur in TCA overdoses or following bupropion. Lorazepam or diazepam should be given intravenously if the fits persist.

Removal of the poison from the stomach is not useful if the drug has been ingested an hour or more earlier. CNS drug overdoses cause drowsiness or coma, so the airway must be protected. Induction of vomiting should not be attempted. Activated charcoal can bind many drugs in the stomach, preventing their absorption.

Many psychotropic drugs are formulated in delayed- or prolonged-release versions. This can pose particular problems, as drug concentrations in the body can remain high for some time.

Active elimination specialist techniques include haemodialysis for lithium poisoning and haemoperfusion for barbiturate overdoses.

Specific psychotropic drugs

Opioids cause coma and respiratory depression.131 Pinpoint pupils are the give-away. Naloxone is a specific antidote but will need to be repeated as it has a short half-life relative to most opioids. Compound analgesics often contain paracetamol, which may cause delayed hepatotoxicity.

Antidepressants in overdose cause a range of serious effects, including coma, respiratory depression, cardiac conduction defects with arrhythmia, and fits. The TCAs are much more likely to induce such effects than the SSRIs.132 Metabolic acidosis may complicate the picture. Symptomatic management in hospital is advisable. Diazepam may calm the delirious patient. MAOI overdose is
uncommon, but tranylcypromine acts like an amphetamine-type stimulant.

Anxiolytics and hypnotics can cause drowsiness, coma, respiratory impairment, hypotension and hypothermia. Barbiturates and meprobamate are much more dangerous than the benzodiazepines. The combination with alcohol is particularly hazardous. Flumazenil can be used to reverse benzodiazepine poisoning, but it may induce fits in physically dependent patients.

Lithium poisoning is usually seen in long-term therapy, where the excretion of the drug is reduced because of dehydration (e.g. in exceptionally hot weather) or impairment of renal function and co-administration of diuretics (or other drugs that interact). Acute lithium overdoses are actually less dangerous. Severe poisoning is associated with vomiting, diarrhoea, ataxia, convulsions, coma and renal failure. The last in particular is an indication for haemodialysis. Irreversible neurotoxicity can occur otherwise.

Phenothiazines and other antipsychotics may cause some depression of consciousness and respiration. Dystonic reactions may ensue and respond to anticholinergic drugs. Arrhythmias need specialist evaluation.

LEGAL ASPECTS OF PRESCRIBING DRUGS

Classes of medicinal product

The Medicines Act 1968 defines three classes of medicines:

- General Sales List (GSL) medicines
- Pharmacy (P) medicines
- Prescription-only medicines (POM).

GSL medicines may be bought from a wide range of retail outlets under certain conditions. GSL products are usually small quantities of oral medicines such as paracetamol and ibuprofen. Pharmacy medicines may be sold only in a registered pharmacy under the supervision or personal control of a registered pharmacist. Prescription-only medicines may be supplied only in accordance with a prescription by an appropriate prescriber (e.g. registered medical practitioner, veterinary surgeon, dentist, nurse prescriber, pharmacist prescriber).

Controlled drugs

The Misuse of Drugs Act 1971 (as amended) controls the use of controlled drugs. The use of controlled drugs in medicine is governed by the Misuse of Drugs Regulations 2001. Individual controlled drugs or drug preparations are classified by five schedules, outlined below.

Schedule 1 (CD Lic)

Schedule 1 drugs are those that have virtually no clinical utility and for which a Home Office licence is required in order to be lawfully in possession. Examples include LSD, ecstasy and cannabis. Doctors, nurses and pharmacists are not permitted to possess these drugs unless properly licensed by the Home Office.

Schedule 2 (CD POM)

This includes most opiates (morphine, methadone), stimulants (amphetamine) and some barbiturates. These drugs may be supplied only against a properly written prescription (see below).

Schedule 3 (CD No register POM)

These are similar to Schedule 2 drugs but are considered less harmful or less likely to be misused (e.g. buprenorphine, midazolam, temazepam, phenobarbital). Storage and record-keeping requirements differ, but prescription requirements are the same as for Schedule 2 drugs.

Schedule 4 (CD Benz POM and CD Anab POM)

Schedule 4 includes most benzodiazepines, anabolic steroids and growth hormones. Controlled drug prescription handwriting regulations do not apply.

Schedule 5 (CD Inv or CD Inv POM)

These are preparations containing small quantities of certain opiates (e.g. co-codamol; co-codaprin). Many are P medicines. CD Inv POM preparations are exempt from controlled drug prescription-writing regulations.

Controlled drug prescriptions

Prescriptions for Schedule 2 and 3 controlled drugs must be written in a certain way. In fact, it is unlawful even to issue a prescription for a controlled drug unless the following requirements are met. The prescription must:

- be signed by the prescriber;
- be dated;
- be indelibly written or printed;
- include the prescriber’s address (unless to-take-away (TTA) medication);
- specify the dose to be taken;
- specify the form and strength of preparation;
- specify the total quantity or number of dosage units in both words and figures;
- specify the name and address of the intended recipient;
- in the case of a quantity intended to be dispensed in instalments, contain a direction regarding the amount and frequency of intended dispensing.

There is now no longer a requirement for the prescription to be in the prescriber’s handwriting, but it must be signed clearly by the prescriber.

Prescriptions for controlled drugs (including temazepam, midazolam and Schedule 4 drugs) are valid for 28 days from the date of issue. Although not a legal requirement, it is strongly recommended that the quantity prescribed should not exceed 30 days’ supply.
USE OF UNLICENSED MEDICINES

Regulatory authorities issue marketing authorization and a product licence to a drug formulation after consideration of evidence relating to efficacy and safety. The product licence stipulates the conditions to be treated and the doses allowed. The prescribing of a licensed drug for conditions other than those stated, or at doses beyond those stipulated, is known as ‘off-licence’ or ‘off-label’ prescribing.

Some medicines used in the UK do not have a formal UK product licence. Examples include drugs licensed outside the UK (ziprasidone, melperone) and UK-licensed drugs available in formulations without a product licence (e.g. buccal midazolam, certain liquid preparations of methadone, sulpiride). These are unlicensed medicines. The prescribing of unlicensed medicines and off-label prescribing require special consideration, not least because accountability for any adverse consequences may lie with the prescriber rather than the manufacturer in such cases.

Prescribing unlicensed medicines

When prescribing an unlicensed medicine, the prescriber should:

- be satisfied that there is no alternative licensed medicine that would meet the patient’s needs;
- be satisfied that there is a sufficient evidence base or experience of using the medicine to assure its safety and efficacy;
- take responsibility for prescribing the unlicensed medicine and for overseeing the patient’s care, including monitoring and follow-up;
- record the medicine prescribed and the reasons for doing so.

When prescribing off-label, the prescriber should:

- be satisfied that it would better serve the patient’s needs than an appropriately prescribed licensed medicine;
- be satisfied that there is sufficient evidence base or experience in using to assure efficacy and safety (this is likely to involve sources other than the manufacturer’s information);
- take responsibility for prescribing the medicine and for overseeing the patient’s care, monitoring and follow-up or arrange for another doctor or prescriber to do so;
- make a clear, accurate and legible record of medicines prescribed and the reasons for prescribing.

When prescribing unlicensed drugs or off-label, patients should be provided with sufficient information to enable them to make an informed decision. This information would normally include an explanation for off-label prescribing or for prescribing an unlicensed preparation. However, where current practice clearly supports the use of a medicine, it may not be necessary to draw attention to the licence. Examples include the use of sodium valproate in bipolar disorder and the use of certain antipsychotics in nonschizophrenic psychosis or mania.

CONCLUSIONS

This chapter has concentrated on the pharmacological attributes of the numerous drugs used in psychiatry that have their action on the brain. The prescriber should ask the questions set out in Box 57.2; if the prescriber does not know the answers, then they should find out from a larger textbook or the BNF.

Box 57.2 Basic knowledge about a drug

- Drug name: generic or brand (trade, proprietary) name?
- Drug class: e.g. antidepressant
- Drug subclass: e.g. SSRI, dopamine antagonist
- What is its broad mechanism of action?
- Indication: why is the drug being prescribed?
- Is this a licensed indication?
- Is this a scheduled drug?
- Route: e.g. oral, parenteral. Is the drug absorbed efficiently in this modality?
- Elimination: how is the drug eliminated? Are there any active metabolites?
- Are the pharmacokinetics influenced by age or ethnicity?
- Dose: especially dosing intervals and factors that might influence this, such as age and coexistent physical conditions
- Monitoring: does the drug need regular monitoring to optimize the risk/benefit profile? Can it aid compliance?
- Duration of treatment: what is the minimum? What is the maximum?
- Could long-term use risk dependence?
- Adverse effects: what are the most common? Which are serious?
- Interactions: does the drug interact with other drugs?
- Patient factors: what should I tell the patient or carers?
- Patient information: are there dependable leaflets available?

Actual management of various disorders lies outside our remit. Reference should be made to other chapters in this book, to NICE guidelines, and to treatment guidelines drawn up by the British Association for Psychopharmacology. The last deal with the drug treatment of depression, bipolar disorder, substance misuse, anxiety disorders, dementia and ADHD.

KEY POINTS

- The study of pharmacokinetics involves observations of what happens to drugs once administered.
● The use of therapeutic drug monitoring of a particular drug requires that its plasma levels should be clearly related to its therapeutic or adverse effects.
● Pharmacodynamics refers to the effect of a drug on biological mechanisms. In psychopharmacology it is specifically to the brain.
● Receptors are complex protein structures, often with different types of sub-units upon which act a large number of neurotransmitters.
● There are two broad groups of antipsychotics: conventional (typical) or first generation drugs; and those termed atypical or second generation.
● Anticonvulsant drugs have an extremely wide range of chemical structures and have a correspondingly wide range of actions and adverse effects.
● Three acetylcholinesterase inhibitors are in widespread use in the UK, as is a drug with multiple actions memantine.
● The main classes of antidepressants include the tricyclic antidepressants (TCAs) and related compounds; the selective serotonin re-uptake inhibitors (SSRIs); the serotonin norepinephrine re-uptake inhibitors (SNRIs); and the monoamine oxidase inhibitors (MAOIs), both selective and non-selective.
● Mood stabilizers are a group of drugs that comprise lithium and several agents used primarily as antidepressants: they prevent both upswings and downswings of mood in bipolar patients.
● Long-acting benzodiazepines are appropriate as anxiolytics, shorter-acting ones as hypnotics: short-term use lessens the risk of dependence.

INTRODUCTION

Electroconvulsive therapy (ECT) is the electrical induction of the type of generalized cerebral seizure associated with a tonic-clonic convulsion, with the aim of treating an abnormal mental state or neurological disorder. Efficacious treatment requires a series of inductions given two or three times a week. The history of convulsive therapies in psychiatry is not to be confused with the history of the use of electricity in medicine. It was Cerletti, later aided by Bini, who developed the means of electrical induction that proved both safer and more reliable than chemical methods of inducing convulsions; the first patient, a man suffering from schizophrenia, was treated in Rome in 1938 and was eventually discharged from hospital in remission. Modern ECT is now modified: it is given under general anaesthesia and with drug treatment to reduce the extent of the convulsion.

MODE OF ACTION

Seminal studies

Almost three decades ago, Kendell reviewed the seminal studies on the mode of action of ECT and concluded that there was compelling evidence that the induction of generalized seizure activity in the brain was the crucial therapeutic element. He acknowledged that several studies had flaws in design that were typical of studies of that time, but two studies still merit particular mention. The first is important in the history of convulsive therapies. Laurell conducted a randomized controlled trial of two different types of convulsive therapy in endogenous depression. One of the convulsive therapies was ECT, and the other fluorothyl convulsive therapy, where induction was by inhalation of a convulsant gas. ECT and fluorothyl convulsive therapy were equally efficacious.

Ottoisson conducted an ingenious experiment to investigate how a modification to the extent of cerebral seizure activity affected the clinical efficacy of ECT in the treatment of endogenous depression. One group of patients with depression was treated with orthodox ECT. In a second group, the electrical stimulus was only just sufficient to induce generalized seizure activity (liminal stimulation). In a third group, a liminal stimulus was preceded by the intravenous administration of lidocaine, which reduced the duration of seizure activity in the brain. Pretreatment with lidocaine considerably reduced the clinical efficacy of ECT. Nearly 50 years after this study was conducted, it can be criticized because the patients were not allocated randomly to the three experimental groups and Ottoisson did not measure the effect of lidocaine on the seizure threshold. This study was important in its time because it showed that the antidepressant effect of ECT depended on the extent of cerebral seizure activity.

Refinements to original theory

A series of studies at the New York State Psychiatric Institute from 1987 led to a refinement of the original theory. The first was a clinical trial of the efficacy of liminal ECT in the treatment of major depression, although Sackeim and colleagues referred to this technique as ‘threshold ECT’. The novel aspect was a randomized controlled comparison of threshold ECT given with either a bilateral or a right unilateral electrode placement (see Electrode placement, below). Only 28 per cent of the patients with depression responded to threshold unilateral ECT, in contrast to a response rate of 70 per cent in the patients treated with threshold bilateral ECT. Treatment was monitored by electroencephalogram (EEG), and there was no significant difference in the length of seizure activity between the two types of ECT. Subsequent studies have shown that when right unilateral ECT is given with a dose of electricity at least six times the seizure threshold – that is, 500 per cent above the seizure threshold – then right unilateral ECT approximates to the clinical efficacy of bilateral ECT.

Although generalized cerebral seizure activity is still a necessary ingredient for the clinical efficacy of ECT, it turns out that how the cerebral seizure is induced has substantial bearing on the clinical outcome of a course of ECT.

Insights from brain imaging studies

A collaboration among neurologists and psychiatrists at Yale University School of Medicine has been important in
understanding why it is that how cerebral seizure activity is induced has a bearing on the therapeutic efficacy of ECT. Single-photon-emission computed tomography (SPECT) was used to study the initiation and propagation of generalized seizures during ECT. The findings challenged the belief that generalized seizures involve the entire brain homogeneously. The regions of the brain where increased blood flow was found during seizures differed, depending on how the seizures were initiated: right unilateral ECT, given with an electrical dose 2.5 times the seizure threshold, caused asymmetrical increases in both cortical and subcortical regions, with relative sparing of the left temporal lobe and left medial thalamus; in contrast, bilateral ECT caused symmetrical increases in blood flow in both the cortex and subcortical networks. Although both bilateral and right unilateral ECT produced generalized cerebral seizures associated with tonic–clonic convulsions, increases in regional cerebral blood flow differed substantially between the two types of treatment. An understanding of the significance in these differences between the two types of ECT will require greater knowledge of the functional neuroanatomy of mood and the pathophysiology of depressive illness. Preliminary studies are already under way with positron emission tomography (PET).

PET, unlike SPECT, can make direct measurements of cerebral metabolism in terms of the utilization of either oxygen or glucose. PET also has a much higher spatial resolution than SPECT. Ten patients with major depression of psychotic subtype were studied with PET using labelled fluorodeoxyglucose before and at least 2 weeks after a course of ECT. Statistical parametric mapping and region of interest analysis revealed a significant increase in function in the left subgenual anterior cingulate cortex and hippocampus; the extent of the increases correlated with the extent of clinical improvement in depressive symptoms over the course of ECT. Treatment was given with either high-dose right unilateral ECT or bilateral ECT. Earlier work with PET found that cerebral blood flow was significantly reduced in the anterior cingulate cortex 10 min after an individual treatment with bilateral ECT. These findings are of interest because decreased function in the anterior cingulate cortex has been described in the resting state in patients with major depression of the psychotic subtype. The subgenual anterior cingulate cortex (Figure 58.1) has also been identified as a putative target for deep brain stimulation in the management of chronic and treatment-resistant depressive illness. Clearly, such small-scale studies will require to be replicated, and several confounding factors may be at work: concomitant psychotropic drug treatment may affect regional cerebral metabolism, and the uptake of tracers may be affected by the amount of cerebral tissue in a region of interest, which in turn may be affected by factors such as age and chronicity of illness. Nevertheless, these preliminary studies point to at least one possible neuroanatomical substrate for the mode of action of ECT.

Figure 58.1 Neuroanatomy of the anterior cingulate nucleus

### Neurochemical effects

There is a laboratory model of ECT called electroconvulsive shock (ECS) in which electricity is used to induce seizures in anaesthetised animals. Repeated ECS, in contrast to a single seizure, has several defined and reproducible neurochemical effects with behavioural correlates that emerge in a comparable time course to how ECT is used in patients with depression. ECT need not have a single mode of action nor work in a way similar to antidepressant drugs. Nevertheless, it is highly relevant that repeated ECS has been shown to increase functional measures of noradrenaline, serotonin and dopamine in the normal rodent brain; functional measures of acetylcholine decrease, which is one plausible explanation for some of the cognitive adverse effects of ECT. The neurochemical effects of repeated ECS include the down-regulation of the number of β adrenoceptors in the cortex and hippocampus, and this is accompanied by behavioural change that lasts for about 7 days after the last ECS. This is an effect of interest also seen after the chronic administration of effective antidepressant drugs in animals.

### The anticonvulsant hypothesis

The development of this hypothesis occurred around the time when there was increasing interest in the use of anti-epileptic drugs as mood stabilizers. Effective ECT has anticonvulsant effects, and these may include a gradual rise in the seizure threshold during a course of ECT. It has been suggested that the magnitude of this rise is related to the eventual clinical outcome of a course of ECT and that it is essential for successful treatment with right unilateral ECT. A study of 80 patients who recovered from an episode of unipolar major depression after a course of bilateral ECT found that the seizure threshold did not in fact change at all in 70 per cent of the patients. These findings do not support the anticonvulsant hypothesis of the mode of action of ECT.
Cellular theory of depressive illness

This theory proposes that effective antidepressant treatments work via intracellular mechanisms that increase neurotropic factors necessary for the survival and function of neurones. This theory is not generally accepted, but there are some striking findings about ECS in the context of this theory. ECS is a much more efficacious and rapid-acting inducer of cell proliferation in the hippocampus than are chemical antidepressant treatments. It has also been shown that ECS increases two important neurotropic factors in the hippocampus, brain-derived neurotropic factor and vascular endothelial growth factor.

INDICATIONS

Major depression

In 2001 the Department of Health in England commissioned a systematic review of the efficacy of ECT using modern methods of evidence-based medicine; the results for the indication of major depression were later published. The UK ECT Review Group found that real ECT was substantially more efficacious than sham ECT (standardized effect size 0.91) and more efficacious than pharmacotherapy (standardized effect size 0.80) in the short-term treatment of depressive illness.

The Royal College of Psychiatrists publishes guidelines on the use of ECT; Box 58.1 shows the recommended indications for ECT in major depression.

It has to be noted that the College recommendations were not consistent with guidance from the National Institute for Health and Clinical Excellence (NICE). This body conducted one of its technology appraisals on ECT and heard evidence from patients that sometimes the cognitive adverse effects of ECT outweighed its clinical benefits. NICE intended to restrict indications for ECT, and the recommendations were that ECS was to be used only to achieve rapid and short-term improvement of severe symptoms after an adequate trial of other treatment options had proved ineffective or when the condition was considered to be potentially life-threatening. A dilemma for clinicians remains, and the extant recommendations from the College also include advice for prescribers to help them accommodate their practice to this discrepancy between the College and NICE. The heart of the advice is that a documented assessment of valid consent after full information about the risks and benefits of treatment would be essential to support any variance from the NICE guidance.

Treatment-resistant depressive illness

The traditional view is that a history of non-response to antidepressant drug treatment during the index episode of depression has no bearing on the clinical outcome of ECT. This view has been supported by studies in the Netherlands and Scotland that have included representative samples of patients with depression referred for ECT – that is, patients with both unipolar and bipolar illnesses and both psychotic and non-psychotic subtypes. The traditional review has been challenged, however, by an open, well-conducted multicentre study in the USA. This study included only patients with unipolar, non-psychotic depressive illness. Adequate antidepressant drug treatment was defined as at least 200 mg per day of imipramine (or equivalent) for at least 4 weeks. The probability of recovery among the patients with depression who had already failed to recover with adequate antidepressant drug treatment was only about 50 per cent, significantly lower than in the patients who had not been treated adequately. A subsequent multicentre observational study in the USA did not find a significant difference in the likelihood of remission between those patients who had and who had not already received adequate antidepressant drug treatment. In fact, the observed probability of remission among the patients who

Box 58.1 Indications for electroconvulsive therapy (ECT) in major depression

- Potential treatment of choice – severe depressive illness when the illness is associated with:
  - attempted suicide;
  - strong suicidal ideas or plans;
  - life-threatening illness because of refusal of food or fluids.
- Treatment to be considered – severe depressive illness associated with:
  - stupor;
  - marked psychomotor retardation;
  - depressive delusions or hallucinations.
- Second- or third-line treatment:
  - depressive illness that has not been treated adequately by antidepressant treatment and where social recovery has not been achieved.

The selection of ECT may be affected by:
- patient choice;
- previous experience of ineffective or intolerable medical treatment;
- previous recovery with ECT.
had already failed to recover with antidepressant drug treatment was lower than in those patients who had not received adequate antidepressant drug treatment; the difference was not, however, statistically significant. Although there may be debate about the impact of treatment resistance on the probability of remission in unipolar, non-psychotic major depression, these two studies were consistent in two points. Neither study found any suggestion that a failure to respond to a selective serotonin reuptake inhibitor (SSRI) or a monoamine oxidase inhibitor (MAOI) affected the probability of remission. It should also be noted that, even with the more conservative estimate, there is a 50 per cent chance of remission with ECT after non-response to a tricyclic (or similar) antidepressant drug, even when it has been augmented by lithium carbonate.

Bipolar disorder

Box 58.2 shows the College recommendations about the place of ECT in the treatment of patients with mania.

Schizophrenia

Box 58.3 shows the College recommendations about the place of ECT in the treatment of patients with acute schizophrenia.

Catatonia

Box 58.4 shows the College recommendations about the place of ECT in the treatment of patients with catatonia.

Neuropsychiatric disorders

ECT is a safe adjunctive treatment for both motor and affective symptoms in patients with Parkinson’s disease with severe disability despite medical treatment. ECT is also an experimental treatment for neuropsychiatric movement disorders such as neuroleptic malignant syndrome. ECT has been shown to be effective in treatment-resistant status epilepticus.

CONTRAINDICATIONS

ECT can be life-saving in severe psychiatric illness and may therefore have no absolute contraindications. The physiology of ECT has been well described. During and immediately after electrical stimulation, there is a reduction in heart rate, which may lead to bradycardia and occasionally brief asystole. Once cerebral seizure has been induced, a tachycardia ensues. Blood pressure generally parallels the heart rate during electrical stimulation and cerebral seizure activity. Patients with pre-existing hypertension do not experience more marked cardiovascular changes. The cerebral utilization of oxygen and glucose and therefore cerebral blood flow doubles during cerebral seizure activity. Patients with pre-existing hypertension do not experience more marked cardiovascular changes. The cerebral utilization of oxygen and glucose and therefore cerebral blood flow doubles during cerebral seizure activity. Box 58.5 lists coexisting medical conditions that may increase the risk of ECT and are understandable in the context of the physiological changes that accompany ECT. It is important that the treatment of any coexisting medical conditions is optimized before elective treatment with ECT.

Box 58.4 The place of electroconvulsive therapy (ECT) in the treatment of catatonia

- Catatonia is a syndrome that may complicate several psychiatric and medical conditions.
- The treatment of choice is a benzodiazepine drug; most experience is with lorazepam.
- ECT may be indicated when treatment with lorazepam has been ineffective.

Box 58.5 Coexisting medical conditions that may increase the risk of electroconvulsive therapy (ECT)

- Increased intracranial pressure
- Recent cerebral infarction
- Severe cardiovascular or pulmonary disease
- Aneurysms or vascular malformations that might be susceptible to rupture with increased blood pressure.
SPECIAL POPULATIONS

Young people
The use of ECT in people under the age of 18 years is now very rare in developed countries. In contrast to adults, the indication in young people is usually the treatment of a severe and treatment-resistant psychotic illness. ECT is still an important treatment for schizophrenia in developing countries, and this may be one important reason that young people still constitute a small proportion of patients treated by ECT in such healthcare systems.

Modern brief-pulse ECT machines deliver an adjustable dose of electrical energy, and it is known that only a small dose is necessary to induce cerebral seizure activity in young people. Stimulus dosing must therefore take into account the lower seizure thresholds in young people, and monitoring of treatment by simultaneous EEG is recommended to detect and manage any resultant prolonged cerebral seizure activity. It is also advisable to try to avoid the concurrent prescription of psychotropic drug treatment that might itself lower the seizure threshold.

People with learning disability
The prevalence of psychiatric illness is higher among people with learning disability than it is in the general population, but it seems that ECT is a treatment of last resort in this special population. It must be acknowledged that there has never been a randomized controlled trial of ECT specifically within this special population, but observational studies have found no evidence for restricted indications or additional contraindications for people who have both a psychiatric illness and learning disability.

Older adults
In contrast to general adult psychiatry, the rate of usage of ECT has only recently started to fall in the practice of old-age psychiatry. Given the importance of ECT in this special population, it is disappointing that there has never been a randomized comparison of real and sham ECT. A small subanalysis of the Nottingham ECT trial was published in which efficacy was assessed specifically in patients with depression aged over 60 years; real ECT was significantly more efficacious than simulated ECT.

Advancing age itself is not a contraindication to ECT. There is a higher prevalence of coexisting physical illness in older adults, but an observational study of patients with depression who were at least 75 years old found that these older adults tolerated ECT in a manner similar to younger people and experienced an improvement at least as great. It is important that the treatment of any coexisting medical conditions is optimized before elective treatment. Cognitive impairment is also more prevalent in older adults referred for ECT, and it is essential to monitor cognitive function carefully during a course of ECT. Pre-existing cognitive impairment or the development of significant cognitive adverse effects during a course of treatment would both be an indication for the use of unilateral ECT.

THE PRESCRIBING CYCLE

Electrode placement
Electrical induction of the cerebral seizure can be undertaken with electrodes over both cerebral hemispheres – bilateral electrode placement – or over the non-dominant hemisphere only – unilateral ECT. The electrodes are applied to both temples in bilateral ECT (Figure 58.2), and to the temple and to the parietal surface in unilateral ECT (Figure 58.3).
It is the selection of electrode placement that has the single greatest impact both on the efficacy of treatment and on the cognitive adverse effects attributable to treatment. The UK ECT Review Group found that bilateral ECT was more efficacious than unilateral ECT (standardized effect size 0.32). Electrical dose in unilateral ECT does, however, have a substantial impact on efficacy, and it could be argued that the comparison is confounded by electrical dose; nevertheless, in direct random allocation comparison of bilateral ECT with high-dose unilateral ECT – that is, an electrical dose six times the seizure threshold – it is still the case that high-dose unilateral ECT only approximates to the efficacy of bilateral ECT. Moreover, there are patients with depression who do not experience remission with high-dose right unilateral ECT but who subsequently do experience remission with bilateral ECT.

The cognitive adverse effects, both acute and longer-term, attributable to ECT are also more marked with bilateral ECT. Patients treated with bilateral ECT take longer to become reoriented after an individual treatment and are at substantially higher risk of prolonged disorientation after treatment. The longer-term adverse effect of most concern to patients is the risk of retrograde amnesia – the realization of gaps in episodic memory for the period of weeks or months before admission to hospital. The risk of enduring retrograde amnesia is also substantially greater in patients treated with bilateral ECT. The Royal College of Psychiatrists has recommended that, where the rate of clinical improvement and completeness of response have priority, then bilateral electrode placement is preferable. Where minimizing the cognitive adverse effects has priority, then unilateral electrode placement is preferable. Neither unilateral nor bilateral electrode placement is therefore the treatment of choice in all indications for ECT, and, where possible, the selection of electrode placement should be part of the process of informed consent for treatment.

Frequency of treatments

The UK ECT Review Group found that treatments three times each week brought about no greater clinical improvement in depressive symptoms than treatment twice a week. A meta-analysis of the comparative effects on cognitive function was not possible. Individual randomized controlled trials find that the outcome of a course of treatment is no different but that the rate of improvement may be greater in treatment three times a week; the increased rate of improvement is at the cost of more marked memory impairment during the course of treatment and up to 1 month after treatment. Twice-weekly treatment is therefore optimal.

The rate of improvement may be crucial for some patients, as in treatment to save life. In this case, an evidence-based strategy to maximize the rate of clinical improvement would be to use a bilateral electrode placement with a high dose – that is, an electrical dose 2–2.5 times the seizure threshold (100–150 per cent above the seizure threshold).

Number of treatments

It is remarkable that observational studies at different times and in different countries find that the average number of treatments in a course of ECT is approximately seven. Nevertheless, it is not possible to predict reliably the total number of treatments that an individual patient will require. A set course of treatment should therefore never be prescribed, and the need for further treatment should be assessed after each individual treatment. If no clinical improvement at all is seen over the first six bilateral treatments that have been administered properly, then it is highly unlikely that more treatments will bring about either significant clinical improvement or eventual recovery. The management of patients who display slight or temporary improvement over the first few treatments is more problematic. It has been shown that a small but significant minority of patients with depression respond fully to treatments only beyond the eighth treatment in a course, having shown only modest improvement with earlier treatments. It may therefore be perfectly reasonable to give up to 12 treatments to patients who display slight or temporary improvement over the first few treatments.

TREATMENT OUTCOME

The most comprehensive survey is from a multicentre study conducted in the USA. The study involved 253 patients with a unipolar depressive illness and who were treated with bilateral ECT, given with an electrical dose 50 per cent above the seizure threshold. A total of 86 per cent of the patients completed the full course of treatment (6% dropped out because of intolerable adverse effects). Among those who completed the full course of bilateral ECT, 83 per cent of the patients with an illness of the non-psychotic subtype remitted, and 95 per cent of the patients with an illness of the psychotic subtype remitted (Figure 58.4). Remission was defined as a score of 10 or less on the Hamilton Rating Scale for Depression after two consecutive treatments, and also a fall of at least 60 per cent in depression rating from the pretreatment score. The final outcome of a course of ECT is similar in patients with a depressive episode in the context of a bipolar disorder but may be achieved with slightly fewer treatments.

ADVERSE EFFECTS

It is disappointing that none of the randomized comparisons of real and sham ECT included a survey of adverse effects. It would have been informative to know which
particular complaints related to the induction of cerebral seizure activity itself as opposed to the effects of anaesthesia and related interventions in a sample of depressed patients. Reported prevalences of specific adverse effects vary among surveys, presumably reflecting differences among samples in age and coexisting medical conditions. Muscle aches, headache, nausea (vomiting is less common) and memory problems are commonly reported adverse effects. Some patients experience repeated headache, and this may be an indication for prophylactic analgesia.

The temporary uncoordination and disorientation after individual treatments is characteristic of the postictal state and usually resolves spontaneously by the time the patient has returned to the ward. The prevalence of prolonged disorientation is much higher after bilateral ECT than after unilateral ECT (see Electrode placement, above). Prolonged disorientation may be an indication for a switch to unilateral ECT.

Prolonged cerebral seizure activity that requires medical treatment complicates 1–2 per cent of courses of treatment and is most likely at the first treatment. It is more likely in young patients and patients with coexisting organic brain disease. The Royal College of Psychiatrists has recommended that EEG monitoring be carried out routinely, at least in the first treatment in a course of ECT.

There is no credible evidence that ECT causes any kind of structural brain damage. Indeed, the animal model of ECT is the most potent known inducer of hippocampal neurogenesis in rodents and non-human primates. Nevertheless, gaps in episodic memory are inevitable during a course of ECT because each individual treatment is followed by a postictal state associated with a temporary period of impaired consciousness. The most important risk factor for the persistence of retrograde amnesia is the use and number of bilateral treatments in the index course.

The calculated mortality rate associated with the induction of cerebral seizure activity is fewer than two deaths per 100,000 treatments; adding deaths plausibly associated with anaesthesia, the rate is 2–10 deaths per 100,000 treatments.

**COMPARISON WITH OTHER PHYSICAL TREATMENTS**

An experimental physical treatment for major depression is repetitive transcranial magnetic stimulation (rTMS); this involves the delivery of intense, ultra-brief magnetic pulses that pass unimpeded through the scalp and skull to induce focal electrical stimulation of the cortex of the brain. rTMS is not a convulsive therapy. A stimulating coil is held over the skull of the conscious patient and is usually tolerated well. A randomized controlled trial has compared the efficacy of ECT with rTMS of the left dorsolateral prefrontal cortex in the context of the National Health Service (NHS). More than four times as many patients treated with ECT attained the a priori criteria for remission after ECT compared with those treated with rTMS. Although it must be acknowledged that rTMS is still in development, ECT proved much more efficacious among the patients with depression presently referred to ECT clinics.

**KEY POINTS**

- ECT is the most efficacious treatment for major depression in the short term.
- Generalized cerebral seizure activity is a necessary ingredient for clinical efficacy, but how the seizure is induced has substantial bearing on the outcome.
- The selection of electrode placement has the single greatest impact both on the efficacy of treatment and its cognitive adverse effects.
- The selection of electrode placement should, where possible, be part of the process of informed consent for treatment.
- Twice-weekly treatment is the optimal frequency.
- There is no credible evidence that ECT causes any kind of structural brain damage.
- The most robust predictor for the persistence of retrograde amnesia is the use and number of bilateral treatments.

**REFERENCES**

Transcranial magnetic stimulation (TMS) of the brain is a somatic treatment in psychiatry approved by the US Food and Drug Administration (FDA) in October 2008 for the treatment of depression under certain conditions. The potential for further development of TMS is great, and psychiatrists should be familiar with its basic principles.

The idea that a rapidly alternating magnetic field induces an electric current was described by Maxwell’s equations in physics in the 1800s, and the idea that nerves work electrically, as illustrated early on by the contraction of a frog’s leg upon the application of a small electric current, was demonstrated by Galvani in the 1700s. It was therefore a short conceptual step to propose that the brain could be stimulated with a rapidly alternating magnetic field and that this could affect various brain functions. Indeed, Thompson patented an idea such as this in 1910 and implied that a magnet applied to the visual areas of the occipital cortex could induce spots of light.

In actuality, the coils required to carry an electric current that is powerful enough to create a magnetic field strong enough to stimulate the brain were not available until 1985. In the first TMS machine such coils depended on metals that were developed for completely different areas of modern technology but became available in the 1980s for electromagnetic coils. The first coil able to stimulate the brain was demonstrated in 1985 by Barker in England. The easy accessibility and large amount of knowledge of the motor cortex of the human brain made this the obvious first choice for demonstration, and it is still most convincing for students of psychiatry and neurology.

The appropriate coil placed over different parts of the homunculus of the human motor cortex can induce a contraction of the appropriate peripheral muscle. For instance, a stimulus above the area of the thumb will give a slight twitch in the thumb that is visible above a certain threshold. Twitches below such a threshold can often be identified by placing an electromyographic electrode on the thumb or other peripheral muscle involved. The homunculus on the brain of the motor cortex is represented such that if one moves on the human brain closer to the midline, one can stimulate the areas of leg and cause the subject’s leg to jerk. Subjects who have had such a TMS stimulus find the movement of the thumb or leg surprising and completely involuntary and do not feel a sense of conscious desire to move the stimulated part of the body. Therefore, it seems that the TMS stimulation of the motor cortex is taking a rather direct route through the descending pathways leading to the motor output.

The first uses of TMS were in neurology and developed rapidly. The progress in neurology was rapid and dramatic and was reviewed by Hallett and Cohen in the Journal of the American Medical Association in 1989.1 The combination of a magnetic stimulus to the motor cortex and an electromyogram of the peripheral muscle, say the finger, could allow the time in milliseconds from the stimulation of motor cortex to the muscle to be calculated. The magnetic coil could then be placed on the neck at the output of the motor nerve to the arm, the stimulation repeated, and the conduction time from the neck to the peripheral muscle calculated. The difference between those two times, the central conduction time, gives a measure of the amount of time from the stimulation of the motor cortex to the output of the motor nerve in the spinal cord. Many types of brain lesions increase this conduction time, and it is studied extensively in neurology. Of course, the peripheral conduction time (the length of time from the stimulus of the motor nerve in the neck to the arm or leg) could also be lengthened in various diseases of peripheral nerves, and this is an important diagnostic tool in peripheral nerve disease.

If the brain works electrically, then why not stimulate the brain with external electrical stimulation to the skull? The skull is highly resistant to electrical current, and a high current is necessary on the skin to achieve only small current passage through the brain. This voltage drop across the skull causes local heat and pain. By contrast, magnetic fields pass through the skull and other tissues as if they were transparent and convert to local electrical currents.
only when ions or electrically charged particles are encountered. Therefore, magnetic stimulation can induce small electrical currents deeper in the brain than external electrical stimulation.

In 1995, two groups independently conceived the notion that if the motor cortex could be stimulated directly by a magnetic field and lead to a definite measurable output, then stimulation of the ‘silent’ areas of the brain such as the prefrontal cortex might affect emotion, thinking or behaviour. These two early papers suggested an antidepressant effect. The idea of an antidepressant effect was also perhaps inspired by a paper that came out in the same year by Sackeim and colleagues in the New England Journal of Medicine showing that differences in the current strength in electroconvulsive therapy (ECT) affected the treatment outcome. Until that time, clinicians using ECT tended to believe that ‘a convulsion is a convulsion’ and that, since a convulsion seemed to be the essential therapeutic element of ECT, it did not matter for therapeutic purposes whether this convulsion was induced unilaterally or bilaterally, barely super-threshold or highly super-threshold. Sackeim found that unilateral barely super-threshold stimulation induced convulsions that were much less therapeutic.

Subsequent research in ECT over the past 15 years has tended to confirm the idea that the nature of the ECT electrical stimulus can affect the therapeutic outcome. The idea that the nature of the electrical stimulus could affect the therapeutic outcome and that the convulsion itself was not critical may have been an essential insight that allowed the early development of TMS. However, it is unclear today whether TMS is in any sense analogous to ECT merely because both of them involve electromagnetic stimulation of the brain. It is quite possible that TMS affects depression via an entirely different mechanism. It is also possible that TMS in different parameters and of different areas of the brain may have differing effects in depression and in other psychiatric syndromes.

TMS has been studied extensively for safety in normal volunteers and in patients with different diagnoses. It apparently has no consistent neuropathological, neuroendocrine or cognitive side effects. Massively repetitive TMS stimulation in animal studies has not led to any clear histological changes. In humans, one main side effect is headache, because of muscle contraction under the site of the TMS electrode. If TMS is repeated rapidly over 20–25 times/s (hertz, Hz) and for more than 2–5 s (train length), there is a danger of seizure. Thus, in ECT a seizure is the goal of the electrical stimulation, but in TMS a seizure is a side effect. During TMS treatment, clinicians should be aware of the possibility of this side effect and should have appropriate equipment such as a respiratory bag and intravenous diazepam available if necessary. Such seizures are extremely rare during usual clinical conditions. To reduce the incidence even more, a TMS safety checklist is recommended before TMS treatment.

The site of TMS stimulation was, for most depression studies, chosen to be 5 cm anterior to the motor cortex area on the left side that leads to stimulation of the thumb. This area in studies combining TMS with magnetic resonance imaging (MRI) is in most patients the lateral prefrontal cortex. However, there is variation in skull and brain anatomy and, particularly in elderly patients with some brain atrophy, it may be that this is not the optimal coil placement. Early studies of TMS in volunteers found that stimulation of the left cortex induced sadness and of the right cortex induced happiness. This is opposite to the effects reported by most investigators for patients with depression or mania. There has been some evidence that in brain stimulation the neurophysiological effects are different if a magnetic stimulus of milliseconds in length is given once per second or less or whether it is given more frequently – rapid or repetitive TMS (rTMS). In some neurophysiological studies, the repetitive TMS is stimulatory and the single TMS inhibitory. These schemes are still theoretical and not consistent between animal in vivo and in vitro models. Human antidepressant studies have been based mostly on a heuristic or arbitrary choice of stimulation parameter and location.

Although a particular stimulation site and parameters and TMS machine were approved by the US FDA in October 2008, the well-trained clinician should realize that these parameters are not set in stone and that future developments might lead to treatments of entirely different areas of the brain with TMS or entirely different parameters of nerve stimulation and certainly other commercial machines.

TMS is usually given daily, except weekends, for 2–3 weeks in the treatment of a depressive episode. Response rates and remission rates are far below those of ECT. It is difficult to compare TMS with pharmacological antidepressant treatment. It is much more expensive, and the FDA approval was for patients who had failed one antidepressant. However, TMS is not indicated for resistant depression, and psychotic patients, suicidal patients and patients who have failed on multiple antidepressants have little chance of success with TMS.

Several companies make TMS devices, but only the Neuronetics® coil was tested, found effective in a multicentre clinical trial and approved by the FDA. There is little reason to think that it is uniquely effective in depression, however, and several similar devices are available in almost every country that are used for evaluation of peripheral nerve conduction and central nerve conduction in neurology. In some countries, it is permissible to use these devices in an off-label manner for the treatment of depression.3

VAGUS NERVE STIMULATION

Vagus nerve stimulation (VNS) derives from an entirely different conceptual tradition than TMS. Many anticonvul-
sants are effective in bipolar disorder as mood stabilizers, and antiepileptic neuropharmacology has been a steady source of new treatments for the somatic treatment of affective disorders. The vagus nerve, the tenth cranial nerve, emerges from the brain and follows a meandering pathway with numerous branches that lead to almost every organ in the body. It has been classically conceived as a parasympathetic efferent nerve, whose fibres secrete acetylcholine at multiple visceral muscarinic receptor innervated end organs, such as the heart, intestines, small blood vessels and sweat glands. However, the vagus nerve has also been found to have numerous afferent fibres that are enteroreceptive and carry information about the state of the peripheral internal organs to the brain. This afferent stimulation affects brain function and was found to have anticonvulsant properties that have been demonstrated in both human and animal studies beyond any doubt. The distance was therefore short until the trial of vagus nerve stimulation in depression.

VNS in the clinical setting involves a small operation. An electrical stimulator that can be turned on and off via remote control from outside the patient’s body is placed underneath the skin. The rate and intensity of the electrical stimulation emitted by the device can also be modified. The device is connected via an electrode to the vagus nerve. The VNS once implanted remains on continuously, but clinical relief of depression is often slow. The studies resulting in FDA approval of VNS showed better results after 1 year than after 1 month. Side effects have been few, although some patients report hoarseness of their voice due to simulation of the recurrent fibres leading to the larynx. The operation, implantation and device are expensive, and the effect size of the key studies suggests that, among treatment-resistant patients, only a small number will achieve response or remission with VNS. Thus, like TMS, VNS is not a miracle treatment, although there is almost certainly a subgroup of patients for whom this may be very helpful.4

**KEY POINTS**

- Neuronal communication involves neurophysiological ion currents.
- Rapidly moving magnetic fields can generate electric currents and move ions at a distance.
- It has long been obvious that rapidly alternating magnetic fields can affect nerve and brain function.
- Magnetic stimulators exist that, when placed over the motor cortex, can induce movements of peripheral muscles given defined rates and length of pulse stimulation.
- Stimulation of certain prefrontal areas has specific effects on mood in controlled double-blind studies.
- These clinical effects are not of the magnitude of ECT and are probably unrelated in mechanism to ECT.

**REFERENCES**

INTRODUCTION

There has been a dichotomy, long-standing within psychiatry, between psychological and physical approaches to treatment. Enlightened psychiatric practice has looked upon these two modalities as equal in value and bemoaned the relative predominance and availability of physical over psychological treatments.

A number of recent developments, most fundamentally in neuroscience, call the basis of this dichotomy into question. Historically, there has been difficulty translating observations of the ‘objective’ anatomical, physiological brain, and the ‘subjective’ brain, the mind. More recently, researchers in the field of cognitive neuroscience have addressed themselves to such subjects as affect and the origins of the experience of self and other, which would previously have been considered to be too ‘subjective’ to be available to rigorous scientific methodology. Researchers in developmental neuroscience have examined the neurobiological consequences of relational trauma in infancy and the impact of the emotional environment upon brain development. Links have been established between such environmental factors and the development of psychological and psychiatric symptoms in later life. Other studies have provided neuroscientific evidence for the presence of psychological defences. Finally, functional imaging has demonstrated neurological changes occurring following both psychological and physical treatments. An early study undertaken by Baxter and colleagues demonstrated a similar reduction in the metabolic rate to the head of the right caudate nucleus brought about by fluoxetine and cognitive-behavioural therapy (CBT) in patients with obsessive-compulsive disorder who responded to treatment.

As neuroscience addresses itself to relevant aspects of psychological function, some of the difficulties translating from the ‘neurological’ to the ‘psychological’ become more negotiable. However, there remain dangers in prematurely and simplistically applying neurobiological findings to psychotherapeutic practice.

Alongside these developments, as evidence for the effectiveness of psychotherapeutic treatments has grown, they increasingly feature in National Institute for Health and Clinical Excellence (NICE) guidelines. This in turn has stimulated investment of public funds in psychotherapy, which is seen as a solution to the problems arising from common mental disorders such as anxiety and depression. The introduction of the Improving Access to Psychological Therapies (IAPT) initiative is perhaps the most striking illustration of the paradigm shift that has occurred in the perception of the psychological therapies as an agent of change. Where does this leave us with the old debates about the relative importance of medication or psychological treatments in mental health services?

Nobel Laureate Kandel has proposed a ‘new intellectual framework for psychiatry’. He makes the case for a rapprochement between neuroscience, psychiatry and psychoanalysis. Neuroscience can help to elucidate the diagnosis and treatment of mental disorders, but reciprocally neuroscientists benefit as psychiatrists pose some of the behavioural questions that biology needs to answer in order to advance understanding of higher mental processes. Kandel’s framework is summarized in Box 60.1.

Kandel made the case for the dissolution of old divisions between:

- functional and organic mental illness;
- dichotomous thinking about the influence of nature and nurture upon higher psychological functions and psychopathology;
- physical and psychological treatments.

For the psychiatrist, the integration of psychological understanding into psychiatric practice has a developing evidence base and forms a scientific basis for clinical work. It is in this context that the Royal College of Psychiatrists has developed its new curriculum for psychotherapy training, with an emphasis on applying psychological principles and skills in psychiatric practice. The competencies required of trainees are shown in Box 60.2.

Although the formal psychological therapies themselves are dealt with in subsequent chapters, this chapter will address various aspects of psychologically informed psychiatric practice.
Making a referral to psychological therapies

Part 5: Approaches to treatment

MAKING A REFERRAL TO PSYCHOLOGICAL THERAPIES

Assessing suitability for therapy

A number of factors may weigh upon the mind of the psychiatrist considering the appropriateness of referral for therapy. Among these is the context within which the patient is assessed. Assessing an acutely distressed patient while on call, the psychiatrist may be anxious about discharge without offering further help. Referral for therapy under such circumstances may reflect the psychiatrist’s immediate anxiety rather than being a thought-through decision about a potentially long-term commitment, there being no such thing as ‘emergency psychotherapy’. Again, referral might be made when the psychiatrist is about to move post, when patient and doctor are facing an imminent loss. Such referrals are unlikely to lead to successful engagement in therapy. Decisions about referral are best made in circumstances in which the patient is free to discuss their mixed feelings about therapy and to arrive at their own conclusions about whether to proceed. The clinician’s job is to ensure that the patient is aware of the options and what therapy is likely to involve and to be realistic about the likely outcome so that the patient can come to an informed decision.

The evidence for the effectiveness of psychological therapies is set out comprehensively in a critical review of psychotherapy research undertaken by Roth and Fonagy. Although in some instances referral is a simple matter of directing a patient to the appropriate evidence-based intervention, factors aside from diagnosis determine whether a patient is likely to benefit from psychological intervention or not. Table 60.1 provides a list of indications and contraindications for therapy set out in the terms used by therapists undertaking an assessment.

Table 60.2 provides a summary of the evidence base derived from Roth and Fonagy’s review, the Department of Health’s Treatment Choice in Psychological Therapies and Counselling, information from Cochrane Reviews, NICE guidelines, and manualized therapies that have been subjected to randomized controlled trials. The table has been adapted from the Royal College of Psychiatrists’ Psychological Therapies in Psychiatry and Primary Care.

It is important that the referring clinician has an idea of the level of therapeutic intervention required and where it can be obtained. Figure 60.1 sets out the stepped care model proposed in the IAPT practice guide.

Writing a referral to psychological therapies

Once the psychiatrist and patient have decided upon referral for psychotherapy, the written referral should include a full psychiatric assessment, including risk to self and others, with particular attention paid to the personal history, including major events of childhood and family relationships. It is useful to describe the discussion that took place about therapy so that the assessing psychotherapist is forewarned about the patient’s expectations.

Jointly managing patients receiving psychotherapy

In many cases it is a good idea for patients with severe and enduring mental health problems in psychotherapy to continue to see a psychiatrist for outpatient appointments. However, the psychiatrist who is not well informed about

the ethos of the therapeutic model being followed may unwittingly undermine the therapeutic work. Different models require different approaches from the psychiatrist.

The following recommendations apply to psychiatrists working alongside psychodynamic therapists:

- The patient may discuss their therapy with their psychiatrist because they are anxious and ambivalent about or disturbed by their sessions. It is important to listen and let the patient know that people are often disturbed by the process of change in therapy. It is important to encourage the patient to tell their therapist, especially when doubtful about continuing.
- The patient may, for example, think their therapist is useless, abusive, silent or intrusive. Although it is important to be alert to bad practice by the therapist, it is also important to recognize that the patient’s feelings may be transference-driven or an indirect expression of anger with the therapist through the psychiatrist. The patient should be encouraged to be honest with their therapist about what they think, this being part of the therapeutic work.
- Periods of disturbance in therapy are often crisis points. A psychiatrist who supports the patient through such crises can make the difference between change occurring or not. For example, if in doubt about whether medication is likely to be helpful, contact the psychotherapist (with the patient’s permission, if this has not already been granted) to discuss the way forward.
- Patients may seek a therapeutic relationship with their psychiatrist while in therapy. It is important to stay within the psychiatric role, since this may well be a part of ‘acting out’ of underlying psychopathology, for example playing one caregiver off against another, without being able fully to trust either.

### cCBT, computerized cognitive-behavioural therapy

---

**PREScribing FOR PATIENTS WHO ARE IN THERAPY**

CBT has successfully established its evidence base, in part through the ways in which therapy is an analogue of medication. CBT models are manualized and can be administered with a comparable degree of confidence about the exact nature of the treatment being delivered and in what ‘dosage’. This has permitted direct comparisons of the effectiveness of medication and CBT, and comparisons between...
the use of CBT and medication together with either treatment alone. CBT and medication augment one another’s actions, and combinations of CBT and medication are therefore recommended in NICE guidelines. Aside from the possibility of synergistic neurological action, there are other reasons that therapy and medication may facilitate or confound the other’s actions (Table 60.3).

<td></td>
</tr>
</tbody>
</table>

There is strong evidence for the effectiveness of combined medication and psychotherapeutic treatments in schizophrenia and depression, and more limited data in the treatment of personality disorders, substance misuse, eating disorders, anxiety disorders and bipolar disorder.21

### Integrated practice (therapy and medication managed by the same person)

Principles of integrated treatment include the following:

- Obtain informed consent at the outset.
- Make a formulation and set treatment goals at the outset of whatever the modality of treatment.
- Focus on alliance rather than compliance.
- Address medication issues at the beginning or end of the session.
- Symptoms are likely to increase at the end of therapy: giving extra medication is not likely to be helpful.

The problems with integrated treatment arise in mastering two complicated approaches and the need to monitor the complexities of the situation moment by moment, which make this a demanding model to deliver.

### Combined, split or collaborative practice (separate practitioners offering therapy and medication)

Split treatment, which is the most usually practised model, requires good communication, especially when working with patients with personality disorder. The treating pair may not arrive at a formulation that covers both aspects of treatment and may give mixed messages to the patient. Collaboration requires commitment from both parties, meeting at the beginning to discuss the treatment plan and to clarify roles. Respective responsibilities in a crisis should be established. A further meeting should be arranged if treatment is not working or tensions arise.

### Prescribing for patients attending psychodynamic therapy

There is perhaps an inherent tension between psychopharmacological and psychotherapeutic practice. Psychodynamic therapy places emphasis on affects and conflicts being made conscious, which might previously have been repressed. Medication can be characterized as opposing this and may indeed do so. A patient may approach their psychiatrist for help when they find the therapy disturbing or having attained a new-found capacity to tolerate depression rather than resorting to symptomatic ways of avoiding it, such as substance abuse or self-harm, which may be a sign of increasing psychological maturity, being unsure if they will be able to cope with such feelings.
If the psychiatrist understands the differing perspectives of psychiatry and psychotherapy, then the need for communication with the therapist when taking action or prescribing should become apparent. Without this, there is the possibility of destructive enactments – at worst, medication becoming a means of transacting a battle between the therapist and the psychiatrist.

PSYCHOTHERAPEUTIC ASPECTS OF PSYCHIATRIC PRACTICE

The role of the psychiatrist in the mental health team is shifting away from direct involvement with large caseloads, towards a consultative and leadership role in teams. Psychiatrist will be required to have expertise to carry out this role.22

The role of the psychiatrist

- Treating complex cases
- Consulting to teams
- Managing and leading teams
- Developing services
- Offering psychologically informed management.

An understanding of the broader implications of psychological models beyond their application in the formal therapies is essential to undertaking these tasks. Being able to make a psychological formulation is helpful in the management of all cases, especially the most complex.

FORMULATION

Psychological formulation is a hypothesis about how the diverse experiences of distress, behaviour, history, and ‘here and now’ interactions can be summarized into a theoretically coherent synopsis of the underlying difficulty and the factors that sustain it. Those aspects of the patient’s difficulty that are remediable are identified, and the means of bringing about change are clarified.

The framework of formulation varies from one model to another. In cognitive analytical therapy (CAT), arriving at the sequential diagrammatic reformulation (SDR) is a major task of the therapy. This diagram identifies reciprocal roles described in terms of the ‘inner parent’ and ‘inner child’ and traces how target problem procedures are executed and how their consequences are self-reinforcing. The diagram provides patients with an overview of their internal world, upon which they can reflect, and is the basis for taking action to shift entrenched patterns of relating.

This demonstrates the power of a well-constructed, collaborative formulation in helping the patient to gain insight, a capacity for self-reflection and a sense of agency in being able to change their ways of relating and their symptoms.

Figure 60.2 Triangle of person

Psychodynamic formulation

Psychodynamic theory has its own diagnostic system that parallels but does not correspond directly with psychiatric diagnosis. Diagnosis is made not on the basis of behaviour or symptoms but on the basis of theoretical constructs, as follows:

- The quality of ‘internal object relationships’
- The nature of defences and conflicts
- Psychological structures and syndromes.

The term ‘object’ is used in psychoanalytical theory to refer to relationships with others, in the first place parents seen through the lens of infantile phantasy life, which have been internalized and form a template of unconscious assumptions, which are then projected on to others in later life.

Symptomatology is seen as secondary to these underlying and largely unconscious forces. A system for diagnostic formulation has been operationalized for research purposes.23

In clinical practice, psychodynamic formulation can be undertaken during psychiatric or psychotherapeutic assessment. In psychotherapy assessments, the formulation is the basis of a trial interpretation, the patient’s response providing a useful indication of the likely response to therapy. In psychiatric assessment, formulation can inform the management of the patient.

Hinshelwood described a framework for psychodynamic formulation in which the clinician hears what the patient is saying as ‘pictures of relationships with objects’, bearing three areas of relationships in mind.24 These can be described in the form described by Malan as the ‘triangle of person’ (Figure 60.2).16

In order to arrive at a formulation, it is important to provide the patient with opportunities to talk without interruption for some portion of the interview in order to observe the way they relate the transference and unconscious themes. A detailed personal history should be taken, including important events such as significant separations and traumas and also the quality of relationships with important figures. The triangle is a tool to assist clear thinking in connecting aspects of the patient’s presentation into a
aggression on the people they love and upon whom they depend, in this instance the mental health team. The patient divides/splits their emotional world into two halves/parts, others who are loved for being present who in the patient’s mind are kept apart from others who are hated for being absent. The patient is defending against the possibility of losing those they are attached to by keeping these two emotional worlds apart.

**Current life situation/symptom**
This way of relating takes the form of alternating idealization and denigration of others, leading to short-term and unstable relationships and decompensation in the form of escalating self-harm when faced with separation.

**Transference**
With the team, this is played out between two factions in the staff group, one idealized/idealizing and one denigrating/denigrating.

**Intervention**
This situation is described to the team and their reactions framed as countertransference. The psychotherapist points out that the truth about the patient lies somewhere between the victim and perpetrator, this being a representation of an internal relationship between abuser and abused, both aspects being part of the patient’s mental life. The team is advised to collude with neither position but to arrange to see the patient at a regular pre-arranged time and to take the patient’s angriness about their non-availability between meetings on the chin, neither retaliating nor giving in to the demand to provide more. After a few angry and disturbed weeks, the patient’s behaviour begins to settle.

### THE UNCONSCIOUS IN TEAMS AND ORGANIZATIONS

Psychiatrists, particularly at senior level, are called upon to help teams work with their most complex patients, to support reflective functioning, to provide leadership and to identify aspects of the team’s work that are dysfunctional. A psychological viewpoint is essential to undertaking this work, providing concepts with which to understand complex interpersonal systems. After the First World War, psychoanalysts began to conceive of object relations theory as relevant to the social as well as the clinical field. In the 1940s and 1950s, the Tavistock Institute of Human Relations collaborated with industry to understand unconscious processes in the workplace, with a view to improving efficiency. These researchers observed that differences in the ways groups organized their work could be better understood if unconscious motives were taken into account. Isabelle Menzies studied the dropout rate from nurse training. She discovered that nurses organized themselves in ways that...
protected them from the unconscious anxieties implicit in their work and that broke up the human aspects of contact with patients. The cost of this defence was limited job satisfaction, resulting in many talented trainees leaving. Such defensive systems are rigid and uncomfortable, but because of their role in defending against anxiety they are difficult to change.

Systems theory has been added to this largely psychodynamic school of thought. In open systems theory, institutions are conceptualized as having a boundary across which inputs are drawn in, processed in accordance with the primary task, and then passed out as outputs, as would be the case in manufacturing processes. Problems often arise in teams and organizations in identifying outputs and managing boundaries. An organizational consultant would take up the position of ‘participant observer’ to observe dynamic and systemic factors contributing to the dysfunction. The purpose of the consultation process is not necessarily to develop the team’s sensitivity to their unconscious processes that might lead to greater frustration and inability to do the task, but rather to help identify the unconscious and structural obstacles to accomplishment of the task.

**Unconscious aspects of organizational life**

The study of unconscious processes in groups began with Freud’s work *Group Psychology and the Analysis of the Ego*. He described a process in which the crowd follows the leader who personifies their own ideals. In doing so, the capacity for thinking and decision-making is projected into the leader, on whom the group becomes pathologically dependent; at this point, criticizing the leader becomes impossible.

**Bion’s basic assumption groups**

Wilfred Bion, a Kleinian psychoanalyst, defined the tendency of a group towards work on the primary task as ‘the workgroup’ and the unconscious tendency to avoid work on the primary task as ‘basic assumption mentality’. Basic assumption mentality is a means of avoiding work when it is painful or causes conflict within the group.

Bion described three basic assumptions that occur in groups:

- **Basic assumption – dependency**: the group behaves as though its primary task is to satisfy the needs and wishes of its members. The leader is expected to look after, protect and sustain the members of the group in order to make them feel good and not face them with the real demands of the task.
- **Basic assumption – fight/flight**: the group behaves as though there is a danger or enemy, which should either be attacked or fled from. The group follows the leader who is its most paranoid member. Such groups are identified by the lack of an effective response to deal with real threats.
- **Basic assumption – pairing**: the group functions in the grip of a phantasy that a future event will solve whatever the group’s problem is. Some imagined coupling will bring about salvation. On the basis of this phantasy, no practical steps are taken to improve matters.

Leaders of all three groups will be followed only so long as they fulfil the basic assumptions of the group.

Different professions may mobilize the emotions of one basic assumption in the pursuit of the primary task. For example, the dependent basic assumption may be a functional adaptation on a hospital ward, where patients are asked to relinquish autonomy in order to contribute to efficient organization. The fight/flight basic assumption may be entirely appropriate to an organization such as the army, where a clear idea of fighting for a good cause against a common enemy and minimization of doubt may be highly functional.

**Common problems in multidisciplinary teams**

Each profession within a multidisciplinary team may have a different valency for one sort of basic assumption or another. The resulting conflict does not necessarily prevent collaboration but can result in breakdown in the functioning of the team.

Multidisciplinary teams often have difficulty developing a sense of shared purpose. The team may not have the authority to make a decision. It may behave like a band of individuals who get together when it suits them and disband when it does not, rather than functioning as a group unified around achieving a specific task.

**CONCLUSION**

The majority of psychiatrists do not practise as psychotherapists. However, psychological thinking has applications far beyond the formal psychological therapies. In fact, psychotherapeutic skills are fundamental to psychiatric practice. These applications take many forms, including well-informed practice in referring patients to appropriate evidence-based therapies, preparing patients for assessment, and providing thoughtful support while therapy is in progress, all of which can improve therapeutic outcomes, including applying psychological understanding to prescribing and knowing how to optimize the use of medication and therapy together. Psychological thinking is also essential to the psychiatrist in their role in teams, both in planning the management of complex patients through the use of formulation and in identifying when a team is not functioning well and making appropriate use of consultation in resolving such difficulties.
KEY POINTS

- The developments in neuroscience, genetics and the changing social standing of the psychological therapies bring with them the opportunity to re-evaluate old distinctions between biological and psychological perspectives upon the aetiology of mental health disorders. This holds out the possibility of new approaches to treatment.
- The new MRCPsych curriculum recognizes that competence in the provision of psychological therapies and an understanding of their application to psychiatric practice are fundamental to good psychiatric practice.
- Assessing suitability for therapy referral requires consideration of the following factors:
  - Factors belonging to the context of the assessment which might affect treatment and referral decisions.
  - The importance of facilitating the patient in arriving at their own informed decision, providing sufficient information about the evidence and adapting the use of the evidence base to the clinical situation.
  - The psychiatrist must be aware of the level of intervention required and local therapy resources in deciding which service to refer to.
- When working as a psychiatrist alongside a psychodynamic therapist it is important to:
  - Support the patient through difficult periods and crises in therapy.
  - Recognize that negative transference can be fundamental to therapeutic change.
  - Encourage discussion of doubts about and problems with the process with the therapist.
  - Avoid splitting.
  - Refrain from embarking on therapeutic work in parallel with the therapist.
- An understanding of the complexities of the doctor–patient relationship is fundamental to effective prescribing. The potentially synergistic effects of medication and therapy can be optimized by integrated or collaborative practice, the relative merits of which are discussed.
- As the psychiatrist’s role in psychiatric teams moves towards a consultation role with the most complex patients, team leadership and management, the application of psychological thinking to psychiatric practice becomes increasingly important. The ability to make a psychological formulation is essential to this work.
- Psychological understanding can be applied to the functioning of mental health teams. Unconscious defensive structures within teams can influence their work, serving to relieve the team of anxiety rather than resulting in the efficient accomplishment of the team’s task. Such forces also affect the way the team selects and relates to its leader.
- Bion identified three types of basic assumption group – dependency, fight–flight and pairing – basic assumptions which may serve as functional adaptation of a teams task or may prevent functioning of the work group towards achievement of the primary task.

INTRODUCTION

Psychodynamic psychotherapy is the oldest established form of psychological therapy that is currently in use. The attention it pays to the relationship between therapist and patient in treatment, and the theory of mental functioning on which it is based, are reasons why all psychiatrists need to be familiar with its principles. For clarity, I refer to any unnamed therapist as ‘she’ and any unnamed patient as ‘he’ throughout this chapter.

ORIGINS OF PSYCHODYNAMIC PSYCHOTHERAPY

Psychodynamic psychotherapy represents the tradition in psychotherapy derived from psychoanalysis. Psychoanalysis was developed by a Viennese neurologist, Sigmund Freud, as a ‘talking cure’ for people with what were then termed ‘psychoneuroses’. These included the somatic presentations of ‘hysteria’ as well as obsessive-compulsive syndromes. The guiding principle was that symptoms arose as a consequence of active suppression of feelings and memories that the patient did not wish to experience. In order for these to remain unconscious, the conscious ‘I’ was protected by a variety of mechanisms of defence (see below). (Translators have used the term ‘ego’ for the ‘I’ when rendering Freud’s work in English. This not only distorts his meaning but also conceals the dynamism of his language.) Different kinds of defence operated in a neurosis such as hysteria compared with in obsessional-compulsive disorder. REMediying this through psychoanalysis meant ‘rendering the unconscious conscious’. As Freud’s own understanding of the scope and operation of unconscious mental processes grew, this could involve the retrieval of suppressed memories, understanding of meaningful but consciously unintended actions (hence the ‘Freudian slip’), and the interpretation of hidden motives from the analysis of dreams. The sorts of hidden motive that Freud emphasized were those in which loving feelings were mixed with sexual excitement. He referred to a distinct kind of energy, the libido, to explain this. The natural expression of libido could become fixated at various points during the early years of life. Unconscious mental life was dominated by the satisfaction of libidinal wishes, the so-called pleasure principle. The rational everyday ‘I’, however, was governed by the reality principle in its efforts to ensure that internal representations reflected what the world beyond the ‘I’ actually was like.

Libidinal fixations could reflect parental behaviour or events that were experienced as highly threatening. Freud was especially interested in how libidinal longings for the opposite sex were resolved. The same-sex parent needed to prevent unrealistic hopes continuing, without crippling their young child’s capacity to express affection and sexuality in their later relationships, through a prohibition that could be experienced as castrating. This was the basis of the Oedipus complex, played out between the child and both parents. Towards the end of his career, as he attempted to explain phenomena associated with depression, destructiveness and morbid guilt, Freud believed that a death instinct afforded an additional source of unconscious motivation. The death instinct became associated with the censorious part of the personality known as the ‘over-I’ (usually translated as ‘super-ego’), whereas the pleasure principle continued to dominate the unconscious mind that he referred to as the ‘it’ (commonly translated as ‘id’).

Once he had moved beyond hypnotism and established a distinctive psychoanalytic method, Freud’s clinical procedures were demanding of both the patient and the analyst. Continuity was prized, with sessions being held daily for 5 or 6 days per week. Patients were expected to avoid being distracted by their surroundings and to verbalize whatever came into their mind, without censorship or selection. This is the process of free association, and the basis of having patients lie back on a couch from which they do not see their analyst. The analyst was also expected to clear her mind and adopt ‘evenly hovering attention’ towards the patient’s associations, so that she did not listen too selectively or jump to premature conclusions about their ultimate meaning. However, as the analyst became familiar with the nature of the patient’s unconscious material, and the ways in which he defended against it, the analyst would assist the process of conscious recognition by interpreting
Interpretations were statements designed to deepen the patient’s conscious understanding of their situation, based on hypotheses that form in the analyst’s mind. They serve to increase the range of the patient’s emotional experience and to link events and meanings that had not previously been associated.

In the early days of psychoanalytic practice, it became clear that analysts would be objects of their patients’ feelings, fantasies and wishes, and that patients commonly projected wishes and expectations derived from their relationships with their parents onto the analyst. This phenomenon was recognized as transference. If ignored, transference could obstruct the analysis as a patient’s desire to act towards the analyst on the basis of such wishes and distortions grew. However, by making transference itself the subject of interpretation, it became a valued tool in the process of making the unconscious conscious within psychotherapy. Transference has remained one of the cornerstones of psychodynamic thinking ever since. It has also received support from independent empirical research. Studies in the 1980s by Paul Crits Christop and colleagues that looked at episodes during which people in therapy discuss key relationships confirmed that patients tend to frame their experiences of other people in terms of a very limited set of templates. These templates are personal to them, and not only are repeated across their reports of current relationships but also mirror the patterns of interaction they will report having had with their own parents.

Defence

The concept of defence is central to psychodynamic thinking. It can refer to attempts to mitigate the impact of external events were we to become fully aware of them (perceptual defence) or from other people (social defence). However, psychodynamic psychotherapists tend to be most concerned about defence mechanisms that operate in reaction to threats from within. Once the mind is understood as being differentiated, with a central, aware part sitting alongside parts having operations and contents of which we are not aware, then the latter can pose a threat in themselves that may be defended against. Although there are different ways of describing and labelling the psychological defences, some are more adaptive than others; that is, they act to allow the conscious self to carry on integrating our experiences and responses in a relatively consistent way without unduly compromising the ability to function. However, other defences, although they may serve to reduce the anxiety that would otherwise be felt if uncomfortable feelings and impulses were not warded off, do so only by impairing the ability to cope in other ways.

Defences of this kind either compromise the individual’s ability to discern what is external reality (as in denial) or disrupt the experienced self’s internal cohesion (as in splitting or dissociation). The distinction between adaptive (or mature) and dysfunctional (or immature) defences has often been upheld by psychotherapy researchers, who have linked reliance on the latter to poor long-term adaptation and risk of psychiatric illness.

Working alliance

Although the term ‘working alliance’ was developed in psychoanalysis, it is frequently encountered in psychology, where it has been strictly defined and investigated. Three components are often defined: agreement on the goals of treatment, agreement on the method of treatment, and the empathic bond between a therapist and her patient. The concept has been extremely influential because studies of factors predicting the success of psychotherapeutic interventions (irrespective of method) have consistently highlighted the importance of a good therapeutic alliance. In psychodynamic therapies, particular emphasis is placed on the quality of the felt bond within the working alliance, which reflects the therapist’s sensitivity to the patient’s internal state and the patient’s responsiveness to the therapist’s attention. Other terms that have been used to articulate this felt sense of responsiveness are ‘rapport’, ‘mutuality’ and ‘attunement’.

Countertransference

Countertransference, like its complement transference, is an important influence on the working alliance in psychodynamic therapies. It refers to responses that an analyst can have to a patient that appear to be irrational or exaggerated and that may also carry a strong emotional charge. Countertransference may reflect projection on the therapist’s part of her own tendency to construe present relationships on the basis of her own past experience. Or it can represent a response to affects that belong to the patient’s transference that are projected into the therapist. In practice, it is usually a complex mixture of the two.

Resistance

Freud used the term ‘resistance’ to describe how patients would obstruct the therapy they were receiving. Although the patient may say he wants the treatment to work, the treatment represents a threat to the patient’s present internal organization. Resistance represents a kind of retaliation in favour of the status quo and may take many forms both inside the therapeutic sessions and between them. Negative therapeutic reactions are a particular form of resistance. They are recognized when a patient has been making evident progress, before a sudden reversal sees him deteriorating, even though he may appear to be cooperating. Acting
out is a less subtle form of resistance. Patients are said to act out when, instead of disclosing their thoughts and feelings to their therapist, they respond to invitations to contact their inner feelings by enacting their conflicts and distress outside of therapeutic sessions. Acting out may take the form of dramatic appeals for help from other people and incidents of self-harm. It is also possible to enact distress, rather than articulating it, during therapeutic sessions, behaviour that is sometimes referred to as acting in.

**Regression**

Regression refers to the tendency, when placed under stress, to revert to ways of coping belonging to an earlier stage of life. Some of the theoretical models of development discussed in the next session describe forms that regression can take in pathological states. Regression is to be expected, and may be encouraged, in the course of exploratory psychotherapy. During therapeutic regression, patients may become more child-like and dependent on the therapist. Indeed, failure to understand and to work with regression is a common cause of worsening, and even loss, of the working alliance. Patients differ significantly in the ease with which they regress in or out of therapy. Some, having an unstable personality structure or a tendency to dissociate, can regress with alarming ease but may also have considerable difficulty in reverting to adult ways of coping afterwards.

**Interpretation**

Interpretation is a key form of intervention in psychodynamic psychotherapy, being a verbal statement by the therapist designed to deepen the patient’s understanding of his difficulties. While transference interpretations, which make explicit links between a patient’s expectations and feelings in relation to their therapist, current significant others in their present life, and parental figures, are frequently cited, interpretation can take many other forms.

**Insight**

Insight refers to the discovery of psychological truths about oneself. It is an emotional as well as a cognitive accomplishment. Real insight therefore is not simply accepting such and such a piece of accurate information. It occurs when a new understanding not only feels right but also opens up new ways of feeling about things for a patient.

**Working through**

Psychodynamic psychotherapy is a process by which, through the modification of defences and the emergence and acceptance of relatively hidden aspects of their personalities, people can find fulfillment in love, work and play. To achieve this, those parts of the personality that are dominated by rigid defences are likely to resist such developments. Help is likely to be needed for them to soften. In practice, this is not a one-battle campaign. Advances are followed by retreats, and insights gained can even seem to disappear. Ground therefore needs to be retrodden within the therapy itself to ensure that more and more of the patient’s resources are recruited to the forces of health. Working through in this way also ensures that internal change translates itself into successful adaptation in the patient’s life.

**Mentalization**

The security of a person’s attachment has been linked to their capacity to appreciate the independence of other people’s minds, or to experience themselves as having a mind in which the ways they feel, think and try to act are interlinked. When attachment is disorganized, as in many people diagnosed with borderline personality disorder, this capacity is severely limited. In response to this, mentalization has become not only a psychological capacity, but also a therapeutic goal. Mentalization-based therapy (MBT) has become a significant offshoot of traditional psychodynamic psychotherapy in which the patient learns to appreciate themselves and others as having minds, with the capacity to interpret things that happen in very different ways and to have quite independent feelings and priorities.

**MAJOR INNOVATORS AFTER FREUD**

**Melanie Klein**

Unlike Freud, Melanie Klein worked extensively with children as patients and drew on her experience as a mother. Her thinking about early development emphasized links between adult psychopathology and failures in the bond between mother and child. Although not jettisoning the idea of psychosexual fixation, Klein emphasized the influence of fantasy in psychological development and the importance of organizers of internal experience that were highly sensitive to experiences of mothering. These were termed ‘objects’, with Klein making two important and closely related distinctions. These are between the experience of part objects as opposed to whole objects, and the capacity of adults to function in either a paranoid schizoid position or a depressive position. Part objects are experienced as essentially good or bad and are associated with very strong, unprocessed feelings of love or hate. They are characteristic of a primitive and developmentally early kind of functioning that Klein inferred from her clinical work. She referred to this as the ‘paranoid-schizoid position’ because of its prominence in these kinds of adult psychopathology. Paranoid-schizoid functioning was associated with particular defence mechanisms, including splitting and what Klein called ‘projective identification’. The latter has continued to
be elaborated in various ways. It is a particularly complex form of psychological defence that implicates the analyst (or mother) as well as the patient, and it is clinically associated with states of mind found in people prone to psychosis or borderline personality.

By contrast, Klein’s whole objects are experienced as embodying both desired and feared or hated aspects. Appreciating that the mother has both of these aspects is seen as a major psychological achievement, and one associated with considerable guilt on the infant’s part for the attacks the mother has been subjected to by the infant when experienced as ‘bad’. The capacity to appreciate and relate to whole objects is characteristic of the developmentally later depressive position. Klein attributed both depressive and manic states to difficulties in negotiating this phase successfully. (For a cogent illustrated summary, see Hinselwood and Zarate.)

Klein’s thinking has given rise to a whole school of psychoanalytic thinking that has been particularly influential in Britain within the psychotherapy of children and adults. Her most important successor has been Wilfrid Bion, whose impact has been worldwide. Bion developed Klein’s interest in severe psychopathology to reformulate the dynamics of psychotic states. His theory of how thinking develops, which makes sense of how it can become disordered during psychotic breakdowns, has been particularly influential. It identifies the psychoanalyst as someone who shares a capacity (which Bion calls ‘alpha function’) with any emotionally competent mother as she interacts with her infant. Alpha function allows either of them to metabolize unbearable feelings on behalf of the patient/infant, so that they can be fed back in a form that the patient/infant can assimilate and thereby link feelings with thoughts for himself. This is the basis of the analytical action that Bion referred to as ‘containment’ – a term that has become very widely used, even if its original meaning has been broadened to refer to a capacity to hold all kinds of anxiety on a patient’s behalf. (A useful summary of Bion’s contributions can be found in Stein.)

Donald Winnicott

This paediatrician was well placed to observe the differences between successful and unsuccessful parenting. He emphasized the importance of play within healthy emotional development, including the healthy expression of aggression. Winnicott identified the importance of transitional objects (e.g. teddy bears) to provide a sense of psychological support as the infant engaged more with the world away from mother. His ideal of the ‘good-enough mother’ was intended to counter anxiety-driven perfectionism that otherwise prevented healthy development, leading to compensatory development of what Winnicott termed the ‘false self’ (for further description, see Phillips).

Although Klein and Winnicott both recognized that we have a fundamental motivation to relate to others that cannot be reduced to other instincts, their thinking continued to combine references to sexual and destructive instincts alongside object-seeking. In Scotland, the philosophically talented psychoanalyst Ronald Fairbairn developed a theory in which object-seeking was primary to any other kind of motivation. A general practitioner (GP)-psychoanalyst, Michael Balint, developed the theory of regression and pioneered the application of psychoanalytic thinking within case discussion groups. These helped non-psychotherapists such as GPs to reflect on the emotional nuances of their clinical interviews, becoming known as ‘Balint groups’.

Sir John Bowlby

Bowlby referred to attachments to other people as ‘affectional bonds’ that are just as biologically based as Freud’s ‘instincts’. He cited evidence drawn from ethological studies of other primates concerning critical development periods and the instinctual responses to separation and loss. The attachment theory that resulted has differentiated the forms or styles that ‘insecure’ attachment can take and linked their occurrence in childhood with vulnerability to psychiatric problems in adulthood. Attachment theory has emphasized the importance of actual parenting experiences (rather than fantasized ones) early in life, and provided a model for the psychodynamic therapist to provide a secure base from which a patient, like a securely attached baby, might find confidence to explore. Attachment theory has emphasized the developmental importance of learning to recognize and moderate strong emotions (‘affect regulation’), a function that has come to be seen as key to much subsequent psychotherapy.

Heinz Kohut

The USA has had a strong psychoanalytic tradition in which both Freudian and object relations traditions have been adopted and adapted. Like Fairbairn, the USA’s most original thinker, Heinz Kohut, developed his ideas in relation to the USA. Kohut’s focus has been the psychopathology of narcissism, which he regarded as widely prevalent. He used the theory of the ‘self object’ to describe how different forms of internal transference within the self were associated with different forms of character pathology. In practice, rather than advocating a challenging, interpretative approach, Kohut championed a gentle, empathic stance towards patients whose narcissism was perceived to be the consequence of poorly attuned caregiving in the past. (For a manageable resume of Kohut’s ideas, see Mitchell et al.)

Carl Jung

Jung was a Swiss psychiatrist who, as a protégé of Manfred Bleuler as well as Freud, worked extensively with people hospitalized for psychotic illnesses. He saw the frustration
of people’s search for meaning as a greater psychological problem than the frustration of sexual expression and drew on studies of ancient symbols and myths, as well as his own and his patients’ experiences, to argue that the individual mind is not a blank sheet at birth but is already primed by a ‘collective unconscious’. Jung elaborated on the concepts of the ‘complex’ and the ‘archetype’, the exploration of these being key to his clinical method. This aims at a rebalancing of the personality through individuation. Although Jungian analysis is often as intensive and prolonged as psychoanalysis in practice, its basis is properly referred to as ‘analytical psychology’.

Jacques Lacan
In continental Europe, the most significant recent figure in developing psychodynamic ideas has been Jacques Lacan. Lacan achieved notoriety early in his career by unpredictably varying the length of his therapeutic sessions. However, his work has represented a highly original reworking of Freud’s ideas that is sensitive to a postmodern world in which the personal self has become deconstructed or reduced to a set of actions, rather than having a knowable centre. Lacan turns to language in an attempt to identify key developmental processes, emphasizing the importance of a paternal function as infants learn to structure their experience of the world, and of themselves, by the way they learn to use words during a ‘mirror phase’ of development. Freud had acknowledged the importance of paternal functions in his conceptualization of the Oedipus complex. Lacan’s reinterpretations counteract a trend in both the Kleinian and attachment-based traditions to emphasize maternal functions in the understanding of early life.

Psychoanalysis and dynamic psychotherapy
Although psychodynamic psychotherapy has continued to be indebted to psychoanalytic innovators for important theoretical ideas, the practice and spread of modern dynamic psychotherapy has depended heavily on the development of relatively brief, structured models of treatment. These have taken many forms, while continuing to emphasize the importance of early development, psychological conflict, exploration, and expression of feelings and transference within the therapeutic setting. Three key figures in the development of short-term dynamic therapies, whose influence has been lasting, are James Mann in the USA, David Malan in the UK and Habib Davanloo in Canada.

GROUP PSYCHODYNAMIC THERAPY

Psychoanalytical and psychodynamic principles have been applied successfully to working with patients in groups for over 80 years, in both out-patient and in-patient settings. Apart from the perceived benefits of providing any psychological therapy in groups in terms of efficient use of the therapist, psychodynamic group therapies afford experiences during therapy that are not available in individual work and that can be particularly helpful for some patients. For example, being in therapy alongside others can reduce the pressure to talk, or to be consistently intimate, which can make groups less daunting for some avoidant patients. Conversely, some patients who form extremely intense attachments to others, fearing abandonment in every gesture a therapist makes, can be reassured by the secure sense of others’ presence that a group affords. Other individuals, normally distrustful of authority and professionals in general, can find it harder to ignore home truths that are spoken by fellow patients.

Therapeutic factors in groups
Other aspects of the group situation are likely to be experienced as helpful by most people who participate in group psychotherapy. These have been labelled by Yalom as ‘curative’ (later ‘therapeutic’) factors. They include the opportunities for what has been termed ‘social learning’ that exposes the gaps between their self-impressions and what others actually see; the quality of support that group members can provide another as they work through challenging situations, both internal and external; and the realization that their problems are not as unique (and they themselves not as abnormal or unforgivable) as they thought. In sum, Yalom’s therapeutic factors are:

- Instillation of hope
- Universality
- Imparting information
- Altruism
- Corrective recapitulation of the primary family group
- Development of socializing techniques
- Imitative behaviour
- Interpersonal learning
- Group cohesiveness
- Catharsis
- Existential factors.

Transference in groups
The growing importance of models founded on object relationships within psychodynamic theory has highlighted the potential of groups as a therapeutic arena where patients’ patterns of relating in the group can be observed and related to hypotheses about their internal world in terms of object relations and attachment patterns. In a group, patients are likely to experience the distortions of transference in relation to other patients as well as in interactions with the group’s conductor. Experimenting with alternative ways of relating with others within the group can then lead to lasting changes in relationships beyond the group.
Principal group therapy theorists

Irving Yalom

In practice, different elements of groups have been emphasized by different authors. Among the ‘curative’ or ‘therapeutic’ factors outlined above, Irving Yalom has emphasized the importance of cohesion to a group’s success. Cohesion is a measure of the positive bonds felt between members. It is reinforced by the group developing values and norms that its members subscribe to. Accordingly, the group leader is expected to assist the group’s moves towards cohesion, as this will allow its members to take more risks in learning from one another.

Wilfrid Bion

Yalom’s approach is antithetical to that of Wilfrid Bion, a Kleinian psychoanalyst who, with Tom Main and others, developed group-based therapeutic programmes in UK military hospitals during the Second World War. Bion felt that people very rarely actually listened or communicated with one another and that claims of agreement were usually illusory and placatory. In group situations, people would try to protect themselves from this unsettling reality by a small number of predictable shared defensive manoeuvres, which he termed ‘basic assumptions’. These were fight or flight (in which members would act from a compulsion to either attack or retreat from the conductor); pairing (in which they would try to form exclusive links within the group, as if the others were not there); and dependency (in which members develop unrealistic expectations that the group leader will rescue them from their discomfort).11 In carrying out the task of what was seen as necessary disillusionment, the group leader would concentrate on interpreting the actions of individuals in relation to herself and the group, to the relative exclusion of the group members’ individual needs.

SH Foulkes

Something of a middle position is represented by SH Foulkes, the founder of group analysis. Like Bion, Foulkes saw the group as an exploratory analytical setting, where dynamics operated at group as well as individual levels. Like Yalom, Foulkes believed that groups needed active help from the conductor if the optimum environment for exploration was to be established. However, this did not necessarily involve cohesion, as Foulkes believed that differences within the group should flourish, necessarily reflecting differences in the social world of which its members were part. For Foulkes, the group conductor’s task was to be a ‘dynamic administrator’, paying particular attention to the group’s boundaries so that the group was at the same time a safe, reflective space protected from the outside world and also one where external matters that contributed to members’ conflicts and difficulties could be admitted and made the subject of dialogue between the group’s members.14

INDICATIONS FOR BRIEF, LONG-TERM AND SUPPORTIVE PSYCHOTHERAPY

Traditionally, suitability for psychodynamic psychotherapies has been assessed in terms of the person’s ability to engage with and use this kind of therapy, rather than the kind of clinical problem they presented with. Capacity to work psychodynamically was therefore judged by whether the person was ‘psychologically minded’ and whether they had ‘ego-strength’. Psychological mindedness is many faceted, but a simple definition includes being aware of and interested in emotions, motivations and potential for change in oneself and in others.15 Ego-strength is a less widely accepted concept, which referred to the person’s psychological resilience as evidenced by their capacity to withstand emotional challenges and to achieve short- and long-term goals despite hindrances. Although these ideas continue to be taught, and to have predictive validity, they can be misleading. Developed at a time when psychodynamic psychotherapies were dominant, the ideas are associated with a greater likelihood of success in almost any of the psychological therapies that are now available. Additionally, although they can appear to be traits that are either present or not, in practice they can each be enhanced as a result of psychotherapy, with the possibility that suitable preparatory work could help a person who might be thought of as unsuitable for therapy to reach and cross the traditional threshold for suitability for psychodynamic work. This may be evident from the description of mentalization already given, with MBT effectively enhancing the person’s psychological mindedness. Similarly, preparatory work aimed at helping the person with ‘affect regulation’ and ‘problem-solving’ is enhancing ‘ego-strength’ when it is successful.

The US psychotherapist Lester Luborsky made a helpful distinction between ‘supportive’ and ‘expressive’ aspects of psychodynamic psychotherapies, recognizing that any therapy contains a combination of both components.16 In supportive mode, coping mechanisms are consolidated. In expressive mode, exploration is facilitated and regression encouraged. The actual mixture can vary from therapy to therapy and within a therapy. Engaging a patient at a point where further consolidation of psychological mindedness and ego-strength is required means that an emphasis on supportive over expressive components would be needed before consistently exploratory work was undertaken. Starting there sets a lower threshold for potential patients to start therapeutic work. It can also render the outcome of psychotherapy even more sensitive to external factors, such as the patient’s current social and family situation.

Alongside the patient’s capacity to engage with a therapy, the evidence-based practice movement has emphasized considerations of presenting problems in treatment choice. There is probably more justification for this stance in the case of physical treatments than psychological ones.
Nevertheless, when the results of formal comparative clinical trials are taken into account, the evidence for the efficacy of psychodynamic psychotherapies is strongest in people with personality disorders, with clear evidence of usefulness in cases of trauma, depression, eating disorders and some kinds of medically unexplained symptoms. This should be taken into account when advising, referring and assessing new patients. (See Appendix 2 in Royal College of Psychiatrists\(^\text{17}\) for a table comparing the evidence base for different psychological therapies. For a fuller treatment of this evidence base, see Roth and Fonagy.\(^\text{18}\))

An important practical consideration is the quantity of therapy that the patient should be given. Time-limited therapies are favoured when patients have relatively circumscribed difficulties and where areas of weakness are offset by personal strengths. Patients need to be motivated and able to use the approach without lengthy preparation, while youth is a definite advantage when significant change is sought. Aveline has described time-limited therapy as contraindicated with people who have marked difficulties over trust and those who have a great deal of pain to gradually uncover and disclose.\(^\text{19}\)

### LEARNING PSYCHODYNAMIC PSYCHOTHERAPY

This brief summary should help to make sense of a number of the key ideas that inform current practice. When undertaking a psychodynamic psychotherapy, the therapist needs to have a working theoretical framework that equips him or her to assess patients and to initiate, carry out and successfully conclude treatments. This can be summarized as a framework of the necessary skills or competencies. Although these will be indebted to the ideas discussed here, they also stand as a body of procedural knowledge in their own right. In the past, these therapeutic skills have been largely implicit, learned by practitioners through a long and sometimes uncertain process of learning by example or osmosis. Undergoing personal therapy, an essential element of training for all forms of psychodynamic therapy, can encourage this as trainees learn to imitate their own therapists. However, the publication of formal curricula for trainee therapists can be invaluable in clarifying the practical as well as the conceptual framework of psychotherapies of all kinds. Useful examples can be found at www.skillsforhealth.org.uk.

### KEY POINTS

- Psychodynamic therapies are derived from psychoanalysis.
- They emphasize the influence of early development and the relationship with the therapist during treatment.
- Therapies are provided in individual and group settings.

### REFERENCES

INTRODUCTION

The word ‘systemic’ has entered popular discourse in a similar way to Freudian concepts, such as unconscious drives and catharsis. It derives from general systems theory, which became one of the guiding conceptual frameworks for family therapy. However, it has a wider range of application than families and is increasingly been used to consider patterns and processes within organizations such as the National Health Service (NHS) in terms of the interactions and problems within and between different services and professional groups. For the medical professions and psychiatry, there are significant issues regarding their power relationships to other professionals and referrers. Interestingly, many of the pioneers of family therapy were medically trained and specialists in psychiatry.1–5 It is perhaps worth speculating from the outset that the type of family therapy models they developed had a tendency to use more directive approaches to family therapy, which utilized their high status and power as physicians and psychiatrists. Later waves of family therapy that advocate more narrative, collaborative and non-directive approaches were developed by social workers.6,7

Family therapy has existed as a form of clinical intervention for a variety of conditions for about 50 years.8–10 Alongside the development of a variety of forms of therapeutic techniques and orientations, ‘the family’ has also continually been a source of social and political debate and intervention.11 More specifically, the concept of ‘the family’ has shifted and been the centre of great controversies over its desired nature and function. There have been dramatic changes in the structure and nature of family life, such that many children no longer grow up in the traditional nuclear family but live in reconstituted families with step-parents or homosexual parents or in adoptive or foster-care situations.10,11 There have even been dramatic attempts to remove the family and replace it with structures such as communes, collectives and kibbutzim.11 Although the debates and issues are complex and controversial, one important dimension has been the extent to which families are seen as the cause of problems – the family to blame – as opposed to the extent to which families are seen as a positive resource. These two aspects are not distinct, but social policy and political rhetoric seem to revolve in cycles between the two extremes, for example increasing attempts to control families and their functioning. Some examples include the development of antisocial behaviour orders (ASBOs), parenting orders in the criminal justice systems, and forms of early intervention such as the Sure Start parenting and child programmes designed to help correct ineffective or destructive parenting. Sure Start and similar programmes attempt to help families to become a positive resource, but possibly they also carry an assumption that something is currently awry and needs repair. The alternative stance emphasizes potential and resources that families may hold and looks to factors that may block or impede this, for example social conditions, housing, ill-health, poverty and crime. This view fosters an orientation of working alongside families to help ameliorate these conditions and free them up to function well.

Where does family therapy fit within these two broad orientations? For professionals such as general practitioners (GPs), who make decisions about referrals, this is an important question. In making referral decisions, they can set in motion pathways that potentially start to label and designate families and their members as ill or as responsible for the problems. Some family therapists have argued that the very term ‘family therapy’ constructs an unhelpful framework in that it implies the position of there being something wrong with the family that needs to be corrected. However politely and diplomatically the referrer tries to reassure clients that family therapy is a non-blaming approach, there is still considerable potential for family members, especially the parents, to feel blamed for the problems that one or more of them is experiencing. For these reasons, the family therapy movement has argued that it would be better to use the term ‘systemic therapy’. Unfortunately, this term, as well as being less blaming, is also incomprehensible to most families and many professionals outside of the family therapy movement.

The above distinction contains some of the core variations in the different models of family therapy and their evolution.9 Specifically, this is the distinction between problem- as opposed to solution-oriented versions of family therapy. In the former, the therapist and the team start with an exploration of the problems – what is going wrong and
that infants do not arrive in the world with such a simple theory and practice.8–10 The most obvious difference the greatest influence on the development of family therapy systems theory, but arguably general systems theory has been Not all family therapy approaches derive from general systems theory, stressing nature of the problems but not encouraging an overly negative or failing framework.

In practice, many family therapists combine features of both approaches, showing that they are aware of the distressing nature of the problems but not encouraging an overly negative or failing framework.

**SYSTEMIC FAMILY THERAPY**

Not all family therapy approaches derive from general systems theory, but arguably general systems theory has been the greatest influence on the development of family therapy theory and practice.8–10 The most obvious difference between family therapy and other forms of therapy is that the target interventions are aimed predominantly at altering families rather than individuals. Consistent with this, family therapists spend most of their time working with groups of people rather than individuals. Of course, some other forms of therapy, such as group therapies, also involve working with groups of people; however, family therapy aims to focus on natural groups of people, such as families, who have spent considerable time with each other. This exposure to each other over time is seen as leading to the development of patterned, repetitive and predictable forms of interaction, and it is these patterns – what goes on between rather than what goes on within people – that are the focus of interest. This distinction between the individual and an interacting system is not a simple one, and it is recognized that drawing the distinction biologically between the boundaries of a person’s body – the perimeter of their skin – and another’s is not as straightforward as it may intuitively seem at first.14 Certainly there is much indication that infants do not arrive in the world with such a simple distinction. For example, infants are intimately connected to the mother in the womb and are highly physiologically responsive after birth to her heartbeat, milk and voice.15

Children differ in how much and how rapidly they separate from their parents to become autonomous, and too extreme separation or lack of it appears to be problematic.5,8 An early and dramatic illustration of some core systemic ideas can be seen in a piece of research conducted by Salvador Minuchin and colleagues.2,16 In an attempt to explore the interconnections between family dynamics and internal states in individual family members, measures were taken of some physiological changes associated with levels of stress. (Ways of measuring stress levels have advanced since this study, but it is presented here since it was a pioneering study and approach to working with families.) The Collins family had two daughters, Dede (17 years) and Violet (12 years), who both had diabetes. There was no obvious difference in the girls’ individual responsiveness to stress, but Dede suffered much more severely from diabetes and had been admitted to hospital for emergency treatment 23 times. Violet had some behavioural problems that her parents complained of, but her diabetes was under good control. Minuchin interviewed the parents for an hour (9–10 a.m.) while the girls watched from behind a one-way mirror. From 9.30 a.m., Minuchin deliberately encouraged the parents to discuss issues of conflict (a structural technique called intensification), which led to some experience of stress, in order to see how this affected the children. Although the children were only observing from behind the screen and could not take part in the conflict, their free fatty acid (FFA) levels rose as they observed their stressed parents. At 10 a.m., the children joined their parents, and their different roles in the family became apparent: Dede physically sat between her parents, and each parent attempted to get her support against the other so that she was in a no-win situation. Violet’s allegiance was not sought in this way, and she could respond to her parents’ conflict without being caught in the middle. The effects of these two roles are indicated by the changes in the girls’ FFA levels (Figure 62.1).

![Figure 62.1 Stress and family structure](image)

FFA, free fatty acid.
Both of the children showed an increase in their stress levels when watching the parents from behind the screen, although Dede showed a much higher increase; most interestingly, Dede then demonstrated a dramatic increase when the girls joined their parents in the room. In contrast, her sister Violet showed an initial increase and then a decrease in her stress level. Minuchin’s hypothesis was that Dede acted as a conduit for the conflict in the family; as Violet saw Dede being drawn into this role, it allowed Violet to feel less stressed. Importantly, after the interview, it took much longer for Dede’s stress level to settle back down in contrast with that of the other family members.

CORE SYSTEMIC CONCEPTS

This study exemplifies some core concepts underlying systemic family therapy. Individual experiences, including physiological states, are related intimately to family dynamics. Since family processes are continual, each member of the family is also continually influenced by these dynamics. Even when physically by themselves, the children may continue (as Dede so clearly shows in the study above) to be influenced by the physiological after-effects and of their memories of relationships. The example given above also demonstrates the concept of triangulation – how the parents pull Dede into their own conflict, for example by changing the topic of the conversation from their marital conflicts to Dede’s diabetes when the discussion becomes too uncomfortable for them.5,5 This shift to looking at processes between not only two but three or more people is one of the critical contributions of systemic family therapy approaches.

Symptoms as relational

The early pioneers of family therapy drew on ideas from general systems to propose that families, especially those that can come to display serious difficulties, could be seen as similar to mechanical and biological systems. Jackson proposed the concept of ‘family homeostasis’ to suggest that a symptom in one or more of the family members develops and functions as a response to the actions of the others in a family and becomes part of the patterning of the system.4 Attempts to change the symptom were seen to encounter ‘resistance’, since the system operated as an integrated whole and strove to maintain the homeostasis. By ‘resistance’, Jackson implied not a conscious but a largely unconscious pattern of emotional responses to change in one or other family members. As an example, if an angry disruptive child starts to behave in a more acceptable way, then it may be that the unresolved conflicts between the parents start to surface or that another sibling starts to display difficulties or to aggravate their reformed sibling to re-engage in problems. Jackson argued that family systems containing problems or ‘pathology’ could be seen to operate as ‘closed systems’. These operated so that any change in the symptomatic member would be met by actions in the others, which would have the sum of reducing, rather than encouraging, change. Despite family members expressing a desire to change, it was argued that the symptoms had been incorporated into the relationship dynamics and served a positive function for the family. Jackson elaborated on this idea by suggesting that families acted as if they were regulated by a set of largely unconscious rules.

This view of problems has had significant implications for our view of problems and for the relationship that systemic family therapy has with diagnostic systems, such as the Diagnostic and Statistical Manual of Mental Disorders (DSM). At the extreme, some systemic family therapists have questioned the value of diagnosis and suggested that it could lead to families becoming stuck around a definition of the problems as existing in one person, possibly serving to aggravate or make a condition chronic.5,17 In contrast, some family approaches, especially the expressed-emotion, psychoeducation-based family interventions, have worked alongside diagnosis to look at how families members can be helped to live with conditions such as schizophrenia, depression autism and attention deficit hyperactivity disorder (ADHD).18

It is probably fair to summarize the current practice in family therapy as a hybrid between an acceptance of diagnostic categories and a fully systemic view of problems. It is recognized that many parents gain a sense of relief and feel the burden of blame lifting when they hear, for instance, that their child has ADHD. Such a diagnosis can offer a window of therapeutic opportunity while the family is less anxious to explore other explanations and to think of ways in which their interactions may make the situation better or worse. On some occasions, the consequence of such a strategy seems to be that, as the family becomes more aware of some of their processes and comes to feel safe with and trust that the therapist and the team are not blaming them, medical diagnostic considerations become less salient. However, here it is especially important to note that families live in different contexts; outside systemic therapy, they may be exposed to perspectives that continue to emphasize medical explanations. Drawing a map of the professionals with whom they are involved can help to create some clarity for the family members so that they do not rattle between competing explanations in unhelpful and confusing ways. One helpful stance can be to suggest that, for some conditions, ‘the jury is still out’ – for example, ‘We are still not absolutely sure what the causes are, but to explore how the condition, whether or not it is an illness, may be ameliorated by the family dynamics and the support possible may be a useful activity to undertake together.’

Power

The question of power has been hotly debated in systemic family therapy. It has been argued that a central issue in a
family is the need for clarity of the hierarchy and decision-making process. Specifically, at significant times the parents need to be clearly in charge of the children and able to exert control and influence over them when necessary. Further to this, it was seen as essential that the parents were able to work together in a consistent way in order to exercise control to ensure the safety and social behaviour of their children. More theoretically, the concept is central to systems theory, as systems are seen as having mechanisms that exert control over, or regulate the dynamics of, a system. However, exerting control is not simply equivalent to power: Bateson criticized a simple conceptualizing of power in human relationships, arguing that one person cannot control another except in the most basic physical ways. Instead, we exert influence over each other through a variety of forms of communication and interaction, such as persuasion, humour, bribery and seduction.

Context

Again drawing on biological metaphors, systemic perspectives emphasize that families and other relationships need to be understood in terms of the environment or context in which they are located. For example, a family may act differently at home, in a supermarket, in the GP’s surgery and in a family therapy session. Likewise, the children may act differently at home, at school and out on the street with their friends. Each situation in effect carries different rules about what is seen as appropriate behaviour and how we ought to behave. Within the family, there can also be seen to be a variety of contexts, for example the parents alone together, the siblings with each other, the parents with the oldest or youngest child, the family with the grandparents, and so on. It is argued that such contexts are in part guided externally, for example what is or is not appropriate for parents to do in front of the children. However, families also improvise and develop their own local contexts; for example, being with the grandparents may be a context for not swearing or being too rowdy, or the grandparents may be considered fun and liked for handing out sweets.

Patterns and process

Systems theory stresses the interdependence of action in families and other relationships. Each person is seen as influencing the others, and their responses in turn influence them, which influences the first person’s responses, and so on. Any action is therefore also seen as a response, and a response also as an action. Paul Watzlawick and colleagues coined the term ‘circularities’ to capture these essentially repetitive patterns of interaction. This represented a fundamental shift from how relationship difficulties had been explained previously. In effect, the question of looking for a starting point – who started it – is seen as unproductive. Even if we can identify who appeared to start a particular family sequence, such as an argument, this may in turn have been a response to a previous episode.

An extremely influential idea that emerged was that problems could be seen in terms of circular patterns, whereby the family has attempted solutions to the difficulties, which instead of improving things have made matters worse. To take an example, parents may decide to take a tougher line and impose firmer rules on a teenager who has shown an angry outburst at school. However, the teenager may feel that his parents, like everyone else, are ‘ganging up’ on him and that this is ‘not fair’, so he becomes increasingly angry and distrustful and engages in another angry outburst. This may propel the parents to believe that they need to do more of the same and that even harsher measures will do the trick. These early ideas led the way to the influential brief therapy and solution-focused therapies that have developed alongside the systemic therapies.

Punctuation

Experience is not what happens to you. It is what you do with what happens to you – Aldous Huxley

The term ‘punctuation’ perhaps captures more than any other some of the key contributions of systemic thinking in offering an important bridge between beliefs and patterns of actions as mutually self-maintaining each other (Figure 62.2). It suggests that family members are always trying to make sense of each others’ actions. Watzlawick and colleagues suggested that the flow of communication and actions in relationships is divided up into meaningful units, or chunks. The term ‘punctuation’ was coined to describe how people develop a set of self-fulfilling perceptions or beliefs about their relationship, which can interlock, like the pieces of a jigsaw puzzle, to produce repetitive patterns. The concept of punctuation introduces the idea of systems as not simply mechanistic but as governed by patterns of beliefs or constructs. Over time, members of a family come to form predictions not only of each others’ actions but also of each others’ thoughts, beliefs and feelings. Since they spend a considerable amount of time together, share similar experiences and communicate continually with each other,
the family members come to form a web of mutual anticipation. This serves both to explain and to predict each person’s behaviour and thoughts, but also to construct and maintain them. Members of a family might be surprised if, for example, one of them expresses beliefs or shows emotions that they regard as unusual; these signs of surprise will serve to attenuate such deviations.

The concept of punctuation suggests that although two or more members of a family may appear to be acting autonomously, their choices can become interwoven, such that they become caught in repetitive patterns of action. A relatively unexplored idea that follows from this is that choice in families can be seen to be contingent – what each person decides to do is shaped and constrained by what the others do and by what they think they will do. Specifically, each member may be involved in making conscious or semi-conscious calculations about the likely consequences of a possible line of action – whether it will produce a rebuke, admiration, agreement and so on. We develop this idea of shared action in the next section. In the example in Figure 62.2, the parents were extremely concerned that Henry was showing signs of ‘childhood schizophrenia’, a concern that was articulated by health visitors and other medical professionals they had consulted regarding Henry’s nightmares and ‘bizarre’ imagination. The more they watched and scrutinized Henry’s behaviour, the more anxious they became about why his parents were so worried and about their disagreement about him. This anxiety led him to tell them more about his scary thoughts and in turn fuelled the parents’ anxiety.

**Family lifecycle**

Family therapy has emphasized the importance of time and development in family life and the nature of problems. A key feature of this is an interest in thinking about families from a transgenerational perspective. Haley made the observation that humans, unlike any other species, are the only species to have in-laws. Of course, there are wide variations in human cultures, with some societies having very close relationships – for example, three generations living in one household – and others having a nuclear family configuration, with children moving far away from their parents as they start their own families. The complex connections across the generations were one of the focal points of early system therapy. Haley described pathological triangles, whereby a grandparent could seriously undermine and disempower their child (parent) by giving contradictory instructions to their grandchild. An anxious parent could, for example, become angry or withdrawn, giving over power to the grandparent and thus making their own ability to parent impossible, leading to their own depression and sense of inadequacy and confusion for the grandchild.

An influential model of problem development and change was proposed in the concept of the family lifecycle (Figure 62.3). This emphasized how families may at times be faced with massive demands for change and adaptation, for example the birth of a child, divorce or remarriage, death or – perhaps due to changes in autonomy within the family – children becoming adolescents, a woman going back to work after childrearing, or retirement. It was observed that the emergence of serious problems was associated with these lifecycle transitions and their inherent demands, anxieties and stresses. Milton Erickson noted, for example, that psychotic episodes in late adolescence were seen to be related to difficulties for the family over the departure of the young person about to leave and set up his or her own home. In response to the anxieties generated by the demands for change, some families appear to attempt to avoid facing these by delaying the transition. One significant way of doing this is for someone – often the person at the centre of the stage, such as the young person leaving home – to become ill in some way such that they are ‘unable’ to leave, which serves to disguise the complex emotional issues and anxieties. There may also be community demands such as local social upheavals and major cultural changes. In this sense, the lifecycle perspective adds to homeostasis the idea that families are not simply stuck but may in fact have to work quite hard to keep things the same, since their environment is continually shifting. It is also possible that such patterns represent wider cultural factors, such as expectations about gender roles and opportunities for work outside the family. Attempts to simply fix such patterns in families without due recognition of the cultural factors were seen as potentially oppressive and as implicitly endorsing such inequalities. It was argued that this model could contain, in a concealed form, a range of normative, patriarchal, middle-class, white assumptions about healthy family functioning.

One of the most frequently used and powerful techniques in family therapy is the use of family genograms. This is employed to trace transgenerational patterns, relationships between the generations, beliefs about the family, and traditions of dealing with problems and distress. It is often...
conducted as a visual activity, with the children doing the drawing, listening and commenting while the parents describe the family contexts. As well as eliciting information, this activity often elicits recognition of powerful transgenerational patterns, for example of divorce, use of drugs or alcohol, separations, gender roles and so on.

A COMMUNICATIONAL PERSPECTIVE

Therapy is essentially about communication between the therapist and the family. For systemic family therapy, communication was also a guiding concept in terms of how families learn to live together and of how problems develop. Bateson and colleagues inverted the typical explanations regarding schizophrenia by asked the question, ‘In what context would schizophrenic behaviour make sense?’. Their observations were that it occurred in relationships characterized by repeated contradictory and confusing communications:26

A young man who had fairly well recovered from his acute schizophrenic episode was visited in the hospital by his mother. He was glad to see her and impulsively put his arms around her shoulders, whereupon she stiffened. He withdrew his arm and she asked, ‘Don’t you love me any more?’ He then blushed, and she said, ‘Dear, you must not be so easily embarrassed and afraid of your feelings!’ The patient was able to stay with her only a few minutes more and following her departure he assaulted an aide and was put in the tubs [restrained].14

Relationships are seen to proceed through successive attempts to make sense of what is happening. At times, people communicate directly about this by phrases such as ‘What do you mean?’ or ‘You don’t seem too happy about that’. A feature of the double-bind phenomenon is that such meta-communication is not allowed, apparently due to unconscious fears of provoking anxiety. Bateson subsequently revised the double-bind theory to suggest that the process is a reciprocal one, with the child also engaged in double-binding communication. Weakland further suggested that double-binding can be seen as a three-person process.27,28 For example, a mother with whom I worked stated that she was sometimes frightened of her son (who had schizophrenia) but also frightened to show her disapproval of some of his behaviours because of fear of rebuke from her husband. Hence, she continually displayed a pleasant smile while she spoke at times of a ‘fear for her life’, which was intended to disguise her anxiety and anger but also communicated a confusing and mixed message to her son. Interestingly, more recent research,29,30 and much earlier research by Bowlby,1 adds support to Bateson’s ideas, indicating that many people with a diagnosis of psychosis have experienced profound episodes of emotional, sexual and physical abuse, which has been disguised and concealed and distorted by parents or other carers.

Family therapists attempt to clarify communication in families in a variety of ways. The therapist typically invites each member of the family to talk about their perspectives; the therapist may also intervene if one member of the family dominates the conversation or constantly interrupts the others. This may allow for more information and points of view to be expressed, but it also starts to give the family experience and practice of different ways of communicating. The observing team also pays attention to possible incongruities in communication between the verbal and non-verbal content and may help the therapist to draw attention to these with the family. Some families describe this as having a ‘referee’ who allows everyone to talk and ensures fair play. An interesting approach is to invite families to take home a DVD of their family therapy sessions and to discuss and comment on their interactions and communication processes in the following session.

THERAPEUTIC ASSUMPTIONS AND PRACTICE

Systemic family therapy was one of the first of the therapeutic approaches, and arguably it is still the major one to employ live supervision of the therapeutic work. Originally this was done in various ways, for example with a team observing the session from behind an observation screen or on video. Alternatively, there could be consultation with a colleague regularly offering advice. This emphasis on live supervision was based on a recognition of the complexity of working with the whole family at the same time and also on the idea that there needed to be some removal from the interaction in the room to be able to detect some of the family pattern maintaining the problems. The therapist would be consulted regularly by the team via telephone or an earpiece and given suggestions – for example, to ask the family to enact how the problems occur at home, to change seats, to engage in role-play or sculpt, for one person to speak more or less, to explore certain areas such as their attempted solutions to the problems more, and so on. After about 40 minutes, the therapist generally took a break to talk with the team and then returned with some substantive intervention, such as a reframe or paradoxical ‘homework’ task.

Early systemic family therapy contained some assumptions about ‘healthy’ family functioning along with the view that alterations made to the organizational structure of a family will change the symptomatic behaviours. Once the rules of the family system alter, so too will the behaviours; for example, if instead of enlisting a child into coalitions against each other the parents start to work together, then the child will no longer display various symptoms. Structural approaches assume that families have an objective structure, and it follows that therapy involves a process of assessment and mapping of this structure, followed by clear attempts to alter it where necessary. The therapist therefore adopts a sympathetic but nevertheless expert role
in which he or she takes on the responsibility of initiating changes. Typically, the approach was to encourage different ways of interacting in the actual family sessions, sometimes with associated ‘homework’ tasks. As in the earlier example from the study on diabetes, Minuchin would utilize feelings in the room, for example to disrupt a triangular process involving the children at the point where the couple’s conflicts were becoming too uncomfortable.3

In addition, early family therapy approaches included strategic techniques. These were designed not to change not only the family organization but also the interactional patterns that were maintaining the problems. Furthermore, therapists adopted a more covert and strategic approach, in the view that in many cases families were not able or were unwilling at some level to follow advice and suggestions from the therapist. The idea here was that if a family repeatedly did the opposite of what the therapist suggested – resisted the therapist’s advice – then perhaps by offering the opposite of what the therapist wanted the family to do this could paradoxically produce the desired result. These interventions often required some humour and a sense of fun and trust between the therapist and the family. In one example, a family complained about how they were continually bickering and sniping at each other. Repeated attempts to explore the reasons for this and to suggest changes did not work. Instead, the therapist suggested that they buy half a dozen water pistols; every time someone sniped or bickered, they were to be shot with a burst of cold water. The family returned, saying they had found this activity so ridiculous that they broke out in laughter whenever they started to bicker, and the problem had decreased. Other, more gentle techniques, such as suggesting that the family observe and in order to do this accurately they do not try to alter the problems, could also be effective in breaking up futile cycles of attempting to solve their problems in ways that lead to an increase rather than a decrease in the problems.

Earlier approaches largely adopted a functionalist view of problems: families were seen as interacting systems in which symptoms functioned to preserve stability. In a perverse way, painful and distressing symptoms rather than threatening family life and stability were often seen as holding families together: symptoms were seen as distracting from or diverting conflicts, anxieties and fears (often unconsciously held) from other areas of the family’s experience. This view was challenged on the grounds that the function of a symptom was not there to be ‘discovered’ but was the therapist’s hypothesis. In turn, how difficulties were handled – the attempted solutions – was seen as linked to the wider belief system of the family.24,31,32

A typical view in families is that the source of their problems lies in one member rather than in their relationships with each other. Once established, this myth can become increasingly painful to confront. For example, if the child’s symptoms become severe, the parents may feel guilty and blaming, by the implication that their conflicts have in a sense been the cause. Young children tend to discover the power that a symptom of illness confers, such as being able to avoid school and unpleasant duties, and gaining sympathy and attention. Therefore, a child may start to collude with this state of affairs and continue to display symptoms, in part because of the apparent advantages he or she gains. This in turn can serve to confirm for the whole family, including the child, the beliefs or myths that the child is the source of the problems.

The parents may hold different beliefs and disagree on how to treat the child (e.g. discipline v. sympathy) and may shift positions, taking turns to side with the child – ‘shifting coalitions’.1 Psychiatric and other agencies may also perpetuate conflicting views about such conditions, which families then come to internalize and act out in their internal dynamics.

FROM PATTERNS AND PROCESSES TO BELIEFS AND NARRATIVES

During the 1980s, there was a gradual shift from an emphasis on patterns of actions to an emphasis on the construction of meanings and their creation in families and between the family and the therapist.7 Inherent in this was a change in the perceived role of the therapist as less of an expert and more of a collaborative explorer who works alongside a family to co-create some new, more productive ways of the family seeing their situation. Furthermore, this represented a move towards an increased sensitivity to therapeutic relationships. Rather than trying to adopt an ‘objective’ stance, the therapist is encouraged to be continually reflective – to monitor his or her perceptions, beliefs, expectations, needs and feelings, especially in terms of how these may in turn have an influence on the family.

OBSERVING SYSTEMS

The process of therapy involves an interaction between two systems – the family and the therapist – and can be seen as a new third system – the therapist/family system. Rather than thinking that we could observe and analyse families in any detached and objective manner, it became increasingly clear that the therapist or observer inevitably perturbed or changed the family system by the very act of observing it. A therapist in effect came to be seen as partly seeing his or her own reflections or the ripples he or she had made in the new family/therapist system. Another therapist with the same family might see quite different things, partly because the therapist was having a different kind of effect on the family. Taken to its extreme, this suggested that there was no such thing as the real family dynamics, only our various perceptions of it.

As therapists, our perceptions and explanations of a family were invariably seen as our own constructions and a
punctuation of the process between the therapist and the family. This view also gave additional emphasis to the importance of live supervision in family therapy. The therapist needed the supervision team to enable him or her to gain some ability to reflect on their joint dynamics. In turn, it was argued that the supervision team could offer only their punctuation of the therapist/family system, and attempts needed to be made to reflect on this in turn. Regular external consultation was therefore also seen as necessary to reflect on these various levels of interacting systems.

**HYPOTHESIZING**

A family therapy team in Milan, consisting of four psychiatrists, developed the idea of family therapy as an involving a process of progressive hypothesizing. There could be no objective truth about a family, simply our subjective perceptions as observers. The best we could achieve was to formulate hypotheses (‘hunches’) about what was going on, which could be more or less helpful in our ways of working. A hypothesis was to be judged not in terms of its ultimate truth or falseness but in terms of how effective it was in facilitating some positive change. In part, this hypothesizing came to centre on attempts to understand each family member’s own explanations and stories. Family members may disagree, sometimes violently, about their explanations and competing stories about each other, the reasons for the problems and what to do.

**CIRCULAR QUESTIONING**

A related idea that emerged from the Milan group was that therapy should proceed on the basis of the therapist asking the family questions in order both to explore their understanding and to trigger new ways of thinking through the questions that are asked. This is one of the most striking features of contemporary family therapy, namely that therapists ask a lot of questions. The Milan team added to this the idea that the questions were systemic in the sense that they invited family members to think about relationships – ‘What does Father do when Johnny and Mother argue?’ – rather than about individual causes in order to help move families away from the frequent cataloguing of complaints about a family member. Furthermore, the questions were not predetermined but were shaped in a circular way by what and how the family had previously responded. Exploration and intervention are seen not as distinct stages but as continually interwoven in systemic therapy.

**REFRAMING AND RE-STORYING**

Contemporary family therapy has come to emphasize as central the stories that family members tell about each other and their lives. Problems are seen to result when these stories become ‘problem-saturated’ – overly focused and preoccupied with their difficulties and failings. From the outset, family therapists employed the technique of reframing, which attempted to offer a new or different way of seeing a problem as an intervention. For example, conflict in a couple could be discussed as showing a fiery passion and as something that could eventually make their relationship stronger. An important ingredient of reframing or re-storying is that the problem may be cast in a less negative and destructive light, and the actions of the family members as having positive intent, even if the outcomes appear to be problematic.

For example, Henry, aged 7 years (see Figure 62.2), was referred with worries about his strange thoughts, nightmares, bizarre images and refusal to get to sleep at night on his own. There were some concerns that he might be displaying some form of childhood schizophrenia. His mother had recently started a training course and was spending more time away from the home, possibly leading Henry to worry that the family was disintegrating. It appeared that both parents had experienced nightmares when they were children and continued to be worried, especially the father, about any indications of unusual internal states.

As a reframe, it was suggested that, rather than seeing Henry as potentially ill, he was in fact a very imaginative and sensitive boy and that he was also following in his parents’ footsteps in being sensitive in this way. Furthermore, perhaps this sensitivity made him concerned about the changes that had occurred in the family, and his thoughts symbolized these. Perhaps Henry also hoped that his symptoms might ensure that his parents stayed together in order to look after him, rather than fulfil his fears that they might be going their separate ways. The reframe of Henry as creative and sensitive rather than odd and ill was accepted by the family, and they started to notice confirming comments, for example when one of his teachers had commented that she thought Henry was an imaginative boy.

**SOLUTION-FOCUS**

Based on the original systemic concept of circularity and failing attempted solutions, this approach attempts to divert families away from these failing patterns to areas of competence and success. As such, the approach challenges prevailing discourses of illness, pathology and dysfunction and, by focusing on competence, the family is encouraged to change how they talk and think about their difficulties. The emphasis of the approach is to move to a focus on solutions rather than only on the problems. For example, parents might describe a child who ‘fights all the time’ or ‘lies all the time’. However, the parents may also be able, if prompted, to recall some examples of when the child has been ‘cooperative’ or ‘honest’. Often these exceptions are seen by the family as insignificant and unimportant. From
a detailed exploration of the exceptions, some clues may emerge suggesting what the family could do more of in order to encourage the exceptional behaviour. There is a related focus on changes that families may already have started to make before commencing therapy – spontaneous recovery. Rather than ignoring such changes, which are said to be common, the therapist draws the family’s attention to such changes and works with them to maintain and build on such changes. Where families find it hard to think of exceptions or changes before the sessions started, they can be invited to imagine possible solutions or to use solutions that they have seen work in their families of origin and elsewhere.

NARRATIVE THERAPY

Some therapists also engage in more or less open discussion of political issues, such as the potentially damaging effects of diagnostic labelling and sense of failure. Narrative therapies recognize the natural ability that people possess to generate and evolve new narratives and stories to make sense of their experiences. In doing this, we draw on culturally shared narratives or ways of interpreting events and also our own family traditions. The narrative therapies draw on many sources, including children’s literature and folk stories, to develop ways of talking about problems and that connect with culturally shared experiences and dilemmas of life.

EXTERNALIZING PROBLEMS

White and Epston suggest that problems are derived from the internalization of oppressive ‘problem saturated’ ways of seeing ourselves. Part of the process of problem formation and maintenance is a process of internalization, so that difficulties are seen in terms of individual or family ‘faults’, something deficient in individual personalities and their relationships.

The techniques for doing this include treating or speaking about the problem as an object or entity outside of the person or the family. As an example, White and Epston cite how a person supposedly with schizophrenia is living an ‘in the corner lifestyle’ and may be encouraged to resist the all-embracing, ‘totalizing’ nature of such a definition of their identity by discussing how she could combat or resist the ‘voices’ that were harassing her. Discussions may also focus on some unique outcomes – exceptions or successful instances of how she had been able to ‘defy the voices’ influence’. White and Epston’s approach appears to have the effect of reducing the all-pervasive nature of the labelling associated with problem, for example that ‘Jim is a schizophrenic’ or ‘Debbie is an anorexic’, and instead considers that the problems may be seen as just one part of the whole of their total identity. Therapeutic discussion invites people to look at the ways that they may have been drawn into accepting such views of themselves and how they have learned to engage in self-criticism, self-blame and self-accusation. More widely, discussions are encouraged about how the whole family has come to consider themselves as pathological, for example seeing themselves as a ‘problem family’.

In externalizing problems, the therapist proceeds not so much by simply identifying this process but by raising questions that invite the person and family members to explore it and to create ways of resisting it. An example is Paul, aged 7 years, who was constantly and apparently uncontrollably soiling himself. Through playful conversations with the therapist, he coined a name for the problem – ‘Sneaky Poo’. Subsequently, he explored how and where ‘Sneaky Poo’ caught him and then discovered ways that he could outwit and resist it. For example, Paul described that he was most likely to be caught when he was distracted, playing or on his computer: ‘I think how I tricked him was when I rushed to the toilet, he thought I was still standing there playing’.

Discussions ensued about the power of mind Paul possessed that he could use to resist ‘Sneaky Poo’ and use the knowledge he was coming to gather about its deceptive tactics.

CONTEMPORARY PRACTICE OF FAMILY THERAPY

Most family therapists and teams now adopt a less directive and expert stance to the early pioneers. Although teams and observation screens are still used, there are attempts to be much more transparent in the process of family therapy. Perhaps the most significant indicator of the changes is the widespread use of reflecting teams.

Instead of consulting in relative secret with an anonymous supervision team, the discussions between the therapist and the team are held openly in front of the family, so that the team members share their thoughts and concerns with the family and also voice any personal connections that team members have with that they have heard about the family. Through the team’s discussion, the family is invited to consider alternative stories and explanations, regarding their lives together. This may allow different family members who are holding opposing views to feel understood and perhaps enable them to move on to more constructive stories. Importantly, the reflecting team enables family members to hear and perhaps internalize a different conversation rather than simply different explanations.

In turn, the family members are invited to reflect back on the reflecting team discussion regarding what they found helpful, interesting, useful and less helpful. The guiding idea is that family members may connect with the stories in different ways and be able to choose what they found to be
helpful. More implicitly, it communicates the idea that there are multiple ways of seeing events, helping to free up some of the family’s more rigid ways of thinking that they may have developed as a result of their sense of anxiety, failure and desperation.

CASE EXAMPLE

The following is a section of a family therapy interview with Dorothy (age 9 years), her step-mother Anne, her father Brian and her older sister Lucy. Dorothy had been self-referred by her step-mother and her father, via their GP, for therapy because she was very angry, showed some violence towards her older sister and anger towards her stepmother, and was not complying with her medication for diabetes. Her father also had diabetes, and this made him especially sensitive to the negative consequences of this non-compliance on Dorothy’s health. The case also gives an indication of the complex family relationships in which many young people who come for assistance are involved.

The following is taken from early in the first interview with Dorothy and her family. The parents had been discussing how angry Dorothy often is after a visit to her natural mother’s (Liz) house. Some links are tentatively made about how these visits may distress her, and then the conversation revolves around a discussion of the inadequacies of Liz as a responsible parent:

- **Anne**: She [Liz] has her own problems; she has a problem with alcohol ...
- **Dorothy**: No, she doesn’t. She never used to ...
- **Brian**: When she drinks ... her personality changes ... that’s all, Dorothy.
- **Lucy**: When she looks after us, she’ll often make us stay up late and drink quite a lot. It’s quite scary.
- **Dorothy**: Yeah, it’s scary, but you can’t ...
- **Therapist**: [to Dorothy] What does that feel like? When other people say she lets you down?
- **Dorothy**: It makes me feel quite sad sometimes ... ’cos people say things like ... it’s hard to explain.
- **Therapist**: What happens to that sadness? Does it turn into something else? Does it turn into other feelings?
- **Dorothy**: It turns into anger ... Sometimes if I get angry it turns into ... like, last few times I have been in my room and I get a bit claustrophobic sometimes. I’m not really a room girl.
- **Therapist**: What helps you sort those feelings out? Can Anne help? Can Dad help? Can Lucy help?
- **Dorothy**: Lucy can help.
- **Anne**: Sometimes, when she’s like that, if you go near her she just says it’s your fault. She’s quite violent towards her, towards Lucy ... and it’s partly my fault ’cos I’m here and I’m not her mum. She’ll never say anything down the phone to her mum she will just ... come off the phone and then go mad ...
- **Therapist**: [to Anne] It must be really hard for you... It can be a no-win situation because you’re not Mum and if you try and be Mum ... and whichever way you try to do it you can get pushed away?

**Comment**

Dorothy appears to want to defend her mother, who is accused by the rest of her family of having alcoholism and being unsafe to be around. Anne, her step-mother, seems to initiate this conversation. Dorothy’s father Brian steps in to support Anne but seems to try to qualify his criticism by saying ‘that’s all’ to reassure Dorothy. Possibly Brian feels caught between a loyalty to his daughter, to his new wife, and perhaps even to his ex-wife, Dorothy’s mother. Also, Dorothy’s sister Lucy supports and in fact elaborates her step-mother’s criticism of her mother; perhaps she has decided to replace her own mother with Anne? Above all, one feature of this short passage is that young people such as Dorothy, who may initially be seen to be causing problems for the family, are typically in a paradoxical way also the same people who are most loyal to both of their parents and trying their best to help.

Interestingly, Dorothy came into this session holding two soft toys: one was a vibrant red and orange tiger and the other was a soft, cool, blue seahorse. As the interview progressed, she started to describe these two sides to her experience – sadness that can turn into anger and no doubt back again. She also says poignantly that she is not a ‘room girl’, perhaps meaning that she wants to be alive and doing things rather than sad and shut away from life.

A little later in the session, the therapist felt it might be helpful to turn the discussion towards an exploration of whether there had been similar experiences in Anne and Brian’s own childhoods. This can often reveal important unexpressed feelings and ideas that are shaping how they are interacting with their own children. The following interesting material emerged from the invitation to consider their past:

- **Therapist**: [to Brian and Anne] Can you say a little bit about your family backgrounds?
- **Brian**: Nasty... With my own children I’ve always wanted to be a full-on parent because I never got it. My parents were never interested in anything I did ... my mum and dad just fell out ... I went to live with my dad.
- **Therapist**: So it’s a bit similar to what happened to your own children?
- **Brian**: Yeah, but then my dad just dropped me at my grandparents and my grandparents brought me up ...
- **Dorothy**: That’s not very nice [gently touching her dad’s knee, and then walking away to get on with some drawing].

In thinking about why it might have been that in this family the decision was made that the children would go with their father rather than the more typical arrangement,
it might have been concluded that it was because of their mother’s alcoholism. Of course there are other important issues here regarding gender roles and how easy it is to make contested assumptions that it is ‘natural’ for children to be with their mothers rather than their fathers. However, we also get a glimpse into what has been called a ‘corrective script’, in that the father wants things to be different from how they were for him in his childhood. He wants to be a ‘full-on’ father. Yet we can also see a pattern repeating itself, in that his daughters, like him, left to live with their father after a divorce. Importantly, we can start to see that, in working with Dorothy and ‘her problems’, we are moving between events in the past, how things are now and people’s hopes for the future. We also get a poignant glimpse of how this little girl Dorothy is listening intently to what her father has to say and provides him with comfort as she senses his sadness as he remembers his childhood. Children not only are cared for but also care for their parents. For example, in families with parents with addictions or who are depressed, disabled or ill in some other way, the children may from a very young age be conscripted in the role of carers – providers rather than receivers of physical and emotional comfort.

OVERVIEW AND SUMMARY

There are many schools of, and recent developments in, family therapy. This chapter can aim to offer only a flavour of some of the main ideas and techniques employed. There are significant debates within systemic therapy, in that some practitioners are very uncomfortable with the concept of ‘technique’. Above all, there has been a move towards flexibility and diversity in how therapists operate, in particular that therapists will work with families, couples or even individuals, as seems expedient. There is also flexibility in working alongside other models, for example that some family members may be receiving medication or individual therapy, such as cognitive-behavioural therapy (CBT). This is still controversial, and there are concerns that the different conceptualizations of problems can cause confusion for families. At the same time, it is evident there has been considerable integration and assimilation across various forms of therapy, so, for example, systemic ideas are included in some individual therapies and likewise systemic therapy has continually drawn on ideas from attachment theory and psychodynamic theory. We have touched on the idea that systemic therapy has expanded to consider not only family dynamics but also the relationships between and within services. Not infrequently, work with families has shown that confusions and conflicts between the professionals with whom they are involved can contribute significantly to ‘stuckness’ or even escalation of their problems. Thinking about problems in such a multilevel way in terms of complex interacting systems continues to be an important area of development in systemic family therapy.

KEY POINTS

- Problems are seen as relational, arising from the interactions between members as opposed to located within individuals.
- Family therapy aims to utilize the potential in families to help resolve problems.
- Problems are seen as related to different contexts, such as grouping within the family and social and cultural factors.
- Families are seen to display repetitive patterns, which can encapsulate and maintain problems.
- Families develop patterns of meanings or punctuations, which can shape and maintain their problems.
- Cycle transitions can involve stress and demands for change, which can trigger problems and also positive changes.
- Family therapy attempts to adopt a non-expert approach in order to invite consideration of new ways of seeing the problems.
- Tasks and family experiments are employed to try out new ways of interacting.
- Family therapy is frequently conducted in teams to allow multiple perspectives to be offered to families.

Marital therapy

David Hewison

INTRODUCTION

Marital therapy is an overall term for the treatment for dysfunctional or distressed adult couple relationships. Although the term ‘marital’ is used in this chapter, the theories and techniques addressed are applicable to all adult couples, whether married, in civil partnerships or not, and whether heterosexual, gay or lesbian. The treatment group is adults in a committed emotional and sexual relationship, and in this sense is both societally and self-defined. It is clear that there are overlaps between the target patient group of marital therapy and those of family therapy, parent–infant therapy and relationship therapy for individuals. One of the consistent themes in surveys of the field is the lack of a clear definition of the patient group, the aims and targets of treatment, the criteria for efficacy, and the correct methodologies for gathering a useful evidence base. Despite this, it is also clear from a number of articles in the British Journal of Psychiatry and other journals that marital therapy has considerable scope for intervention in depression, as recognized by the National Institute for Health and Clinical Excellence (NICE). In addition, marital therapy not only is valuable in reducing distress in relationships but may also be a highly cost-effective treatment. The book by Snyder and Whisman is of particular relevance in addressing patients where there are coexisting mental health and relationship difficulties.

This chapter aims to introduce the most common ways of treating the couple relationship psychotherapeutically in the UK, giving their characteristics and techniques and when they may be particularly indicated as a treatment. These techniques, in alphabetical order, are:

- Cognitive-behavioural marital therapy
- Emotionally focused marital therapy
- Psychodynamic/psychoanalytical marital therapy
- Systemic marital therapy.

COGNITIVE-BEHAVIOURAL MARITAL THERAPY

Key texts include Baucom et al. and Rathus and Sanderson.

Characteristics

Cognitive-behavioural marital therapy is an overall term for a range of different treatments that share key elements. It emphasizes the importance of interactions with the environment, and the feedback loop between the individual (with their own ways of perceiving the world and their own set of skills in influencing it) and others around them (who respond positively to some behaviours, so encouraging them, and negatively to others, so discouraging them). Cognitive-behavioural marital therapy addresses the role of individual cognitions and attributions of meaning to behaviours. It recognizes that patterns of interaction and response to relationship demands are ingrained from past experiences (‘overlearned’) and that they may result in extremely anachronistic interpretations of the current relationship, giving rise to disturbing behaviours, thoughts and feelings in one or both of the couple that are difficult to shift.

Problems in couples arise when the balance between behaviours and how they are interpreted is felt to move from largely pleasing and rewarding to largely displeasing and punishing; the way in which they do so is unique to the couple. Couples may suffer from a lack of relationship and communication skills, or they may be poor or patchy at putting into use the skills they do have. Similarly, couples will bring a set of pre-existing assumptions and beliefs about what a relationship is, which they will make use of in an automatic way to interpret the behaviours of their partner. The theory holds that changing the nature of these automatic cognitions and ways of processing the information received will lead directly to positive changes in both emotion and behaviour. As a result, this therapy focuses on relatively small behavioural interactions between the couple, examining how they are received and categorized by each partner, and aiming to minimize those that are negative and to maximize those that are positive. Problem-solving skills are developed or enhanced. Some cognitive-behavioural therapists also use elements of emotionally focused therapy in order to give the couple greater abilities to manage their affective responses to each other.

Techniques

Cognitive-behavioural therapy (CBT) is a short-term therapy of up to 25 sessions, which may begin weekly and then
reduce in frequency once the therapist has understood the nature of the maladaptive interactions and goals have been set for change. It tends to be highly structured, with the therapist taking the role of collaborator, seeking the couple’s agreement with their evaluation of the nature of the couple relationship and the steps that will be taken to bring about change. Attention is paid to ensuring a balance between identifying areas of conflict where things have gone wrong and areas of harmony where the couple have the experience of positively relating with each other. This keeps optimism alive in the couple relationship in the face of pessimism stemming from their difficulties.

Assessment of the couple relationship is seen as an ongoing task, clarifying unwanted target behaviours and cognitions, and setting new goals and strategies to achieve them. Goals are specific, targeted and achievable, and are sequenced in five ways:

- Goals that are more likely to be achieved are set first, as this gives the couple a positive reinforcement that change is possible and that it is achievable through the therapy process.
- Goals that are less central to the couple’s sense of their difficulties are aimed for first, as this is less likely to evoke strong negative responses based on raised anxiety.
- Goals are set that increase positive interactions between the couple.
- Goals that do not impinge upon the core values of either of the couple are set before those that require more work and mutual understanding.
- Those things that simply have to be dealt with first, such as reducing the risk of violence, come before those that are important but can wait a little.

The techniques for achieving goals vary from didactic input from the therapist, informing and teaching the couple about a particular element in their relationship, through to role-play in the session, coaching and advising, and homework and exercises to do between sessions and reviewed at the next. In general, the therapist will, where necessary, train couples in basic skills of communication, such as taking responsibility for their own statements and active listening to the other; identifying faulty or dysfunctional attributions to each other’s behaviour; and utilizing strategies to replace displeasing behaviours with pleasing ones.

The therapist needs to be able to de-escalate heightened levels of negative emotion and inappropriate behaviours, intervening directly where necessary to bring the couple back to the programme of work. This means that the therapist is highly active in initial sessions, tapering off as the couple are able to identify the skills they need and put them into practice.

### Indications

- Where both partners are prepared to work on their relationship, and are willing to do so with a cognitive-behavioural approach

- Where there is a clear communication problem between the couple
- Where there is not an ongoing affair
- Where there is not simultaneous substance abuse
- Where neither partner is suffering from overwhelming individual difficulties stemming from their own psychopathology (although some cognitive-behavioural work may help the other partner cope with them, e.g. in maintaining social skills).

### Emotionally Focused Marital Therapy

Key texts include those by Johnson.16,17

#### Characteristics

This marital therapy has its roots in attachment theory,18 which puts relating at the heart of human survival. Attachment theory has investigated the kinds of attachment relationship that infants and children make and has shown how they lead to either secure or insecure dependency on another. An inner sense of secure attachment enables continual adjustment to the world and to the challenges of relating; this sense of security comes from the repeated experience of emotional responsiveness and recognition from the primary caregiver, which includes the expression and recognition of anger and distress as well as concern and love. It is the engagement with emotional life that is important, as it allows the young child to know that the other is a person like themselves, with a mind that registers feelings and that can manage the difficulties and joys of emotional awareness (an ‘internal working model’). Where dependency needs have been met insufficiently or in an inconsistent way, the child will grow up with an insecure attachment, uncertain whether they are existentially safe in the world or whether another person can truly be relied upon.

Attachment theory suggests that we utilize an attachment system of alert and response whenever we come across anything that impacts upon our connection with an attachment figure, such as a parent or a partner. This will happen inevitably and may be triggered by a substantial period of absence or indeed merely a sense that the person’s attention is elsewhere at the point when we are trying to be in contact with them. Its manifestations vary. With secure attachment, things such as separations will have a typical pattern: a degree of protest, a wish to cling, followed by more depressed feelings and then a kind of detachment, which is based on knowing that we are still in touch, internally, with our attachment figure. With insecure attachment, these feelings will arise more swiftly and will be far less moderated: the protest may be fury, the clinging highly intrusive, the depression turning to an inconsolable despair, and the detachment either an empty, lost hopelessness or a
cold, indifferent turning-away. These feelings tend to manifest themselves either as states of anxiety or as a push to avoid an unwanted emotional experience. In adult couple relationships, the anxiety may well manifest itself as anger and rage, and the avoidance may well be seen in hostility (and the attribution of this to the partner), which even gets triggered when the partner themselves shows distress or their own dependency needs, making for stormy and difficult relationships.

Emotionally focused marital therapy seeks to enhance secure attachment ways of experiencing emotion and to reduce the anxiety or avoidance that comes with insecure ways. It is based on the assumption that it is the degree of emotional security in the relationship that is key to meeting adults’ innate needs for being in a reliable, responsive and reciprocal relationship. It attempts to intervene by directly changing the experience of emotional relating in the couple.

Techniques

Emotionally focused marital therapy is a short-term therapy of 8–20 weeks that seeks explicitly to give couples a corrective emotional experience. It focuses on the internal working models of the couple that structure their relating, as these not only give rise to the specifics of the emotional exchanges between them but are themselves generated by these exchanges. An internal working model of greater security in relating allows the couple to experience a wider range of feelings, needs and wishes in relation to each other without leading to a catastrophe. The couple become more resilient and empathic as a result. Anger and distress can be seen as just what they are: feelings that stem from an attachment system being activated, rather than being blown out of all proportion. Emotions are seen as either primary emotions, which are the immediate feeling response to something experienced, or as secondary emotions, which are the ways in which the primary emotions are responded to, coped with or hidden – an outburst of anger is a secondary emotion having its roots in a primary feeling of loss; giving up and turning away has its roots in despair and loneliness, for example.

The therapy is characterized by a movement between the therapist attending to an emotional experience between the couple, and deliberately structuring and shaping one. It has three main tasks:

- Creating and actively maintaining a positive therapeutic alliance by the use of acceptance and empathy, together with a willingness to demonstrate engagement with the couple through actively validating each partner’s experience while seeing it in the context of attachment reactions.
- Seeking out emotional experiences in the sessions – specifically, focusing on instances of anger, fear, surprise, joy, shame and disgust, hurt and anguish – in order to identify the primary feelings behind the secondary feelings. This can lead to a greater understanding in the couple of the way the feelings of each person are affected by the feelings of the other, giving rise to a greater emotional intelligence and the capacity to experience a wider range of feeling. This enables the couple to stay more in touch with each other and not have to resort to dysfunctional coping strategies that leave them distressed and disaffected.
- Using an explicit attachment model to help the couple understand why they are responding to each other in the way that they are, so continuing to normalize their feelings. Then, the therapist will direct the couple to experience a new way of responding to each other when their attachment systems are activated, actively enabling the couple to respond to each other and give voice to their feelings. This deepens their emotional engagement with each other and strengthens their attachment to each other, making them and their relationship more secure.

Indications

- Where the couple want to rebuild the relationship, despite the difficulties between them
- Where the couple have a clear attachment system pattern going on, such as one partner pursuing/attacking and the other withdrawing/avoiding
- Where the couple are not already in the process of separating or divorcing
- Where the couple are able to experience a heightening of difficult emotions between them without recourse to violence.

PSYCHO_DYNAMIC/PSYCHOANALYTICAL MARITAL THERAPY

Key texts include Ruszczynski and Clulow.

Characteristics

Psychodynamic and psychoanalytical marital therapy are similar in that both assume the presence of processes operating between the couple that are unconscious to them but that exert a powerful influence on their cognitions, affects, attributions and overall experience of what a couple relationship is for and like. These unconscious processes are seen as having their roots in the childhood and background of the respective partners, including their conscious and unconscious experience of their parents’ couple relationship and their reactions to it. Although the roots of the unconscious processes lie in the past, the couple will be actively engaged in something in the present. The understanding of this takes different forms, according to the theoretical orientation of the therapist: some will focus on the manifestation...
of internalized representations of the parents – the internal parental couple – and the way they seem to encourage or prohibit particular ways of relating; others will focus more on the state of mind of the couple, by which is meant the way in which the couple as a couple and as individuals approach their emotional life at any particular moment. This is not so much the nature of any emotion that may be being expressed but rather the inner attitude to it in each of the couple, no matter who is feeling it at that point: is dependency or neediness treated with contempt or sympathy? Are loving feelings cut off prematurely or allowed to flower despite the difficulties? Is anger met with indifference or a struggle for acceptance? And so on.

Key to the psychodynamic/psychoanalytical understanding of the couple relationship is the idea that it is a ‘phantasy’ relationship – that is, a relationship permeated with unconscious projections on to, and in part accepted by, each other. This means that one partner will manifest emotions, thoughts and behaviours that actually belong to the other partner, forming a complex interlocking system of experience that can be very difficult to unravel. This projective system will be complicated further by the unconscious fit between the couple: what are they trying to achieve in forming a relationship with each other and above falling in love? Some couples will be attempting to find someone with whom they can develop emotionally, while others will be seeking someone who will protect them from the need to change, in a defensive relationship.

The role of the therapist is to create an environment in which these internal patterns of relating can be seen and experienced ‘live’ in the room, not only between the couple but also between the couple and the therapist (the transference). The therapist is additionally seen as a ‘receiver’ of the couple’s disavowed emotional life. The therapist uses material that obviously belongs to the couple – for example, what they say or how they feel – and compares and contrasts it with their own shifting internal state (the counter-transference) to form an interpretation as to what might be going on unconsciously in the couple. The idea is that, the more conscious the couple are of what they are doing, and who they really are rather than who they think they are, the greater freedom they have to relate fully with another person.

Techniques

There are regular weekly sessions of 50–60 min, generally on an open-ended basis. The sessions require strict technical handling: informal interactions are kept to a minimum and the sessions are deliberately unstructured with no teaching or guiding. The therapist creates a neutrally expectant space for the couple to use in whatever way they will. Characteristically, the couple will experience this emptiness as though it were full of demands, expectations, prohibitions and punishments, so revealing their unconscious relating. Attention is paid to everything that happens in the room as of potential meaning for the couple, including asides, jokes, slips of the tongue, and deeply engaged conversation and interactions.

The therapist’s personality is used as a tool and as a source of information. Therapists expect to be stirred up by the couple, and their ability to contain this has an impact on the couple. Interpretations are used as a main instrument of change. Although the therapist will not deliberately create a corrective emotional experience as in emotionally focused therapy, change does not occur without the engagement of both thoughts and feelings, and it is the relationship with the therapist that enables this.

Indications

- Where a couple have a particular interest in the meaning of their relationship – why it is like it is – and want to change it
- Where a couple can make use of symbolism and are not excessively concrete in their thinking
- Where dysfunctional patterns of relating have proved unshiftable through other means, including other therapies, and the couple are prepared to engage in what might be long-term work
- Where one or other of the couple has a narcissistic personality structure.

SYSTEMIC MARITAL THERAPY

Key texts include Weeks and Treat and Jones and Asen.

Characteristics

Systemic marital therapy, like cognitive-behavioural marital therapy, is an overall term that covers a range of different theoretical positions that share common features. Most obviously, there is a focus on a system of interaction and the ways in which the couple act as though responsibility for the system lies with one or other of them. In particular, there may be a focus on the patterns at work in the families of origin of the couple, including a focus on family secrets or on specific behaviours or roles that seem to be repeated through the generations. Some systemic marital therapists also consider the role that the individual has, focusing on the strengths and difficulties (including personal psychopathology) that are brought into the couple system; others see these as more of a manifestation of the action of a wider-arching system, so downplaying the individual.

Systemic therapists are active and assertive, on the basis that changing a destructive system requires greater energy than exists to maintain it. They can take up different roles at different times – guide, teacher, confrontor, referee, empathizer – and they may set homework to be done by a
couple between sessions. Their aim, however, is to ensure that the couple take more and more responsibility for the quality of their relationship. Attention is paid to the balance of the therapy: the amount of attention paid to each partner, the degree of intensity of confrontation with each, the assumption that both partners are involved in the problem, the equal treatment of both in terms of any individual sessions, and so on.

Systemic therapists assume that any behaviour has a role and a meaning in the system – in effect, that there is a purpose to a behaviour, no matter how reactive it appears. Part of the work of the therapy is to identify why this behaviour has been utilized at this point and to draw the couple’s attention to what they are doing and how it has its origins in the different systems at work in the relationship. The couple then have the opportunity to change their actions and so change the system.

Attention is also paid to the use of language by the couple – both at the level of specific content (including the kinds of words chosen) and at the level of process or what the language is meant to do in the couple system. Typically, language patterns are used to manage distance/closeness, to act aggressively or submissively in the relationship, to deal with reactions or responses to the partner, to act defensively to what are perceived as attacks of one kind or another, and to manage levels of intimacy. Attention is also paid to the use of power in the system.

Techniques

Regular 50- or 60-min sessions are held weekly or fortnightly, either open-ended or for a contracted period of time. There may be a reflecting team that observes and comments ‘live’ on the therapy.

Circular questions such as ‘What does he/she do when you are angry?’ as opposed to linear questions such as ‘How does he/she make you angry?’ emphasize the system at work between the couple. Questions such as ‘Were your parents angry like this?’ emphasize the intergenerational aspect of the couple symptom.

The defensive use of language is addressed, and what it is that is being defended against is looked at. This may involve focusing on the words used and inviting the speaker to say the same thing differently, or it may need to be dealt with by the therapist opening up the feeling behind the words at greater depth, including using comparison and imagery.

Reframing is a key technique in which an intervention is made that describes a process going on between the couple in a way that enables them to change. This is not an attempt to give the couple the truth of what they are doing; instead, it seeks to redefine what is going on in positive terms and in ways that emphasize the system at work between the couple. An example may be when a couple present with one partner suffering from depression; the therapist might indicate how committed that partner is to the relationship as their depression stops them showing angry feelings that they fear their partner would not be able to deal with and so leave. The couple can then be worked with to understand the reciprocal nature of the symptoms of depression and to find a better way of managing feelings in the relationship.

The four different systems at work at any point – the individual, the couple, the families of origin and the social context – are attended to.

Using genograms not only to capture the members of a family but also to explore the feelings they have expressed or avoided can be helpful.

Indications

- When there are clear patterns of relationship stemming from families of origin perceptible in the couple
- Where one partner will need active and effective engagement to join the couple therapy
- Where there are complexities and confusions stemming from multiple sources of input into the couple system (e.g. from social services, schools, other extended family members).

KEY POINTS

- Marital therapy has a supportive and prophylactic role to play in the treatment and management of individual symptoms, in addition to being the treatment of choice in relationship distress.
- Marital therapy is supported by NICE guidelines as a treatment for depression.
- All types of marital therapy recognize the interrelations between communication, behaviour and emotion, though they each emphasize different elements of it.
- Marital therapy is available as short-term, focused treatment and as long-term, exploratory treatment.

INTRODUCTION – PSYCHOTHERAPY AND SYSTEM: WHAT THE PSYCHIATRIST NEEDS TO KNOW ABOUT GROUP PSYCHOTHERAPY AND GROUP DYNAMICS

Our approach to thinking about groups, emphasized in the subtitle of this chapter, embeds a specific treatment modality in a more comprehensive understanding of group processes. From a biopsychosocial perspective on human development and psychopathology, human beings are group animals – Aristotle’s phrase was ‘political animals’ – through and through. The three major clinically oriented theories of group dynamics – those of Irvin Yalom in the USA and SH Foulkes and WR Bion in the UK – are based on the premise that we are as hardwired through natural selection to interact within groups as we are to breathe air: the group is our natural medium.

The group is essential for survival and protection, originally from external predators and, using a psychodynamic lens, every bit as much from internal predators of the mind, which are frequently externalized in and between groups. The group is also a crucible of identity formation and malformation. Family group cultures and relationships evoke, nurture, facilitate and elaborate the expression of individual potentials, traits and skills on the one hand, and fix, compensate for or further skew immature, maladaptive or pathological responses, patterns and defences on the other. Interactions within school, peer and professional groups continue to shape the development of personality. Our group memberships both as a source of loss of identity (depersonalization) and as a matrix of human creativity. The essence of the group’s therapeutic potency derives from this duality of group life, for patients are supported to attend to and understand the reasons for their pathological identities and identifications, which are constantly displayed in the sessions; to relinquish them, usually slowly and painfully (to disinvest from maladaptive ways of experiencing themselves and others); and to create through their interactions with others in the group new capacities for emotional experience, interpersonal sensitivity and relationships.

In a seminar, the authors were discussing how group membership profoundly affects the ways in which individuals feel, think and behave, often out of conscious awareness. Two members of the seminar group, who were trainee psychiatrists from South America, began to talk about ‘the bane of our professional life back home’. One described how he had examined a middle-aged woman with a life-threatening condition who had arrived at a large urban hospital from her tribal area some hundreds of miles away. He told his patient that an immediate operation could save her and offered to put her at the top of the list for surgery; otherwise, she would probably die. The woman replied that she must return to her village and consult with her tribe about what to do.

These ‘sophisticated’ psychiatrists believed that they were merely relating interesting anthropological data from a different, if contemporary, group culture. And it is true that, historically and culturally, enormous variations have existed and continue to exist regarding the degree to which group norms recognize, value, and encourage the differentiation of group members. Individuals as autonomous agents did not inhabit ancient Greece or medieval Europe and emerge only gradually during the Enlightenment; those seventeenth- and eighteenth-century individuals did not view themselves in accordance with our current conception and experience of subjectivity. The authors were able to explore with the seminar members, as we intend to do in this chapter, how an understanding of group dynamics reveals our complex and not always welcome rootedness, as human beings and as professionals, in the ubiquitous play of group forces to which we contribute; and how the potential clinical efficacy of group psychotherapy arises only from this understanding. The unavoidable dilemma, which is intrinsic to the human condition and had been alluded to by our student psychiatrists, was grasped most cogently by Bion.

One of the problems of group therapy, then, lies in the fact that the group is often used to achieve a sense of vitality by total submergence in the group, or a sense of individual independence by total repudiation of the group, and that part of the individual’s mental life, which is being incessantly stimulated and
activated by his group, is his inalienable inheritance as a group animal... The individual is a group animal at war, not simply with the group, but with himself for being a group animal and with those aspects of his personality that constitute his 'groupishness'.

KEY GROUP DYNAMICS

The curriculum of the Royal College of Psychiatrists explicitly and implicitly recognizes the group context of normal and abnormal personality development. There are references, for example, to sociocultural and social psychiatry; to the interactionist approach; to the development and change of attitudes and behaviour, the emergence of visual and auditory perceptions, and the development of self-recognition and personal identity through social interaction; to affiliation, person perception and attribution theory; to social influence, leadership, persuasive communication and obedience in small and large groups; to conformity, polarization and 'groupthink'; to altruism, interpersonal cooperation and social exchange theory; and to the sociology of residential institutions. The Royal College Summary of Areas of Core Medical Knowledge Underpinning Specialist Training in Psychiatry even relates the conceptualization of a ‘theory of mind’ to interpersonal issues and social behaviour. We would emphasize that the rationale for group psychotherapy rests on the interpersonal basis and manifestations of psychopathology, whatever its ultimate origins. Three group dynamic concepts inherent in the curriculum require further discussion, for they are central to an understanding of the therapeutic action of group psychotherapy and to much of the research in group psychotherapy over the past 30 years: group interaction, group norms and group cohesion.

Group interaction

A group can be defined by the number of interactions between its members. Homans, a sociologist, suggested:

If we say that individuals A, B, C, D, E ... form a group, this will mean that at least the following circumstances hold. Within a period of time, A interacts more with B, C, D, E, ... than he does with M, N, L, O, P, ... whom we choose to consider outsiders or members of other groups. B also interacts more often with A, C, D, E ... than he does with others, and so on for the other members of the group.5

Quantity of interaction is very close to intensity of interaction as the emotional significance of group members for one another increases over time. Through the process of interaction, internal differentiations occur with regard to activity, roles, power and status; and the interactions between members are structured accordingly: quantities of sustained interactions become relatively predictable, qualitative patterns of relationship.

Hare studied the process of interaction in small groups (the quantity, sequence and interrelation of acts over time) and found that much human behaviour in groups is directed to solving problems.5 He highlighted group problems and individual problems, and at each of these levels problem content concerned either tasks or social-emotional issues. The group task is to further the publicly stated aims of the group, the objectives and purposes for which it was formed. In order to succeed, the group members must devise an effective division of labour, but they must also attend to the social-emotional coherence of the group by addressing anxieties, conflicts and special personal relationships that arise in the course of group interaction, which may interfere with or severely jeopardize group survival, let alone realization of the primary task. At the individual level, the task is to achieve those personal goals (to belong, to feel secure, to train, etc.) that led the individual to join the group. Simultaneously, in the social-emotional arena, the individual must manage the strains of membership and self-integration under the impact of multiple interactions.

Most evidently, interpersonal interaction in the psychotherapy group is intimate, intensely emotionally significant and of the utmost importance to group members in terms of their life goals, often literally their life or death. They will be deeply involved at both levels of problem content. The group therapist must also keep in mind the two levels of group problem content. The therapist must structure the group as a goal-directed, focused therapeutic enterprise and contain the inevitable emotional turbulence intrinsic to severe mental illness.

The psychiatrist, even if he or she does not take on the role of group psychotherapist, must be aware of this aspect of group interaction, for psychiatrists are members of groups known as multidisciplinary treatment teams, whether in hospital or community settings. It has been well established that group social-emotional functioning in organizations, in response to intense anxieties posed by the nature of the work, often takes the form of maladaptive defensive behaviour.10–12 For example, warmly supportive interactions among members of one professional group may be combined with hostile, blaming interactions towards members of another profession (including managers) within the multidisciplinary team. Although such patterns of interaction protect group members from severe tensions, they can divert their efforts away from a clear focus on the vital jobs that need to be done in order to accomplish both group and individual objectives. Psychiatrists’ interventions, like those of other colleagues, make up part of a total group response to patients. It is incumbent on the psychiatrists, and perhaps particularly on consultant psychiatrists as highly trained and specialized professionals,13 to take a leading role in monitoring whether the social-emotional defensive system, a vital ingredient of staff cohesion when it offers mature protection from anxiety, threatens to shift collective work in an anti-task direction.
Group norms

We have mentioned that group interaction sustained over time becomes highly structured and predictable. Task and social-emotional systems must be flexible and adaptable to changing realities, but they need to have a core of stability. Group norms are central to the development of patterned behaviour, which, while sparing individuals from chaos, also determine much that they feel, think and do as group members, both in and out of their awareness. Norms have been studied extensively in the group dynamics and group psychotherapy research literature (see Whiteley and Gordon1 and Yalom2 for extended discussions of norms in particular and group dynamics in general).

Mills considers group norms as:

... a set of statements about feelings and behaviour. They are cognitive and moral statements which screen, evaluate, prescribe, and proscribe feelings and actions. As statements they are distinct from feelings and from behaviour. They exist in symbolic form in the mind, and are elements of group culture.14

Group norms define, explicitly or implicitly, what is appropriate expression, belief and action for individuals in their specific roles as group members in interaction with one another. The normative system offers definitions of deviance, sanctions and how members may legitimately alter the arrangements for social control in the group.

Two classic and very influential studies of group norms stand out from an extensive literature. Sherif demonstrated experimentally the development of group norms when individuals are ‘placed in an objectively unstable situation in which all basis of comparison, as far as the external field of stimulation is concerned, is absent’.15 Individuals were asked to estimate the perceived movement of a point of light in a totally dark room (the autokinetic effect). Alone, each would establish a range of estimations; and within that range, a subjective reference point – the norm – emerged and became fixed over successive trials of 100 judgements. The ranges and norms of individuals varied, but when the individuals were placed together in groups their differing estimates tended to merge. For subjects who faced the experimental condition for the first time not as isolated individuals but in a group, a specific group range and standard were clearly established. Sherif commented that ‘every individual need not be aware of the fact that he is being influenced in the group situation, or that he and the other members are converging toward a common norm’.15

Asch studied the effects of group (normative) pressure on members’ perceptions of an obvious, clearly visible situation.16 A naïve subject placed in a group situation was asked to match the perceived length of a line, drawn on a piece of paper in front of him or her, to one of three other lines drawn on another piece of paper. The experimental condition involved all the other group members, confederates of the experimenter, giving the wrong answer to this extremely simple task at specified times. Asch sought to determine ‘the social and personal conditions that induce individuals to resist or to yield to group pressures when the latter are perceived to be contrary to fact’.16

Although overall 68 per cent of successive estimates were correct and only very few subjects yielded completely in the face of majority group pressure, one-third of erroneous estimates were identical or similar to the (incorrect) majority. Of greater significance from our clinical perspective, however, were the differences among the independent subjects. Only one-quarter were totally independent, while one-third altered their judgements towards the majority norm in 50 per cent or more of the trials. This means that three-quarters of the subjects were affected in some way. Furthermore, not all independents were confidently so. Some maintained their judgement but were emotionally shaken by their deviance from the other group members. Others showed evidence of dissociation, loss of self-esteem or paranoid reactions. Distortions could occur in action (going along with the group majority even while knowing they were wrong); in judgement (the belief that others were probably right despite one’s own correct estimate); and, most profoundly, in perception (yielding without knowing that one has been influenced).

The implication of this research is that carefully communicated and consistently applied norms are a pre-eminent therapeutic factor in group psychotherapy. In assessment, pre-group preparation and for the duration of treatment, in every session, the group psychotherapist must reinforce patients’ role expectations for productive clinical work and watch for deviations from them. We clarify with prospective patients our recommendations for open and honest communication in the group – about their lives, their reactions to the therapist and to other group members – and underline the primacy of thought and exploration of strong impulses and feelings, rather than immediate resort to action. In particular, we rule out physical violence to others and promote extended working-through of termination in the face of strong temptation towards evasion of mourning. All interactions between group members outside the sessions (if only in the waiting room) should be brought into the group for mutual discussion.

All psychiatrists operate as members of their multidisciplinary work groups; depending on their grade, it is vital that they take responsibility to synchronize the normative system – how professionals ought to behave – both with the reality of the primary tasks of the organization and with the requisite and mature social-emotional relations between group members that enable the work to proceed. Compliance with and submission in group norms can allow the consequently depersonalized individuals to experience tremendous collective vitality, usually based on scapegoating ‘deviant’ members or attacking external groups. Psychiatrists can and should be representatives of norms based on reality – the reality of the world outside the hospital and the reality of engagement with the patient.
Group cohesion

Perhaps no other concept in the field of group dynamics has been elaborated so thoroughly, and is so connected with research into the effects of group psychotherapy, as group cohesion (see Yalom\(^1\) for a comprehensive survey of the research literature).\(^{17–19}\) Group cohesion has been conceptualized as a force, pressure or interpersonal glue that attracts individuals to, and involves and maintains them in, the group. The multiple incentives to join a particular group, whether reflecting a basic need to belong, admiration of the group members, identification with the values, norms or goals of the group, or the status and prestige deemed to flow from group membership, all operate as forces pulling individuals towards and into the group and securing – for as long as they remain salient – allegiance, conformity and commitment.

The ‘cohesiveness’ of a group is the constellation of such forces at any one time, a resultant of all forces acting on members to stay in the group which takes into account the attractiveness of alternative memberships.\(^1\)

No group can exert power and influence over its members greater than its cohesiveness, for the capacity to influence wanes with the diminution or loss of group attractiveness.

In essence, group cohesiveness refers to the sense of affiliation and belonging shared among group members, the ‘we’ feeling in the group. In his anthropological study of urban gangs, Whyte demonstrated how deeply dependent the individual’s experience of personal identity, esteem and mental health, as well as his perceptions, beliefs and behaviour, are on close patterned relationships with other members of his social group.\(^20\) In the absence of such interactions, due to various interferences with the performance of their accustomed roles, psychosomatic and confusional states affected group members. Their being, just like the South American woman mentioned earlier, was anchored in the group. Such reference groups,\(^21\) those groups of paramount significance to which we belong or to which we aspire to belong (a group in the mind), constantly inform our attitudes and actions even when we are not in immediate contact.

Yalom considers cohesion as the group counterpart to the therapeutic relationship in individual psychotherapy, a key element of therapeutic outcome in all forms of treatment, including – as psychiatrists know – psychopharmacology.\(^2\) In itself, group cohesion is only an essential but not a sufficient factor in bringing about change. However, in conjunction with group norms that promote intense and intimate personal interaction, with an emphasis on open disclosure and a willingness to give spontaneous, frank and respectful feedback to others, a cohesive group provides the safety and containment that enable group members to persevere with their difficult and very painful task.

Psychiatrists will be all too well aware of the organizational complement to group cohesion: the vicissitudes of group morale in health service settings that can so affect the state of mind, ranging from creative collaboration to despair, in which professional tasks are addressed. Whether as clinicians or as clinical managers, a consultant role mandates sustained attention to this aspect of group life.

TRANSITION

Before considering group psychotherapy proper, we offer an example from everyday psychiatric practice of how the group dynamic dimensions just reviewed can affect the psychiatrist’s work with patients within the context of the wider professional and hospital systems. A group of junior doctors had been meeting regularly during their rotation with a senior consultant psychiatrist in psychotherapy. The task of the group (a Balint group) was to give the doctors an opportunity to present case material in order to reflect on their interactions with their patients and other staff from a psychodynamic perspective. On this occasion, the consultant arrived to find an apparently random discussion taking place about a recently introduced computerized assessment and selection tool developed to recruit junior doctors.

This new method of job-seeking had confronted doctors with a radical change in the regularized patterns of interaction, expectations (norms) and cohesive primary professional group support for managing an extremely significant career transition. It had been introduced without sufficient communication with the profession, whose leaders had warned of serious problems. Such apprehensions were confirmed, as doctors increasingly found themselves living in uncertainty regarding their futures. They also were concerned about the required online exposure of personal details and were intensely anxious about the severe disruptions to the group patterns of relationship that had enabled them to navigate a difficult stage in their medical training.

The Balint group members were coming to the end of their rotations and were clearly worried about their subsequent employment prospects. The consultant noted that they voiced their anxieties as though they were having a pre-group chat. Soon, one of the psychiatrists began to present a patient. This patient had been in the service for many years, but every time he seemed to his team to be ready for discharge he would act in a manner that would guarantee readmission. The presenting psychiatrist felt frustrated, upset and even angry with herself for feeling so critical towards her patient; she was unable to tolerate or talk to him about his behaviour. She added that the patient had always been in a state of total uncertainty regarding his life. He had experienced no family care and had been in institutions since childhood.

The consultant’s intervention linked the psychiatrists’ supposedly pre-group anxious preoccupation with their careers to the professional problem in relating to the
patient. The patient’s terrible history of lack of care and abandonment to institutional processes mirrored these psychiatriasts’ own current struggle with the effects of losing their accustomed group-based affiliations and patterns on which their professional and (to some extent) personal security depended. Their professional group and system dynamics had been transposed to the treatment setting, where the particular patient repeatedly expressed both the terror of separating from a familiar ward and hospital group and – what the psychiatrists could not put into action – a persistent capacity to control all attempts to make him face an uncertain, even bleak, future. Thinking about the intra- and intergroup interactions in this way supported the members of the Balint group to get more in touch with their own appropriate professional anxieties. They could begin to realize how this discussion of their worries, bringing them in from outside (‘pre-group’) to centre stage, could provide a model for how to approach the patient and his catastrophic separation anxieties in relation to the ward/treatment group.

GROUP PSYCHOTHERAPY

Just over a century ago, Joseph Hersey Pratt, a physician, conducted ‘thought-control clinics’ in which he lectured groups of patients with tuberculosis. Through his charismatic leadership, he taught them how to deal with their sputum and attempted to inspire them to live with their illness. Pratt observed the powerful impact of mutual encouragement and learning that inevitably developed among the group members; and with this combination of therapeutic leadership and supportive interpersonal interactions, he had inadvertently stumbled on the basic features of group psychotherapy. Pratt’s example gave rise to a number of early, primarily psychoeducational, groups conducted by physicians and psychiatrists with a range of patients, including psychotics.22 By the late 1920s and 1930s, and particularly during the Second World War,1 the interest in groups mushroomed, to an extent that the literature – theoretical, clinical and research – became prodigious. A review found that 500–600 articles a year were published on groups in over 400 different sources.23 Subsequently, the same author estimated that, overall, the group literature consisted of approximately 20,000 articles published in hundreds of different journals and thousands of books, while ‘literally tens of thousands of psychologists, psychiatrists, social workers, and other mental health practitioners, as well as millions of clients, spend portions of their time in group psychotherapy or group counselling each week’.24

Our own review of the more recent literature from the main journals (International Journal of Group Psychotherapy, Group Analysis, Group, Small Group Behavior, Group Dynamics: Theory, Research, and Practice), covering the period 2001–07 amply confirms Dies’ account. In out-patient and in-patient (setting), homogeneous and heterogeneous (patient diagnostic mix), exploratory and structured (therapeutic focus), time-limited and open-ended (duration), peer- and professional-led (leadership role), supportive, psychoeducational, cognitive-behavioural and psychodynamic (theoretical orientation) groups, an unimaginable range of patients are treated (see Montgomery25 and Knauss26 for further discussion of these group dimensions). Severely and persistently mentally ill patients; university students with bulimia; residents of nursing homes; gay male survivors of childhood sexual abuse living with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS); patients with fibromyalgia; patients with eating disorders; patients with chronic physical illness; parents; mothers of aggressive children; psychosomatic patients; children with pervasive developmental disorders; homeless people; patients with cancer; traumatized adolescents; patients with bereavement and complicated grief reactions; children with learning disorders; adult survivors of childhood sexual abuse; patients with bipolar disorder; depressed elderly women; patients with post-traumatic stress disorder (PTSD); male spouse abusers; substance abusers; offenders; patients with co-morbidity ... this is only a sample of the types and number of patients treated in group psychotherapy. We will consider separately the indications for group psychotherapy below, but in general, research into group dropout, process and outcome indicates that diagnostic category is no obstacle to referral to a group:

Thus, the age range and the range of diagnosis would not be considered in itself a problem unless the members were too different to be able to communicate with each other (rather rare, in our experience).27

The functioning of psychotherapy groups

The referring psychiatrist, according to the Royal College curriculum, should understand the principles and characteristics of group psychotherapy, and the therapeutic factors in groups, in order to explain this prospective treatment to patients. Our discussion of group dynamics has prepared the ground: group interaction, normative influence and cohesion are central to what happens in psychotherapy groups. Patients who are prepared for and able to participate in these dynamics are likely to derive most benefit from group psychotherapy. To re-emphasize their importance, we briefly consider the clinical theories of group psychotherapy of Yalom,2 Foulkes3 and Bion.4 All reflect the key group dynamic elements, but each theoretical perspective illuminates one of them in a telling way.

From 1970, when the first edition of The Theory and Practice of Group Psychotherapy was published, until the (at the time of writing, most recent) fifth edition, Yalom2 has kept the clinician and researcher in touch with the latest developments in the field. We have relied on his work in this chapter as the most up-to-date and comprehensive
handbook for practitioners and referrers. For Yalom, the
group is a social microcosm in which interpersonal interac-
tion in the here and now plays the essential role. A patient’s
capacity to disclose, receive and give personal feedback,
and to tolerate the revelation, understanding and reworking
of distorted perceptions and interpersonal relationship pat-
terns, indicate the patient’s suitability for group treatment,
whatever the diagnosis. Sooner or later, the patient will re-
enact within the group those maladaptive aspects of his or
her personality and symptoms for which he or she has con-
sulted the psychiatrist, and they can be studied in depth as
they affect the patient’s relationships with other members
of the group.

Based on his own and other research, Yalom has elabo-
rated the most significant therapeutic factors. Some factors
are inherent in groups, while others pertain to all forms of
psychotherapy but take on a particular resonance in the
group setting: instillation of hope, universality, imparting
information, altruism, the corrective recapitulation of the
primary family group, development of socializing tech-
niques, identification/imitative behaviour, interpersonal
learning, group cohesiveness, catharsis and existential fac-
tors. Of these overlapping and mutually enhancing factors,
Yalom distils two vital, group-specific features, each of
which potentiates the group as a holding environment
(cohesiveness): the group as a here-and-now social micro-
cosm of patients’ lives, and the opportunities for therapeu-
 tic interventions to derive from member–member, not just
therapist–member, interactions.

In the group, hope can come from seeing changes in
others with similar problems to one’s own, entirely absent
in individual forms of treatment. The experience of finding
that one is not a unique, irreparably damaged, repulsive or
unworthy individual (universality); that, however low one’s
self-esteem, something one says to another group member
is perceived as extremely valuable by the recipient (altru-
ism); that the whole interpersonal configuration of patients’
families, through the processes of transference and uncon-
scious role induction, comes alive in the session – these are
distinctive group phenomena. Furthermore, in a group,
even the non-specific therapeutic factors become socially
relevant: imitation of others’ self-disclosure, honest, direct
feedback, and accurate empathy contribute to a patient’s
development of social skills. The shared expression of deep
feeling (catharsis) and the realization that everyone is to
some degree alone, will struggle in life and will die (exis-
tential factors) can be especially poignant and meaningful
in group psychotherapy, paradoxically helping individuals
to overcome states of loneliness and isolation. Yalom’s
theory highlights how social interaction, connection and
integration act as a protective factor and cites ‘persuasive
evidence that the rate for virtually every major cause of
death is significantly higher for the lonely, the single, the
divorced, and the widowed’.2

Foulkes, the founder of group analysis, propounded a
clinical theory that fundamentally located the individual
within group relationships, the social matrix. From Foulkes’
perspective, there is no such thing as an abstract individual
apart from his groups. The concepts of individual and group
(society) are totally interrelated; they mutually constitute
one another. No other theory so clearly views the individual
as contained in and containing (internalizing) the social.
Through cultural transmission, group norms are profoundly
active inside individuals and make up their identities, pat-
terning the forms of physical, temperamental, emotional
and behavioural expression. Although Foulkes fully recog-
nized, depending on the focus of investigation, the concep-
tual usefulness of distinguishing between a separate
‘inside-the-individual’ and ‘outside-the-individual’
(group/society), he suggested that this dichotomous
approach could obscure a more complex reality. In this
respect, for Foulkes, even the individual mind, inhering in a
physical brain, is considered as a reification of mental
processes occurring within a wider group network, like neu-
rons interacting within a neural system and being affected
by the electrical and chemical properties of the whole.

This enabled me to say that it is mental processes, not persons,
that interact... To do justice to the fact that this mental field of
operation very much includes the individual but also trans-
gresses him, I have used the term ‘transpersonal processes’.
These processes pass through the individual, though each indi-
vidual elaborates them and contributes to them and modifies
them in his own way. Nevertheless, they go through all the indi-
viduals – similar to X-rays in the physical sphere.28

The most important clinical implication of Foulkes’ work is
that the aetiology, development and maintenance of an indi-
vidual’s mental health and illness, including psychiatric
symptomatology of all kinds, can be understood only by
taking account of the group matrix within which wellbeing
or psychopathology arises. Only by attention to the X-ray-
like group norms, particularly those bearing on the deepest
formation of identity, perception of self and others, the range
of permissible relationship and feelings, pressures for self-
sacrificial loyalty and compliance as opposed to creativity
and freedom of thought, can the roots of maladaptive patho-
logy and suffering be identified. This approach has long been
accepted in systemic family (group) therapy. In child and
family clinics, psychiatrists and other professionals evaluate
a child as ‘the identified patient’, basically an unconsciously
constructed (by others and the child) scapegoat whose symp-
toms play a vital role in securing family homeostasis. Parents,
siblings and the child patient all turn out to be invested in keeping the focus away from multiple serious
relationship issues and psychopathology of other family
members. Treatment characteristically involves supporting
others to relinquish their reluctance, often amounting to
intense denial of any need, to open up communications
within the family network. When this happens, the identified
patient is usually freed up from his or her static, painful role,
and other members are able to address their problems. The
same principle applies fully in group psychotherapy of
adults, whose every gesture, symptom and communication can be imbued with meaning when the specific interpersonal context of what seemed before a virtually autistic idiosyncrasy is made evident.

In *Experiences in Groups*, Bion made perhaps the greatest contribution to an understanding of group cohesion by delineating a ubiquitous and powerful type of cohesive group formation that conflicts with the positive cohesion/therapeutic rapport considered so important in group psychotherapy as a necessary condition for successful therapeutic work. Bion’s insight, quoted above, is that as group animals we have a built-in capacity to join with others, out of conscious awareness, in ways that undermine more realistic efforts to communicate and to work together. Feelings of vitality, power and even omnipotence can be achieved through such cohesive merger in the group (the depersonalization referred to by Freud), and consequently group members may act in accordance with impulses and emotions that would never be expressed by any one of them as an individual. The group tasks, ultimate objectives and values may be subverted, as more mature forms of thinking and organizing give way to convictions bearing the stamp of reality solely on the basis of the degree of emotion invested in them. As conscious individuals, group members often fear and deny this aspect of their functioning: they are intimidated by their ‘groupishness’.

We believe that this form of group cohesion, potentially so destructive of development, can be turned to therapeutic advantage in group psychotherapy. Gordon has pointed to some neglected passages in *Experiences in Groups*, where Bion shows the direction of this positive clinical application. To follow Bion here, the psychiatrist needs to be aware of a particular defence mechanism, projective identification, which is exceedingly prevalent in human relationships, individual and group. Projective identification involves an unconscious phantasy whereby the individual seeks to remove a feared, painful or endangered part of his or her personality or experience. Through ‘psychic surgery’, an intolerable emotion (grief) or a terrifying impulse (rage) is split off, disowned, from the personality and attributed to (projected into) an object, usually a person in the external world. That person, the recipient of the projected aspect, is identified and perceived as containing the disowned feeling or impulse and will accordingly be treated as, for example, needing consolation or extremely violent and dangerous. In addition to the phantasy of splitting off and projecting, the projector usually exerts real interpersonal pressure on the recipient to elicit feelings and responses in them that mirror the phantasy contents that have been externalized.

In the psychotherapy group, Bion showed how members, including the therapist, are constantly and variously recruited by one another into ‘playing a part, no matter how difficult to recognize, in somebody else’s phantasy ...’ The resulting dramas may, at a more mature level, be re-enactments of family scenes; but the more primitive and enmeshing cohesive configurations reflect the predominance of projective identificatory dispersion of problematic aspects of individuals’ identities throughout the group. Thus, one patient may be permanently locked into the ‘competent’ role, another enact ‘anguish’, a third ‘rage’ and yet another ‘withdrawal’. Each role or identity represents a fragment of a potentially whole, integrated personality that no patient is yet able to sustain. These configurations – in effect, the ways in which group members attempt to maintain stable, if conflictual, arrays of depersonalized cohesion – can be made the central focus of group exploration, leading to gradual reintegration of personality and concurrent development of realistic empathy in interpersonal relationships. Bion’s work demonstrates how, when positive cohesion (the work group) prevails, analysis of the forms of negative cohesion becomes a royal road to therapeutic change.

**Indications**

On the basis of a considerable corpus of research literature (outcome and dropout studies, in particular) and clinical experience with a huge range of diagnoses and problems, the referring psychiatrist should adopt two approaches to the issue of selection of patients for group psychotherapy: (i) to focus on patient characteristics linked to positive outcome, and (ii) to deselect – to refer everyone except those patients for whom group interaction would be too intolerable or harmful. In order to best apply these perspectives, referrers should be aware of the types of group available in their settings in terms of the multiple dimensions already described (setting, patient mix, therapeutic focus, duration, leadership, theoretical orientation). This requires close collaboration of the psychiatrist with multidisciplinary colleagues and members of his or her own workgroup in order to ascertain whether, for example, even apparently highly unlikely group referrals such as a severely narcissistic patient, a patient with antisocial features, a paranoid personality disorder or a recovering but still hallucinating person with schizophrenia might be able to be placed in a mature, long-term psychodynamic group whose members would be able to contain such seductive, manipulative, aggressive or disturbing patients, who in turn would stimulate the established members to access deeper levels of their maladaptive relationship patterns.

In other words, indication/contraindication inevitably shades into the question of group composition, specifically a matter for the group psychotherapist but which the psychiatrist generally must keep in mind during a consultation. From this perspective, the referring psychiatrist might ask ‘Is there a group that can contain this patient and with whose membership and task he or she might identify?’ rather than ‘Is this patient suitable for group psychotherapy?’ Patient variables such as problem complexity, chronicity, functional impairment, coping style, resistance level and degree of distress must all be treated as both relevant and relative to the answer the psychiatrist gives to this question.
However, patients with problems in relationships; those who may have failed in individual treatment because of too intense re-enactment of interpersonal pathology with the therapist, whether becoming overintensely intimate or eliciting repeated and intractable negative therapist responses, those who intellectualize excessively and are unaware of their effects on others; those with high psychological mindedness, positive motivation and expectation of treatment, and those with sufficient intelligence and capacity to communicate – or with time to develop this capacity – are all group referrals who could benefit particularly.

Regarding contraindication:

Here is the major guideline: clients will fail in group therapy if they are unable to participate in the primary task of the group, be it for logistical, intellectual, psychological or interpersonal reasons.2

This may include antisocial patients, suicidally depressed patients, and patients with acute situational crises or psychiatric emergencies; vulnerable, easily wounded or intensely socially phobic patients; patients with a history of poor attendance in therapy, intimacy problems generalized to extreme personal distrust, excessive use of denial or impulsive behaviour patterns; and patients with grave inhibitions in raising or discussing important issues in the presence of others or intolerance of the limited amount of time exclusively devoted to the individual (need to share the therapist). But each of these patient characteristics should be placed in context. If the psychiatrist integrates into the evaluation a survey of previous group memberships experienced by the patient throughout his or her life, the extent to which these features reach an exclusionary threshold for the specific groups at the psychiatrist’s disposal should become apparent and can be discussed frankly with the patient.

One of the authors (JG) has for 15 years held two twice-weekly out-patient groups for patients with severe personality disorder. Only one patient out of over 100 referrals, who smoked 30 marijuana joints a day, was rejected, with the recommendation that he first attend to his substance abuse. Although the groups are part of a more comprehensive, hospital-based step-down treatment for personality disorder, group dropout rates within 1 month are considerably lower than the average (8.8%); Yalom gives a rate of 17–57% in a wide range of groups) under conditions in which virtually the only selection criterion is a patient’s willingness to try. Nevertheless, clinical outcome and associated major reductions in health service use costs are exemplary for patients in these treatment groups.

CONCLUSION: EVIDENCE-BASED PRACTICE AND PRACTICE-BASED EVIDENCE

Yalom is characteristically upbeat about developments in the research evidence for group psychotherapy over a generation:

Does group therapy help clients? Indeed it does. A persuasive body of outcome research has demonstrated unequivocally that group therapy is a highly effective form of psychotherapy and that it is at least equal to individual psychotherapy in its power to provide meaningful benefit.2

In 116 chapter notes, many containing 10 or more individual research studies, Yalom goes a long way to backing his judgement. Although other commentators temper unbridled optimism with concerns about methodological complexities that render any long-term group psychotherapy research extremely daunting, ‘It is questionable whether it is possible on the basis of economic as well as practical and ethical reasons to create study designs for long-term dynamic therapies according to a randomized clinical trial model’ – several thorough surveys concur with Yalom’s positive evaluation. It is also vital, when evaluating the evidence base, to realize that even randomized controlled trials of psychotherapeutic interventions typically exclude 45–50 per cent of patients.52

Lorentzen comments on the over half-century of systematic reviews of the group research literature. From the 1960s, the positive effectiveness of group therapy compared with waiting-list and individual treatments was demonstrated. The development of meta-analysis, using a standardized measure, the effect size, confirmed these positive outcomes, as comparable effects 0.90 for group and 0.76 for individual psychotherapy were found. Summing up the period from 1960 to 1990, Lorentzen concluded that group psychotherapy had better outcomes than placebo or waiting list and was equivalent to individual and other psychological interventions. Tschuschke and colleagues confirm effect sizes beyond 1.3 for long-term, out-patient analytical group psychotherapy.54

Burlingame and colleagues, agreeing with these positive overall conclusions, also emphasize a consideration that, in the present era of financial constraints and managed healthcare, can only become more and more pertinent: the established cost-effectiveness of group psychotherapy. This is both a tremendous advantage and a pitfall of group psychotherapy. MacKenzie, quoting Charles Dickens, called it ‘the best of times [and] the worst of times’ for group psychotherapy. For although the increasing demand for group treatments should be excellent news, the fact that this development is a result of the primacy of cost-effectiveness over clinical experience – practice-based evidence – and careful evaluation of individual patients’ long-term needs may threaten even the most evidence-based practices.

For example, the therapeutic community, based on a rigorous integration of those principles of group dynamics and group psychotherapy highlighted in this chapter, seems to be going the way of many international in-patient psychotherapy settings, whose survival is affected as much by the reality of financial policies as by evidence-based imperatives. However, whatever happens to such exemplars of group dynamic and psychotherapeutic milieu treatment
as the Henderson and the Cassel Hospitals, the psychiatrist should continue to view their day-hospital, out-patient and outreach group psychotherapy successors (and any in-patient groups that continue to be provided, especially for severely mentally ill patients) as highly effective and efficient treatment formats. It is now abundantly clear that psychotherapy can induce robust changes that are detectable with neuro-imaging (see also Spence). Such research findings may herald an end to the radical separation of psychiatry and psychotherapy. But beyond the question of treatment outcome, psychiatrists must remain alert to their own inescapable group memberships and the ubiquitous intra- and intergroup dynamics within the hospital or community setting. Whatever the specific mix of clinical interventions deployed, including group psychotherapy, the process and outcome of patients’ treatment will depend on this overarching awareness.

KEY POINTS

- Human beings are group animals through and through.
- Group membership crucially affects how we feel, perceive, think and behave.
- All groups have tasks, and interpersonal interaction patterns within groups may facilitate or undermine the achievement of group objectives.
- Groups are characterized by conscious and unconscious norms: rules and sanctions regarding how members should interact.
- Group cohesiveness refers to the sense of affiliation and belonging which members experience.
- The more cohesive the group, the more its members will comply with the group norms.
- Cohesiveness can contribute to effective group development or prevent it, depending on the nature of the norms.
- Symptoms – including psychiatric instability – can arise in individuals from either a too intense compliance with maladaptive group interaction patterns or from a loss of regular group interactions which bolster secure identity.
- Effective psychotherapy groups encourage specific interpersonal interactions based on norms of disclosure, the reception and giving of feedback and the toleration, understanding and reworking of distorted perceptions.
- The theoretical and clinical work of Yalom, Foulkes and Bion are central to the development of group psychotherapy.
- Research in group therapy indicates considerable effectiveness, and selection (i.e. finding a group with which a particular patient can identify) is a crucial consideration.
- Patient variables such as problem complexity, chronicity, functional impairment, coping style, resistance level and degree of distress are relevant and relative to the extent to which a patient can identify with the membership and task of a particular group.
- Group dynamics in general pervade all mental health settings; we live and work in groups so all psychiatrists need to understand them, even if they do not specialize in group psychotherapy.

ACKNOWLEDGEMENT

The authors would like to thank Dr Lakshmimaraman Alla, Dr Reshma Inamdar and Dr Himanshu Tyagi, and especially Dr Paul Gilluley, Consultant Forensic Psychiatrist, for their valuable comments on a preliminary draft of this chapter.

REFERENCES

Cognitive-behavioural therapy

Rebecca Martinez and Chris Williams

INTRODUCTION

After reading this chapter, you will:

- understand the principles and techniques used in cognitive-behavioural therapy (CBT);
- be able to describe behavioural interventions and when they are indicated;
- know when and how to make an appropriate referral for CBT;
- be able to explain to a patient what CBT entails if they are referred for treatment.

CBT is a form of psychotherapy developed by Aaron ‘Tim’ Beck in the 1960s. In his seminal book *Cognitive Therapy and the Emotional Disorders*, Beck states that psychological problems may result from commonplace processes such as:

- faulty learning;
- making incorrect inferences on the basis of inadequate or incorrect information;
- not distinguishing adequately between imagination and reality;
- thought processes occurring as a result of erroneous premises;
- behaviours that are self-defeating because they are based on unreasonable attitudes.

CBT is characterized by:

- being short-term, problem-focused therapy;
- using step-by-step clear interventions;
- being psychoeducational in nature;
- working by asking effective questions and seeking the right information at the right time;
- a clear underlying model and structure;
- a focus on current problems;
- building on the relationship with the practitioner.

CBT has been researched extensively in a number of different disorders and is recommended for practice by the National Institute for Health and Clinical Excellence (NICE) and Scottish Intercollegiate Guidelines Network (SIGN) guidelines for the following disorders (www.guidance.nice.org.uk/topic/behavioural):

- Anxiety
- Depression
- Panic
- Agoraphobia and other phobias
- Social phobia
- Bulimia
- Obsessive–compulsive disorder (OCD)
- Post-traumatic stress disorder (PTSD).

In addition CBT can be delivered in various self-help formats. These include the following:

- **Written (bibliotherapy) books and workbooks**: currently recommended for use for mild to moderate depression and anxiety.
- **Computerized CBT (CCBT)**: the NICE CCBT guidelines recommend the use of CCBT products, with no specific named products suggested. They accept the concept that CCBT has a class effect and that any competently produced package can be effective with support. Such packages include Mood Gym (www.moodgym.anu.edu.au/welcome) and Living Life to the Full (www.livinglifetothefull.com) both free, as well as paid for licenced products such as Beating the Blues (www.beatingtheblues.co.uk) and Fearfighter (www.fearfighter.com).

There is likely to be a significant increase in the delivery of such approaches as part of the English health service emphasis on increasing access to psychological therapies (IAPT) and National Health Service (NHS) Living Life in Scotland where www.livinglifetothefull.com is provided with telephone support from NHS24 staff (the equivalent of NHS Direct in England).

There are no differences in effectiveness between written and computerized self-help approaches, and it is likely that the delivery options for self-help should be based on patient preference.

HOW DOES CBT WORK?

The assessment model based on five key areas provides a clear structure within which to summarize the range of problems and difficulties faced by people. It emphasizes the links between each of the following components:
Life situation, relationships and practical problems
Altered thinking
Altered emotions (also called mood or feelings)
Altered physical feelings and symptoms
Altered behaviour or activity levels.

Think of a depressed person with whom you are working at the moment. What do they:

- feel emotionally?
- feel physically?
- say?
- do and not do?

What life situations do they often face?
Use the language they would use and summarize their problems in Figure 65.1.

The assessment from a cognitive-behavioural perspective contains all of the elements shown in Figure 65.1, and they form the initial formulation of the patient’s difficulties. From a CBT perspective, it is also important to think about how each of the areas interacts with the others and the impact that they may be having in the patient’s life. It is useful to think of this five areas assessment as a vicious circle. Problems in any of the areas create and worsen difficulties in the other areas too. This is also a major strength, because it means that making helpful changes in any area is likely to lead to improvement in other areas as well.

### CONTENT OF THOUGHTS IN DIFFERENT EMOTIONAL STATES

Experimental research data have confirmed that both the processing styles and the content of thinking vary in different emotional states.7,8

#### Characteristic changes in thinking in depression

Patients with depression are more negative about things when compared with other clinical groups and controls.9,10 The CBT model proposes the negative cognitive triad:

- Negative view of self
- Negative view of the world
- Negative view of the future.

The following cognitive processes exist in depression:

- Patients with depression have impaired problem-solving skills.
- They take longer to retrieve positive memories and are more readily able to access negative memories.11 This might explain the common clinical situation when such patients tell you that they have ‘done nothing’ over recent weeks, despite evidence to the contrary – they are simply remembering the negative and overlooking the things that they have achieved (‘negative memory bias’).

These thoughts lead to altered behaviour such as reduced activity or unhelpful behaviours such as drinking or cutting to block how they feel.

#### Characteristic changes in thinking in anxiety disorders

For patients with anxiety disorders (panic disorder, agoraphobia, generalized anxiety, OCD, phobic disorders), the following are common thinking themes:

- Increased perception of danger and threat
- Decreased perception of their own ability to cope with that danger.

Typical thoughts and images include themes of:

- vulnerability;
- loss of control;
- fear of social ridicule;
- physical harm;
- death (e.g. in a panic attack).

In terms of how information is processed, anxious patients are more prone to:

- scan for potential threats;
- have lower thresholds for noticing potential threats.

The result might include the following changes in behaviours:
Avoidance of anxiety-provoking situations (including people, places and events)

Start of unhelpful behaviours such as:
- reassurance-seeking;
- drinking to excess;
- misusing sedative medication.

**IMPACT OF THOUGHTS ON EMOTIONS**

The CBT model emphasizes the reciprocal links between mood state (e.g. anxiety or depression) and altered thinking. Either can affect the other. Thus, adverse changes in mood are associated with extreme and unhelpful thoughts (i.e. thoughts that are more negative or catastrophic). For example, if an individual experiences thoughts such as:
- ‘Other people do not like me’,
- ‘I am inferior to others’,
- ‘The future is bleak’ or
- ‘Everything always goes wrong’,

then they are likely to feel more anxious or depressed.

Similarly, if mood changes for the worse, then thinking is likely to become more extreme and unhelpful. In this way, a reciprocal relationship is established between extreme thinking and altered mood. Clinically, asking the person ‘What went though your mind when you noticed feeling angry/sad/anxious/ashamed?’ can help the person to identify upsetting thoughts.

One way of describing such thoughts is negative automatic thoughts. This implies that, during times of low mood, upsetting thoughts pop into the mind more frequently and are harder to dismiss than non-upsetting thoughts. A more user-friendly concept is the idea of ‘extreme and unhelpful thoughts’. These are thoughts that make you feel worse, or alter what you do.

**What people think can affect what they do**

Extreme thoughts may lead individuals to reduce or stop doing activities that previously gave them a sense of pleasure or achievement, or to start doing things that actually worsen how they feel.6 This establishes a reciprocal relationship between extreme thinking and reduced/avoided activities or unhelpful behaviours.

I’ll never pass the MRCPsych → Give up revising and start watching too much television

Based on this, psychological problems may be tackled by noticing these patterns, correcting misconceptions and learning more helpful attitudes through processes such as reality-testing, introspection and learning. As all of these are cognitive processes, this form of therapy has therefore come to be known as ‘cognitive therapy’.

**THE CBT FORMULATION (COGNITIVE CONCEPTUALIZATION)**

In CBT terms, a formulation is a shared understanding between the therapist or practitioner and the patient about the patient’s difficulties, how they came about and what is keeping them going. The formulation acts as a sort of map to guide treatment. CBT is a collaborative form of therapy, which means that the therapist and patient together can discuss and decide on appropriate actions and plans.

CBT can help your patients to make sense of overwhelming problems by breaking them down into smaller parts. This makes it easier to see how they are connected and how they affect your patients. It can also be helpful to see how making changes in one of the five areas can result in improvements in other areas.

Generic CBT skills provide a readily accessible model for patient assessment and management and can usefully inform general clinical skills in everyday practice. CBT can therefore provide an integrated biopsychosocial assessment and management approach.

In the CBT approach, cognitive content or processes, emotional responses and behaviour are all seen as being important for assessment. The form of symptoms is still assessed, as this is needed for effective diagnosis. The CBT and diagnostic approaches can be combined, however, within a single assessment and are seen as compatible rather than in opposition.

The CBT five areas approach can be used to summarize depressive disorder as described by the *International Classification of Diseases*, tenth revision (ICD-10)12:

- **Altered mood:**
  - Depressed mood
  - Loss of interest and enjoyment, with anhedonia present for more than 2 weeks

- **Altered thinking:**
  - Reduced self-esteem and self-confidence
  - Thoughts concerning guilt and unworthiness
  - Bleak and pessimistic views of the future
  - Ideas of self-harm

- **Altered physical symptoms:**
  - Diurnal variation of mood
  - Early-morning wakening and disturbed sleep
  - Diminished or increased appetite or weight
  - Loss of libido, fatigue and reduced energy
  - Reduced attention and concentration
  - Constipation

- **Altered behaviour:**
  - Acts of deliberate self-harm or suicide
  - Reduced social activity/work/domestic activities.

A full CBT formulation will contain other elements, as illustrated below, that will help understand how the person has developed these difficulties, what is happening now and what keeps them going (Figure 65.2). Each of the elements of the formulation is explained below.
Formulating a treatment plan

SOME TRADITIONAL CBT DEFINITIONS

- **Relevant childhood data**: aspects of the person’s early experience that may have an impact on their current difficulties, beliefs and recurrent patterns of behaviour.
- **Core beliefs**: beliefs and statements that the individual makes about the self or the world. They tend to be global, overgeneralized and absolute, e.g. ‘I am useless’, ‘You can’t trust anyone’.
- **Dysfunctional assumptions/beliefs/rules**: these are deeper-seated than automatic thoughts and are ‘understandings about how the world works’; they may take the form of ‘should’ or ‘must’ statements, or they may be expressed as conditional, in the form ‘If ..., then ...’, e.g. ‘If you don’t please everyone, then they will be upset with you’, ‘I must never complain’.

NEGATIVE AUTOMATIC THOUGHTS AND FORMS OF COGNITIVE BIAS

The cognitive model states that it is our interpretation of a particular situation, rather than the situation itself, that may lead to distress. These interpretations of situations are usually manifested in the form of thoughts, which may be verbal in form or reflect images (black and white, colour, moving, still) or memories.

The term ‘automatic thoughts’ refers to the stream of consciousness. These thoughts are the overt thoughts that go through a person’s mind at a given time.

People experiencing psychological difficulties may distort situations that could otherwise have been conceived as neutral. This is due to certain biases in the thinking patterns, also known as thinking errors or cognitive distortions.

**Commonly seen cognitive distortions**

(Adapted from Beck.13)

- **All-or-nothing thinking (back and white thinking)**: a situation is viewed under only two categories rather than on a continuum, e.g. ‘Unless I do everything right, I am a failure’.
- **Catastrophizing**: predicting worse-possible consequences without considering other possible outcomes, e.g. ‘If I fail this exam, I will lose my job’.
- **Discounting the positive**: positive experiences or qualities are frequently discounted, e.g. ‘I did well in my last exam, but that was just luck’.
- **Emotional reasoning**: thinking that something is true just because it ‘feels’ true, e.g. ‘I feel like such a failure’.
- **Labelling**: giving a global label either to oneself or to others, without considering all the evidence available, e.g. ‘I am an idiot’.
- **Magnification/minimization**: a way of manipulating the evidence by magnifying (overly focusing on) the negatives or minimizing (playing down) the positives about a given situation, e.g. ‘Anyone can get a good reference’.
- **Mind-reading**: believing that you know what other people are thinking, e.g. ‘They think that I can’t do anything right’.
- **Overgeneralization**: assuming that, because something has happened once, it will happen again, e.g. ‘I can never do anything right’.
- **Personalization**: believing that other people’s actions are because of you or something you have done, e.g. ‘My colleague didn’t stop to talk to me – maybe I have done something wrong’.

FORMULATING A TREATMENT PLAN

The cognitive formulation will help to identify problematic areas in the person’s difficulties, which contribute to or help to maintain the problem. Once these areas have been iden-
tified, they can become a target for change, and the therapist and patient will use relevant techniques to tackle these difficulties. The areas that may be tackled may be in the cognitive or the behavioural domains – or in other key aspects of the person’s life, such as relationships, physically or emotionally (i.e. in any of the five areas).

**Cognitive techniques**

Cognitive techniques focus on the identification and challenge of negative automatic thoughts. This is done during the encounter with the therapist, which will help to guide the patient through the process.

A technique of dialogue with the patient commonly used in CBT is guided discovery, also known as ‘Socratic questioning’. This asks questions to help the person discover or work out the links between their thoughts and how they are and to discover new ways of understanding these.

CBT uses a tool commonly known as the ‘thought record’ to evaluate and challenge a distressing thought and to help the patient come up with an alternative, more balanced thought (Table 65.1).

It is important for both the patient and the therapist to decide whether to focus on a particular thought, as people have thousands of thoughts in any one day. It is important to work on those thoughts that are associated with situations that have been particularly emotionally charged and upsetting or disruptive for the patient.

Cognitive techniques such as the thought record are commonly used by cognitive-behavioural therapists in a range of disorders. The thought record helps the patient to engage and to become aware of how the cognitive model works in practice.

**Behavioural techniques**

**Behavioural interventions**

Behavioural interventions target specific problematic behaviours that are targeted for change.

The initial basis for the development of behavioural techniques was rooted in the theories of operant conditioning. Operant conditioning forms an association between behaviour and a consequence. The nature of the consequence will determine whether the behaviour is reinforced or not.

Reduced activity, such as reducing things that used to give a sense of fun, pleasure, achievement, mastery or closeness to others, and unhelpful behaviours, such as drinking to excess, comfort eating, self-cutting, lashing out or withdrawing from others, can continue to affect the individual’s mood and energy levels and can maintain the difficulties that they are experiencing.

Using the operant conditioning model, one may understand that individuals who, for example, have a spider phobia would avoid spiders, as in their experience they have learnt the association between spiders and adverse consequences (i.e. symptoms of extreme anxiety). This pattern can be corrected using behavioural techniques.

Unhelpful behaviours can be identified and challenged using a number of behavioural interventions, such as:

- behavioural or functional analysis;
- behavioural activation and activity diaries;
- behavioural experiments;
- systematic desensitization, also called progressive exposure/graded and cue exposure;
- habituation.

**Behavioural or functional analysis**

Behavioural or functional analysis will help to identify relevant unhelpful behaviours. The aim of the behavioural or functional analysis is to review the details of each of the problem or target behaviours in order to understand the process of precipitation and maintenance, and then to be able to work collaboratively with the patient to tackle these areas.

One method of doing this is to use the ABC approach.14

- A: antecedents
- B: behaviours and beliefs
- C: consequences.

When doing this with a patient, it is useful to get the patient to reflect about a recent example and to give as much detail as possible about their understanding of the situation.

**Behavioural activation and activity diaries**

An activity diary may help to assess the types of activity that the patient is currently engaging in and those that they:

- avoid as a result of anxiety;
- have reduced doing, e.g. because of symptoms of depression.

It can also be used to establish the links between certain activities and changes in mood states.

In this way, it is important to collaborate with the patient to establish goals that relate to their activities and those that they are avoiding. Some diaries also allow the person to rate their activities for pleasure, achievement and closeness to others. The activity diary is a useful tool to incorporate activity-scheduling and to monitor regularly the progress that is being made. An example of an activity diary is shown in Table 65.2, and copies of an activity diary and blank five areas assessment sheets can be downloaded free of charge from www.fiveareas.com.

There is a growing evidence base for the use of behavioural activation in depression.15 The so-called dismantling studies that have examined separately the added benefits of offering cognitive, behavioural or combined cognitive-behavioural approaches suggest that, at least for depression, behavioural activation appears to be as effective as a treatment of depression as offering the full CBT model.15
<table>
<thead>
<tr>
<th>1. Situation/relationship or practical problem when your mood altered</th>
<th>2. Altered emotional and physical feelings</th>
<th>3. What immediate thoughts are present at the time?</th>
<th>4. What unhelpful thinking style(s) occur?</th>
<th>5. Impact of the immediate thought(s)</th>
</tr>
</thead>
</table>
| Think in detail: where am I and what am I doing? Consider:  
- The time: what time of day is it?  
- The place: Where am I?  
- The people: who is present? Who am I with?  
- The events: what has been said? What events happened? | Am I:  
- Low or sad? Guilty?  
- Worried, tense, anxious or panicky?  
- Angry or irritable?  
- Ashamed or suspicious?  
(i) State the feelings strongly. Try to be as precise as possible. If more than one feeling occurs, underline the most powerful feeling.  
(ii) How powerful is this feeling (0–100%)?  
(iii) Note down any strong physical sensations you notice.  
(i) My feelings:  
(ii) Powerfulness: 0–100% = | What is going through my mind?  
How do I see:  
- Myself? How do others see me?  
- The current events/situation?  
- What might happen in the future?  
- My own body, behaviour or performance?  
- Any memories or images?  
(i) State the thought(s) clearly. Try to be as precise as possible. If more than one thought occurs, underline the most powerful thought.  
(ii) Rate how strongly you believe the most powerful thought at the time (0–100%).  
(i) My immediate thought(s): if you have noticed more than one thought, underline the most powerful thought | - Bias against myself  
- Putting a negative slant on things (negative mental filter)  
- Having a gloomy view of the future or jumping to the worst conclusion?  
- Negative view about how others see me (mind-reading)  
- Bearing all responsibility  
- Making extreme statements and rules, e.g. using ‘must’, ‘should’, ‘ought’, ‘always’ and ‘never’ statements  
If any of these styles is present, then you have identified an extreme thought  
Which unhelpful thinking styles are present? (state numbers or types) | (i) What did I do differently?  
Consider any:  
- Reduced activity  
- Unhelpful behaviours  
(ii) What was the impact on:  
- Myself?  
- My view of others?  
- How I felt?  
- What I said?  
- What I did?  
Overall, was the impact helpful or unhelpful?  
If there is an unhelpful impact, you have identified an unhelpful thought  
(i) What did I do differently?  
(ii) Overall, is it helpful or unhelpful for me to believe the thought? |

### Behavioural experiments

Behavioural experiments help patients to collect real-life evidence in order to test out or refute their underlying assumptions and rules. Behavioural experiments can be very effective at producing both emotional and cognitive shifts. The *Oxford Guide to Behavioural Experiments* provides detailed and useful guides to setting up behavioural experiments and tasks in a collaborative manner with clients:16

- Practitioners need to present a rationale for conducting the experiment, e.g. that experiments are needed in order to collect solid data regarding central problems and situations.
- The practitioner and patient, collaboratively, are seen as co-investigators, working together to design real-world experiments that test out the validity and utility of dysfunctional cognitions (thoughts, underlying assumptions, and family and cultural rules are amenable to this as well).
- Experiments can take place during a session or set for homework.
- Presenting a rationale, grading tasks and making a task fail-proof can motivate the patient to try it out to see what happens.

When setting up a behavioural experiment, the following steps should be followed:

1. Identify the thought or assumption to be tested – write it down.
2. Brainstorm possible experiments with the patient to come up with activities that will challenge the assumption.
3. If necessary, grade the activities. Start with something easy and make it fail-proof – don’t set your patient up for failure.
4. Plan the experiment – specifics, how, when, what, etc.
5. Write down the patient’s predictions of the outcome of the experiment (‘What do you think will happen?’).
6. Carry out the experiment.
7. Record the outcomes.
8. Repeat if necessary, collecting more and more evidence.
9. Analyse the outcomes with the patient.

It is important to keep written records of the experiments. Examples of worksheets on behavioural experiments can be found in the CBT self-help literature and provide a helpful record of the experiment.17

### Systematic desensitization

This process was described by Wolpe.18 Initially the patient is taught relaxation techniques, followed by the elaboration of a collaborative hierarchy of feared stimuli with the patient. The patient is encouraged to progress step by step with exposure to each of the stimuli in the hierarchy, starting with those that are predicted to produce lower levels of anxiety, and progressing to those that produce higher levels of anxiety. While they do this, the patient maintains the relaxation, which will *reciprocally inhibit* the fear response.

In reciprocal inhibition, a response that is antagonistic or incompatible to anxiety (e.g. relaxation) is present when the stimulus is presented, and then there is a subsequent reduction of the anxiety response.

### Graded and cue exposure (progressive exposure)

Graded exposure is a form of exposure treatment in which the patient and therapist collaboratively create a list or
graded hierarchy of feared situations. The patient is exposed to those situations that are predicted to provoke fewer anxiety reactions, until these are mastered. They then gradually work through the hierarchy until the feared stimulus can be faced in its full form. Having a clear step-by-step plan allows progressively more anxiety-provoking situations to be faced and tackled. They key is repeated practice at each step along the way, always then moving on towards the goal. There are no surprises, and always the aim is to push the person forward, but at a pace that they can cope with. This is very different from the flooding approach, in which the patient is exposed to the feared stimulus all at once and is maintained in this situation until the anxiety symptoms decrease. Although effective for some patients, flooding risks the possibility of patient disengagement and anger.

Cue exposure is the exposure of the patient to a ‘cue’ to a particular stimulus, when the stimuli are paired. This may be encountered in substance abuse, where, for example, a person who may have been previously dependent on alcohol may start to experience cravings or even withdrawal-type symptoms with a stimulus such as the smell of alcohol, which in turn may motivate them to drink alcohol. Cue exposure involves the repeated exposure to such cues so that this extinguishes the response, in this case the craving for alcohol.

**Response prevention**

Progressive/systematic exposure is especially helpful for phobic anxiety states and obsessive–compulsive symptoms. The person plans how to face up to their fears in a planned, step-by-step way. At the same time, they are encouraged not to leave, run away or try to neutralize the anxiety in unhelpful ways such as using medication, alcohol or distraction. This latter approach is called response prevention. It involves helping the person to recognize the ranges of so-called safety behaviours that they use to cope with symptoms and then to plan to slowly drop these behaviours, thereby helping them face their fears more effectively and habituate (get used to) the anxiety, which slowly drops away.

Introducing such behavioural change is also an excellent way of testing out catastrophic fears and building confidence that the very worst does not happen.

**Habituation**

Habituation is a simple process by which, following repeated exposure to a particular stimulus, the subject stops responding to it. This is also called extinction of the response. So, a particular stimulus that may have provoked an anxiety reaction will stop producing this reaction once the patient has been exposed repeatedly to the stimulus.

**DEFINING OUTCOME IN CBT**

As CBT is a problem-focused and evidence-based approach, monitoring progress is a central part of the therapy process. Treatment outcome measures that are commonly used in CBT practice are self-report measures such as the Beck Depression Inventory (BDI)\(^\text{19}\) and the Beck Anxiety Inventory (BAI).\(^\text{20}\) These can be done weekly just before the start of the session, and they will be used as feedback tools for the patient at review points in the therapy.

Other self-report measures that may be used with the patient are continuum measures for each of the target difficulties, where the patient can rate where they feel they are at. This can help to monitor the patient’s progress. Figure 65.3 shows an example.

![Figure 65.3 Self-report measures: continuum](image)

Readers should be aware of moves to standardize outcome measurement, such as that suggested for the IAPT minimum dataset.

**THE EVIDENCE BASE**

CBT has been studied for a number of disorders. The evidence base includes randomized controlled trials and meta-analysis of these. The data have been summarized in evidence-based practice guidelines and are recommended for practice by the NICE and SIGN guidelines for the following disorders (www.guidance.nice.org.uk/topic/behavioural):

- Anxiety
- Depression
- Panic
- Agoraphobia and other phobias
- Social phobia
- Bulimia
- OCD
- PTSD.

**Selecting and referring patients for CBT**

- Consider current evidence-based guidelines.
- The patient prefers to use psychological interventions, either alone or in addition to medication (N.B. the CBT model readily allows the use of medication alongside therapy and may indeed focus on increasing compliance and adherence).
- The target problems for CBT (extreme unhelpful thinking, reduced activity, avoidant or unhelpful behaviours) are present.
THE THERAPEUTIC RELATIONSHIP

The CBT model brings three key characteristics seen in evidence-based therapeutic models:

- A model or structure that helps to people understand why they feel as they do
- A focus on problems and symptoms relevant to the patient
- Delivery within a supportive therapeutic relationship.

It is clear that, for any form of psychotherapy, so-called non-specific therapist factors such as warmth, empathy and genuineness contribute the majority of therapeutic effect in a clinical encounter. On top of this, however, the focus and step-by-step structure of CBT have contributed to it having the widest range of NICE recommendations of any of the existing forms of psychotherapy.

CONCLUSION

CBT is a pragmatic, problem-focused therapy that can be used alongside medication and diagnostic approaches. Developed by a medic and founded in empirical research, and yet retaining a strong focus on the individual, it has become the predominant form of psychotherapy offered within the health service today. Increasingly wider and rapid access will occur through routes such as telephone CBT, group-based CBT and the use of CBT self-help alongside the traditional forms of face-to-face CBT. Pragmatically CBT core skills can provide a useful part of the psychiatric armamentarium for everyday clinical use.

KEY POINTS

- CBT is an evidence-based treatment approach
- Central to effectiveness is working with a clear structure and targeting problems identified through a joint formulation such as the five areas approach
- Translating CBT into accessible language – and helping people make small step by step changes is the key to success
- Psychiatrists can use CBT approaches in clinic sessions by utilising key CBT concepts; targeted cognitive, behavioural and problem solving interventions; or the use of CBT self-help

REFERENCES

INTRODUCTION

This chapter primarily describes art therapy and music therapy, which are two of the arts therapies. The arts therapies consist of art therapy, music therapy and dance therapy. (Note that psychodrama is not conventionally considered to be one of the arts therapies.) Although the current body of solid research for creative arts therapies is small compared with that of more traditional medical specialties, the arts therapies are now validating their research through more controlled experimental and descriptive studies.\(^1\) Scientific studies of some of the physical and cerebral effects of music are described in this chapter. At the end of the chapter there is a very brief mention of a few other individual therapies. It should be noted that although the therapies mentioned in this chapter may be used on an individual basis, some of them, such as music therapy, may also often be used in group settings.

ART THERAPY

As David Lomas has pointed out in his foreword to Susan Hogan’s history of art therapy, Healing Arts, Sigmund Freud, in an essay on Michelangelo’s Moses, pointed out that the artist’s intentions should be capable of being communicated and comprehended in words, which in the case of great works of art might require the application of psychoanalysis; to discover the intentions of the artist, one must be able to interpret the artist’s work of art.\(^2\)

Classification

Three groups of art therapy have been differentiated:\(^2,3\)

- Art therapy: emphasis is placed on the production of the artwork itself, which is not usually interpreted
- Art psychotherapy: verbal analysis of the artwork by the therapist takes place; the artwork illustrates the therapeutic relationship or recounts some aspect of the history
- Analytical art psychotherapy: draws on the theories of psychoanalysis and emphasizes the transference between client and therapist.

In this chapter, the term ‘art therapy’ is used as a generic term to refer to all three types.

Techniques

Art therapy may take place on an individual basis, in a small group setting or in an ‘open studio’ format. The types of artwork that may be produced by the client can involve use of various modalities, including:\(^2\)

- painting;
- collage;
- clay pottery;
- sculpture.

Case vignette

Joy Schaverien has published the paintings shown in Figures 66.1 and 66.2 as part of an instructive case vignette from therapy sessions with a patient named ‘Jacqui’.\(^4\)

Jacqui’s mother had died suddenly, in her late fifties, when Jacqui was 22. Now Jacqui was in her early fifties but she still felt oppressed by her mother. The internalized mother dominated her every move and denigrated her attempts to work or make relationships ...

Figure 66.1 is of a tree, which she described as showing her chaos, insecurity and depression on one side, and the lively

Figure 66.1 Painting of a tree by ‘Jacqui’, created as part of art therapy
Reproduced from Schaverien.\(^4\)
part of her life on the other. It shows the distorted growth that had emerged as a result of her parental domination and lack of autonomy. The dominating mother had a brother who was ‘simple’ and who was never really able to function in the world. The family viewed him as rather pathetic and hopeless. At times he was admitted to the local psychiatric hospital for in-patient treatment. Jacqui loved him but her fear of her own vulnerability was at times associated with her uncle and at worst she feared that she was mad. This sense of her own vulnerability, associated with the flaw in her family, emerged as a dark area in many of her paintings.

In a session soon after an insight that connected her fear of madness with her beloved uncle she made Figure 66.2, another painting of a tree. It was an image of growth and she explained how one colour represented the warmth of her feelings for her uncle. The tree had strong roots and branches, but a dark patch, which she felt indicated her relationship to her parents, was like a flaw that ran throughout it.

5. **Disposal** of the artwork, which holds powerful affect – before the end of therapy, a conscious decision needs to be made regarding the disposal of the artwork. Will the client take the artwork away with them, or leave it in the art room, or destroy it?

It has been suggested that a transference to the artwork, and the associated transference–countertransference dynamic, may allow art to offer a particular means of psychological transformation in states that may otherwise not be expressible by the client.\(^5\)

### Specialized types

There are several variants of art therapy that have been created. For example, the Conversational Model may be applied to art therapy. This model, created by Robert Hobson and Russell Meares, is a developmental model in which what is said and done in therapy is aimed at promoting understanding; a ‘conversation’, a meeting between two experiencing subjects (an I and a thou), here and now, in such a way that learning can be effective in other relationships.\(^6\) Unconscious traumatic memory may lead to a relative loss of inner speech and intrusion into conventional verbal therapeutic conversation;\(^7\) the client may find it easier, under these circumstances, to express him- or herself by means of artwork.

In image art psychotherapy, free expression, spontaneous expression and thematic drawings are utilized simultaneously. Tokuda has argued that there are image expressions applicable not only to one graphic representation but to a whole series involving the ‘drawing–observing–examining–continuing to draw again’ process, and somatic self-expression; that these too reflect the preconceptual emotion and total psychosomatic rhythm; and that there exists a process of approaching the true self over the ordinary defences.\(^8\)

### Patient groups

A pilot study in 26 patients in a psychosomatic day hospital, involving 16 sessions of art therapy and utilizing standardized rating questionnaires to quantify changes in mood and somatic symptomatology, showed a reduction in somatic symptoms and a tendency to be in a more positive mood during the course of the day treatment.\(^9\) The paintings dealt mainly with the patients’ own (current, problematic) issues; the colours chosen for the paintings were particularly important to most patients, and often there was no connection to paintings created during the previous sessions. Subjectively, the patients felt better after the art therapy session. They indicated that they mostly use art therapy as a way to express their problems, and only very few also named other goals of art therapy, such as creativity or relaxation.\(^9\) There is also evidence that art therapy may help to produce a slow partial recovery in patients with chronic somatic symptoms, in whom inability to express emotions

### Stages of separation differentiation

Joy Schaverien has identified the following five stages of a separation differentiation that are common in art therapy:\(^3\)

1. **Identification**, which occurs immediately after the creation of the artwork, when there exists a strong connection between the client and his or her artwork.
2. **Familiarization** of the content of the artwork by the client, who begins to become conscious of what it reveals and starts to differentiate its elements.
3. **Acknowledgement** at a conscious level by the client of the implication of his or her artwork; at this stage, discussion with the therapist is possible and interpretations may be received.
4. **Assimilation**, which is the stage of re-integration of the elements of the artwork, which is now owned and the implications of which are now assimilated.
is common and is associated with incapacitation and impaired quality of life.  

There is preliminary evidence suggesting that art therapy may be helpful to older people with mild to moderate depression, and stronger evidence that it helps to reduce depressive symptoms in prisoners. In a study of 46 seriously delinquent incarcerated male juvenile offenders, Persons examined how art therapy addressed the boys’ psychological needs by analysing their self-selected artwork. In descending order of frequency, the eight most frequent need themes were: identity issues; need for security and tranquility; need for freedom, adventure and fun; need for ideal parental relationships; need for affiliation and affection; erotic and sexual needs; expression of depression, childhood trauma and other psychological problems; and religious or spiritual needs. The juvenile offenders’ perceptions of what was most helpful about art therapy, in descending order, were: stress relief and relaxation; reduction of boredom; pride and self-confidence; positive recognition; working through frustration; enjoyment and fun; improvement of ability to concentrate; and the way they were treated.

It has been suggested that art therapy should perhaps be restricted and not applied to patients who are psychotic. A systematic review of art therapy for schizophrenia or schizophrenia-like illnesses has found that randomized studies are indeed possible in this area, but that thus far its benefits or harm in these disorders remain unclear.

Art therapy is used to help children with emotional, developmental and behavioural problems. A study of 64 young (age 6–21 years) recipients of renal transplants showed that although art therapy may be of utility in the identification of those who are suffering from depression, it lacks sufficient sensitivity to warrant its use in this population.

A significant improvement in the Hospital Anxiety and Depression Scale (HADS) scores has been reported in patients with cancer receiving chemotherapy who participated in at least four weekly art therapy sessions. Coping resources also improve in women with breast cancer after taking part in art therapy intervention.

In a randomized comparison of a 1-h art therapy session versus watching videos of art therapy in 79 patients with human immunodeficiency virus (HIV) infection, physical symptom mean scores were found to become significantly better for those who participated in art therapy compared with those who viewed the video.

There is preliminary evidence that art therapy may help the speech of children with cerebral palsy, particularly in respect to intelligibility, volume, tempo and control of pauses.

**Inter-rater reliability**

Eitel and colleagues systematically studied the assessments of 86 raters who evaluated a picture created during an art therapy session. The rating was based on formal (colour, lines, shapes) and contextual criteria. The resulting inter-rater agreement was relatively poor (intraclass correlation coefficient = 0.18–0.52). They also addressed the question of whether raters were able to determine which picture was created at the beginning of the art therapy and which at the end; on the basis of the examination of five sets of pictures, they concluded that the raters were not reliably able to distinguish between the two.

---

**MUSIC THERAPY**

**Definition**

Patients are offered the opportunity to make live music, either improvised or precomposed, with a music therapist who is a trained musician and music therapist, or to listen to music with therapeutic intent.

**Techniques**

Music therapy may take place on an individual basis or in a group setting. Live music-making may involve:

- tuned and untuned percussion;
- a piano;
- an electric keyboard;
- single-line musical instruments;
- the subject’s voice.

Music being listened to may be live or recorded. In the latter case, it may take the form of prerecorded compositions or consist of recordings of music made by the subject.

**Cardiovascular, respiratory and mid-cerebral arterial flow velocity effects**

Music and musical pauses induce cardiovascular and respiratory changes in the listener. Bernardi and colleagues asked a group of 12 practising musicians and 12 non-musicians to listen, after a 5-min baseline, to a presentation in random order of six different musical styles (first for a 2-min track and then for a 4-min track), with a randomly inserted 2-min pause, in either sequence. Their main findings were as follows: Ventilation, blood pressure and heart rate increased, and mid-cerebral artery flow velocity and baroreflex decreased with faster tempi and simpler rhythmic structures compared with baseline; no habituation effect was observed; the pause reduced heart rate, blood pressure and minute ventilation, even below baseline. An order effect independent of style was evident for mid-cerebral artery flow velocity, indicating a progressive reduction with exposure to music, independent of style. Musicians had greater respiratory sensitivity to the music tempo than did non-musicians. They concluded that music induces an arousal effect, predominantly related to...
the tempo, with slow or meditative music being able to induce a relaxing effect; relaxation is particularly evident during a pause. Music, especially in trained subjects, may first concentrate attention during faster rhythms, and then induce relaxation during pauses or slower rhythms.23

### Cerebral changes

Menon and Levitin used functional and effective connectivity analyses to show that listening to music strongly modulates activity in a network of mesolimbic structures involved in reward-processing, including the nucleus accumbens and the ventral tegmental area, as well as the hypothalamus and insula, which are thought to be involved in regulating autonomic and physiological responses to rewarding and emotional stimuli.24 Responses in the nucleus accumbens and the ventral tegmental area were correlated strongly, pointing to an association between activity in a network of mesolimbic structures and the ventral tegmental area, as well as the hypothalamus and insula, which are thought to be involved in reward-processing, including the nucleus accumbens and the ventral tegmental area, as well as the hypothalamus and insula, which are thought to be involved in regulating autonomic and physiological responses to rewarding and emotional stimuli.24 Responses in the nucleus accumbens and the ventral tegmental area were correlated strongly, pointing to an association between dopamine release and the response of the nucleus accumbens to music.24 The same group have investigated the neural dynamics of event segmentation in entire musical symphonies under natural listening conditions, by isolating time-dependent sequences of brain responses in a 10-s window surrounding transitions between movements of symphonic works.25 A strikingly right-lateralized network of brain regions showed peak response during the movement transitions when, paradoxically, there was no physical stimulus. Model-dependent and model-free analysis techniques provided converging evidence for activity in two distinct functional networks at the movement transition: a ventral frontotemporal network associated with detecting salient events, followed in time by a dorsal frontoparietal network associated with maintaining attention and updating working memory. These results provide direct experimental evidence for dissociable and causally linked ventral and dorsal networks during event segmentation of ecologically valid auditory stimuli.25

Blood and colleagues carried out a study of emotional responses to pleasant and unpleasant music in subjects who were not professional musicians and who underwent positron-emission tomography (PET) neuroimaging while listening to six versions of a novel melody. As shown in Figure 66.3, they found a significant negative correlation between the degree of dissonance (using major triads as having the least dissonance, and flattened thirteenth triads as the most dissonant) in the melody and the subjective rating of pleasantness.26 An analysis examining regional cerebral blood flow (rCBF) changes from the PET neuroimaging as a function of increasing dissonance identified significant positive correlations in right parahippocampal gyrus and right precuneus regions, while significant negative correlations, corresponding to increasing consonance, were found in large areas of orbitofrontal cortex bilaterally, medial subcallosal cingulate region (3 mm to the right of

![Figure 66.3](image_url)

**Figure 66.3** Examples of music stimuli and average subject ratings of unpleasant versus pleasant and happy versus sad for each version. (a) Excerpts from the most consonant version (major triads, Diss0) and the most dissonant version (flattened thirteenth triads, Diss5) of music stimuli used in the positron-emission tomography (PET) study (see text). (b) Line graphs demonstrating averaged subject ratings following scans for each of the six versions, Diss0–Diss5. Ratings of very pleasant (+5) versus very unpleasant (−5) demonstrated significant interactions (P < 0.001) and a high correlation coefficient (r = 0.57) with dissonance level. Ratings of very sad (+5) versus very happy (−5) did not demonstrate significant interactions and had a lower correlation coefficient (r = 0.33) with dissonance level.

Reproduced from Blood et al.25
the midline) and right frontal pole.\textsuperscript{26} Ratings of increasing unpleasantness correlated, albeit weakly, with rCBF activity in the right parahippocampal gyrus, but in the identical location to that found in the regression with dissonance level; increasing unpleasantness also correlated with activity in the posterior cingulate, whereas ratings of increasing pleasantness correlated with activity in the right orbitofrontal and medial subcallosal cingulate cortex.\textsuperscript{26}

Blood and Zatorre went on to use PET to investigate neural correlates of intensely pleasurable responses to music. rCBF changes were measured while subjects listened to music that they selected predictably to elicit the euphoric experience of ‘chills’ (or ‘shivers-down-the-spine’). These were pieces of classical music, such as Rachmaninov’s Piano Concerto No. 3 in D Minor, Opus 30, Intermezzo Adagio and Barber’s Adagio for Strings. Listening to the chills-inducing musical pieces was associated with increased cardiac rate, electromyographic changes and increased depth of respiration (Figure 66.4)\textsuperscript{27} Regression analysis correlating rCBF with increasing chills intensity ratings in the subject-selected and control music conditions identified rCBF increases in the left ventral striatum, dorso-medial midbrain, bilateral insula, right orbitofrontal cortex, thalamus, anterior cingulate cortex, supplementary motor area and bilateral cerebellum, while rCBF decreases with increasing chills intensity were observed in the right amygdala, left hippocampus/amygdala and ventromedial prefrontal cortex, and in widespread, bilateral posterior neocortical regions, particularly in the cuneus/precuneus regions.\textsuperscript{27} Subtraction of noise and silent baseline conditions from subject-selected and control music conditions confirmed that activity in the right amygdala, left hippocampus/amygdala and ventromedial prefrontal cortex decreased from baseline during subject-selected music, whereas no cerebral blood flow changes were seen in these structures during control music as compared with the noise and silent baselines.\textsuperscript{27} The authors concluded:\textsuperscript{27}

As intensity of these chills increased, cerebral blood flow increases and decreases were observed in brain regions thought to be involved in reward/motivation, emotion, and arousal, including ventral striatum, midbrain, amygdala, orbitofrontal cortex, and ventral medial prefrontal cortex. These brain structures are known to be active in response to other euphoria-inducing stimuli, such as food, sex, and drugs of abuse. This finding links music with biologically relevant, survival-related stimuli via their common recruitment of brain circuitry involved in pleasure and reward.

In 1993, Rauscher and colleagues published a study in which they asked students to listen for 10 min to part of

![Figure 66.4](image-url)
Mozart’s Sonata for Two Pianos in D Major, K448, a relaxation tape designed to lower blood pressure or silence, before taking three sets of standard intelligence quotient (IQ) spatial reasoning tasks. Those listening to Mozart’s K448 performed significantly better than the other two groups; the mean standard age scores and corresponding spatial IQ scores are shown in Figure 66.5. Pulse rates were measured before and after participation in this experiment, and there was no interaction or main effect for pulse, thereby excluding arousal as a cause for this effect. This effect has come to be known as the Mozart effect and in this original study it was found that enhanced spatial reasoning did not last beyond the 10–15 min during which the subjects were engaged in each spatial task. Subsequently, the Mozart effect has been found to occur in rats.29

Rats were exposed in utero plus 60 days post-partum to either complex music (Mozart Sonata (K. 448)), minimalist music (a Philip Glass composition), white noise or silence, and were then tested for five days, three trials per day, in a multiple T-maze. By Day 3, the rats exposed to the Mozart work completed the maze more rapidly and with fewer errors than the rats assigned to the other groups. The difference increased in magnitude through Day 5. This suggests that repeated exposure to complex music induces improved spatial-temporal learning in rats, resembling results found in humans.

Extended exposure to learning and playing music by Mozart and Beethoven has been found to be associated with improved spatiotemporal reasoning that was still present 24 h later in preschool children. With extended exposure, rats have also shown long-term enhancement of maze learning. Furthermore, electroencephalographic studies in humans have shown that the Mozart effect is associated with right frontal and left temporoparietal coherent activity. Hughes and colleagues carried out an impressive study on the effects of listening to Mozart’s K448 on epileptiform activity: The ‘Mozart Effect’, using the Piano Sonata in D Major (K.448), was examined in patients with seizures. In 23 of 29 instances significant decreases in epileptiform activity were noted from patients even in coma, with status epilepticus or with periodic lateralized epileptiform discharges (PLEDs). The effect may be immediate or require 40–300 sec to manifest itself. The change in the amount of ictal activity in one patient in coma was from 62% before the music to 21% during Mozart. Amplitudes of these discharges also have often decreased. Examples of PLEDs on both temporal areas are shown in which the effect was only on the left temporal area but in other patients only on the right temporal area. Brain maps during the music showed theta and alpha activity decreased on the central areas, while delta waves increased on the frontal midline area. The basis of this effect is likely that the superorganization of the cerebral cortex with its highly structured radial columns seen throughout both hemispheres may resonate with the superior architecture of Mozart’s music.

It is not known how specific the Mozart effect is to his K448 composition. Certainly, there is evidence that the minimalist music of Philip Glass and certain types of pop music do not show beneficial changes in spatial task performance or epileptiform activity. On the other hand, another piece by Mozart, his Piano Concerto No. 23 in A major, K488 has also been found to be associated with improved spatial task performance.34

**Patient groups**

Gold and colleagues have published a systematic review and meta-analysis of the benefits of music therapy for patients with psychiatric disorder. From an initial 166 potentially relevant studies for any mental disorder, they selected 15 studies fulfilling their criteria, which included having a prospective group design. Their findings and conclusions were as follows:15

Results showed that music therapy, when added to standard care, has strong and significant effects on global state, general symptoms, negative symptoms, depression, anxiety, functioning, and musical engagement. Significant dose–effect relationships were identified for general, negative, and depressive symptoms, as well as functioning, with explained variance ranging from 73% to 78%. Small effect sizes for these outcomes are achieved after 3 to 10, large effects after 16 to 51 sessions. The findings suggest that music therapy is an effective treatment which helps people with psychotic and non–psychotic severe mental disorders to improve global state, symptoms, and functioning. Slight improvements can be seen with a few therapy sessions, but longer courses or more frequent sessions are needed to achieve more substantial benefits.

The dose–response relationship of music therapy for general symptoms is shown in Figure 66.6, while the dose–response relationships of music therapy for negative symptoms, depressive symptoms and functioning are shown in Figures 66.7, 66.8 and 66.9, respectively.
Figure 66.6 Dose–effect relationship of music therapy for general symptoms. Each individual study is plotted at the position indicated by the number of sessions provided and the effect size found in that study. The box symbol for each study is filled white if the majority of participants had a psychotic disorder, and black otherwise. The size of the box represents each study’s weight in the analysis. The vertical line added to each individual study indicates the 95% confidence interval (CI) of the observed effect; the line type (solid, dashed, dotted) indicates the strength of the study’s design. Finally, the dashed regression line shows the result of a mixed-effects meta-regression analysis, indicating the relationship between the number of sessions provided and the predicted effect size. The 95% CI of the regression is shown by the dotted lines around the regression line.

### KEY POINTS

- Art therapy and music therapy are two of the arts therapies.
- Types of art therapy include art therapy, art psychotherapy and analytical art psychotherapy.
- Five stages of separation differentiation have been found to be common in art therapy: identification, familiarization, acknowledgement, assimilation and disposal.
- Art therapy may be helpful to patients with depression, somatic symptoms, cancer and cerebral palsy.
- The inter-rater reliability between art therapists is relatively poor.
- Listening to music is associated with cardiovascular, respiratory, cerebral blood flow, emotional and cognitive changes.
- Listening to certain works by Mozart may be associated with improvement in spatial tasks.
- Music therapy, when added to standard care, has strong and significant effects on global state, general symptoms, negative symptoms, depression, anxiety, functioning and musical engagement; significant dose–effect relationships occur in general, negative and depressive symptoms, and in functioning.
- Other psychotherapies that can be used on an individual basis include Gestalt therapy, narrative therapy, person-centred therapy and personal construct therapy.

Therapeutic communities

Kingsley Norton and Fiona Warren

DEFINITIONS

Therapeutic communities (TCs) developed before the psychopharmacological advances of the 1950s and long before the arrival of care in the wider community. Initially, they had represented a psychotherapeutic and sociotherapeutic response to the needs of the huge number of psychosocial casualties generated by the First World War. At that time, TCs were experimental treatments, innovated separately in different institutions. Working at Northfield Hospital, South Birmingham, Tom Main coined the term ‘therapeutic community’. For him, the TC was

... an attempt to use a hospital not as an organization run by doctors for their greater technical efficiency, but as a community with the immediate aim of full participation of all its members in its daily life and the eventual aim of the re-socialization of the neurotic individual for life in ordinary society.

Main further defined the TC as ‘a spontaneous and emotionally structured organisation rather than one which is medically dictated’. He stresses how important it is that

... the daily life of the TC [is] related to real tasks, i.e. those which are truly relevant to the needs and aspirations of the small society of the hospital, together with the larger society in which it is set.

For him, it is crucial that patients are viewed as having sincere adult roles to play and (are) free to reach for responsibilities and opinions concerning the community of which they are a part. Main recognizes the central importance of the interaction between patients and the staff – specifically, how the expectations and behaviour of staff exert a profound effect, for good or ill, on patients’ treatment outcomes.

TC ideas and practices were extensively developed and deployed, in the UK and North America, by another pioneer, Dr Maxwell Jones. Indeed, the latter was credited by Main with influencing many professionals via his voluminous writings. Working in Surrey, in the UK, at a unit within Belmont Hospital (later named Henderson Hospital), Jones structured the therapeutic day in his TC, giving the community meeting a pre-eminent position and using this forum as the place to sort out the most important and pressing clinical issues that arose. The patients occupied positions of unusual power, for example as enacted through their ‘chairing’ of some crucial meetings, including the community meeting. When his TC was evaluated over a period of years by a visiting team of social anthropologists, the final report of their research appeared in the form of a book entitled The Community as Doctor. The collective, therapeutic essence of the TC is captured by this title.

Subsequently, democratic TCs have been developed, especially along the lines of Henderson Hospital, in many psychiatric subspecialties, including forensic, and in different parts of the world. Therefore, different patient groups and disorders have been treated using Jones’ TC approach. In the UK, its application has been deployed most conspicuously in relation to personality disorder (PD).

There is a promising and growing evidence base to support the application of this approach to such patients (see below), and recent service developments in the National Health Service (NHS) have seen a resurgence of TCs in community settings. (In this chapter, we concentrate on the ‘democratic’ TC, as defined by Main and as pioneered in the 1940s, 1950s and beyond by both Main and Jones. We are not concerned here with ‘concept’ TCs, which have grown up in relation to the treatment of substance misuse, especially in the USA. See also Kennard for a discussion of similarities and differences between these two approaches.)

PRINCIPLES OF TREATMENT

The magnitude of the organizational change in the style and extent of patient–staff collaboration within a ward or unit, which is implied by the TC ideology, requires a radical rethinking of the operation of the multidisciplinary staff team. Importantly, there is a de-emphasis of the staff’s technical expertise and the recognition that patients are also ‘expert’ in the knowledge and experience of their own conditions and disorders. The effect is to flatten the traditional staff hierarchies and to blur the roles that previously were the sole preserve of a particular profession. In practice, this means that nurses and some relatively untrained
professionals take on tasks that previously were carried out by more highly trained, including medical, staff.

The democratic TC is exquisitely patient-centred, requiring patients’ active involvement in their own and others’ treatment, via the preponderance of group-based activities. The therapeutic energy of all who inhabit the environment is needed to carry out its essential activities and functions. In the process, the patients’ emotional and interpersonal difficulties, which they might struggle to put into words, are behaviourally manifest, hence potentially easier to recognize and understand. Maladaptive behaviour can be challenged and, with support and encouragement from their peers, patients can learn from one another (as well as from staff) to develop insights and be helped to experiment with other, more effective, more socially acceptable means of coping and expressing themselves.

What appears to make an effective TC is not so much its ‘structure’ – for example, the presence of community meetings – but the nature of its ‘culture’. Main referred to the particular requirement for a TC to provide ‘a culture of enquiry ... into personal and interpersonal and intersystem problems and a study of impulses, defences, and relations as these are expressed and arranged socially’. This phrase, reflecting Main’s psychoanalytical and systemic orientation, articulates a concern about the TC as a whole and the way in which its constituent human parts need to interrelate. Therefore, an aspiring TC needs to be able to communicate, to disagree (when necessary) and to reach majority decisions with a minimum of hierarchical domination and a maximum of democracy, based on mutual respect for others’ viewpoints. Such a culture supports the capacity of a TC subsystem (e.g. patients, as a group) to question directives from its super system (e.g. the staff group). The latter is required to listen to and respond, other than defensively and self-protectively. In this way, an enquiring culture drives the structure, leading to: authentic dialogue among and between staff and patients; conflict identification, based on the empowerment of patients; and collaborative (democratic) management of problematic personal, interpersonal and social situations. This maintains the ‘therapeutic’ nature of the TC enterprise.

It is within the forum of the community meeting that it is plainest to observe the patient subsystem interacting with that of the staff. The nature and quality of this patient–staff relationship are important signifiers of the health of the TC. A healthy TC’s patient subsystem is appropriately empowered, and its staff subsystem is able to relinquish, at least temporarily and thoughtfully, some of the authority invested in it. Internal organization and operation are such as to make use of a range of therapeutic approaches and disciplines, each with its own processes and techniques (e.g. group analytical psychotherapy, art therapy, psychodrama). The TC’s hallmark is its successful blending of such individual ingredients, thereby producing a whole that is greater than the sum of its parts.

**INDICATIONS FOR REFERRAL AND PREPARATION**

TCs have been set up, utilized and, to differing extents, evaluated in disparate settings and with respect to different patient groups, including:

- children and adolescents;
- people with severe and enduring mental illness;
- adults with acute mental health problems;
- people with emerging or established personality disorders;
- offenders;
- people with learning difficulties.

Making judgements about which patients to refer, and when to refer, to TC treatment is dependent on many factors. The referring clinician needs not only to recognize patients who might benefit but also to know about what the treatment entails, so as to prepare the patient to have realistic expectations. As many TCs operate on an in-patient basis, they represent a costly resource. Therefore, most patients who are considered for such specialist treatment will have been marked by failure to improve with less intensive and less costly treatment alternatives. Indeed, such ‘failures’ might have exacerbated their presenting difficulties and worsened their prognosis. Engaging the patient, while avoiding the raising of falsely high expectations, represents a crucial clinical task. Although insufficient in itself, a reasonably robust therapeutic alliance is needed to support the necessary discussion of the relevant treatments available, enabling the patient to enter the process of referral on an informed basis, with realistic expectations and, optimally, appropriate motivation. As with imparting information to any patient about their possible treatment, much will depend upon the particulars of the case, especially what prior experience and knowledge the patient may already have. Below, we indicate some of the main points of which patients should be made aware in discussions about referral to a TC for treatment. Clearly the language used will need to be tailored to the requirements of the individual patient.

**Delegation of traditional power and authority**

In a TC, the patients may be struck initially by a difference in the way that patients and staff in a TC relate to each other. This is because the staff offer up to the patients some of the power and authority that are traditionally invested in them by virtue of the role as staff member. However, the relinquishing of authority by staff is not ‘all or nothing’. The type and amount of ‘power’ that is delegated to the patients will vary from TC to TC and within the same TC. In a forensic setting, the range of tasks safely delegated will be narrower than in a non-forensic setting. The degree of the delegation of power to patients will be revealed in the extent to which patients may:
play a role in selecting new patients for the TC;
• provide some of the response to untoward events that take place in the TC;
• play a part in interpreting rule violation and its consequences;
• exert an influence on continuing memberships of the TC of those who repeatedly break the TC’s rules.

Patients need to be aware of this delegated responsibility, not least since it may contradict their previous experiences of being in therapy. This delegation of power contributes to the potential for the patient to have a different experience of themselves and others, including healthcare staff.

Staff–patient collaboration

Many patients (especially patients with antisocial PD) have had unsatisfying interactions or relationships with staff, and their trust in professionals may be low. However, this is not necessarily the case, and the referral to a TC might itself be a marker that the relationship with the referring professional is positive. What should be transmitted to the prospective TC patient, however, is that they should expect an opportunity for genuine empowerment that they might not have encountered previously. There is an expectation, within the TC, that there will be active involvement and a working together with staff, if not from the start, as they become familiar with the treatment model.

Collaboration is thus a potential to be realized, which can only come about as a result of the patient’s experience of the TC – that is, via a process that includes mistrusting and testing out (see below).

Rights and responsibilities

Enjoying the privilege of power-sharing comes at a price. There is an expectation on all TC members that their membership is ‘active’. This means taking part both in the formal therapy programme, including adhering to the rules (see below), and in the more mundane aspects of the TC’s everyday life, including necessary ‘domestic’ functions, such as washing up, cleaning, ordering and storing food, and creating rota for escort duties and other support functions. Patients need to engage in therapy sessions (psychotherapy) and also become part of the daily social life of the TC (sociotherapy) in being both a recipient and a provider of therapy. This requirement for them to be part of the whole treatment programme represents a significant challenge. However, there is an expectation that this occurs only gradually, as part of the therapeutic process, and there is much support from their peers, who are struggling, like them, to achieve this.

Rules and rule-breaking

Just as in wider society, from which patients are drawn and to which they will return post-discharge, there are rules in the TC. These mirror (in most instances of open, as opposed to secure, TCs), the mores and laws of the relevant society. Therefore, violence to others and property is proscribed, as is the taking of illicit substances. Other than this, there may be rules governing aspects that ordinarily do not obtain in wider, free society – for example, the proscribing of alcohol (at least the imbibing of it on the TC premises) or the avoidance of sexual contact between patients. What is crucial for a given TC is that its rules are relevant to the TC’s membership, neither set too high and outlawing behaviour that cannot voluntarily be curbed, nor set too low, requiring no thought or effort to comply. The optimum is that the patients are under a tolerable degree of stress or anxiety, which enables them also, over time, to reflect on their attitude to rules and authentic belonging to a group. Many habitual rule-breakers exhibit a hypocritical attitude to rules, not relishing others to behave like themselves.

Interaction, exploration and experimentation

During a successful stay in a TC, it is likely that patients will experience and recognize different phases and processes of the therapy, which can be summarized as interaction, exploration and experimentation. In practice, it is difficult for patients to avoid the first – interaction – although some may attempt to do so. There will be a full programme of activities, most of which are group-based, and absences are questioned – part of the culture of enquiry (see above). Exploration relates to this latter aspect, for example to understand the possible meaning of a patient’s non-attendance at a therapy session or failure to undertake a practical task, such as doing their share of the communal washing up rota. In this way, the patient’s social behaviour (as well as what they might talk about during the therapy sessions) is considered and commented on by their immediate peers and the wider TC, including staff. This provides food for thought; hence, there is scope for the patient to try out new ways of thinking and behaving. Such ‘experimentation’ can take many forms, and failure is often tolerated by the TC membership, provided that the collective perception is that the member’s attempt to reflect and change or adapt is sincere. A patient’s successful stay will be marked by involvement in all these phases and processes, including the carrying out of ‘failed’ experiments. All phases and processes need to be encountered, although the proportion varies according to the patient’s requirements. Avoidant patients require more peer support and pressure to interact and experiment, while those with impulse-control problems benefit from peer group reactions and pressure to abstain from their habitual actions and to reflect.

Transition, discharge and aftercare

Leaving a TC can be problematic; therefore, attention is focused on relevant attachment and separation issues from the start of the patient’s stay. Those who complete their
stay – by no means all who start out – will probably find themselves having become attached to it. For some, it is the first time they will have felt ‘at home’. As a consequence, dealing with the leaving process is painful and potentially problematic for all concerned – those remaining as well as those actually departing. TCs vary in how they approach and deal with this crucial phase of the therapeutic journey, although each emphasizes its importance. In many instances, there is an acknowledgement, due to the extent and complexity of the patient’s presenting problems, that the patient has not been ‘cured’ but has made an important start on the road to recovery. Relevant gains often require consolidation, from further out-patient work.

TREATMENT OUTCOME

Studies of the effectiveness of therapeutic community treatment for personality disorder have addressed the key problem domains, from symptomatic change to re-offending, and included studies of cost. Lees and colleagues subjected to meta-analysis 29 studies of TCs, 8 of which were randomized controlled trials (RCTs). They found a summary log odds ratio of −0.512 (95% confidence interval (CI) −0.598 to −0.426), a strong treatment effect. These studies included a range of outcome measures and included both concept and democratic TCs.

In the first study of the effectiveness of the Henderson Hospital therapeutic community, Rapoport’s team of researchers classified 64 patients 1 year after their discharge, judging 41 per cent to be ‘improved’ compared with pretreatment. Subsequent, more rigorous studies have found similar proportions of improvement. Eight months following discharge, 55 per cent of patients improved reliably and 32 per cent improved clinically significantly on the overall measure of neurotic symptoms (Global Severity Index, GSI) of the Symptom Checklist 90 (SCL-90). Over 40 per cent of clients who under democratic therapeutic community (DTC) treatment versus 18 per cent of those who were not admitted had improved clinically significantly in symptoms of borderline personality disorder (BPD). In a comparison study with allocation to treatment group on geographical grounds, 80 per cent of clients at the Cassel Hospital had improved clinically significantly on the GSI at around 2 years post-discharge. Importantly, these studies also reported rates of deterioration, which were very small.

Personality-disordered clients are high users of a range of services, from medical through psychiatric to social and criminal justice, and both service usage itself and costs of this have been studied. At Henderson Hospital, early studies of re-admission and reconviction found that at 3 years’ post-treatment follow-up, 71 per cent of those patients who stayed in treatment for 9 months or more were neither reconvicted nor re-admitted (v. 23% in the not-admitted group, as above); 65 per cent of them remained free of reconvictions and re-admissions at 5 years post-treatment (v. 19% in the not-admitted group). An early study of cost-offset showed that post-treatment costs could be as little as 10 per cent of pretreatment costs and offsetting the investment in treatment in just over 2 years. Subsequent studies support cost-effectiveness against baseline costs and against general psychiatric service input.

Although there is a demonstrable positive relationship between length of stay in a residential therapeutic community and improvement in symptomatology over the first 3 months, and in symptoms and service usage at 1 year, 3 years and 5 years post-discharge, there is some evidence that a shorter period of inpatient treatment, with outpatient follow-up (6 months + 6 months) may be more effective than 12 months of in-patient treatment alone: a significantly larger proportion of patients in the two-stage (39%) than the one-stage (18%) treatment offered at the Cassel Hospital were reliably improved. Research findings suggest that continued improvement may continue beyond the end of treatment.

Most of the research on TCs is effectiveness rather than efficacy research – the majority of studies have been naturalistic studies rather than RCTs – although type 1 evidence is also available, suggesting the effectiveness of the TC approach to treating PD. Methodological sophistication has increased as the field of study has developed, and as the rhetoric that funding for services be tied more closely to evidence of effectiveness has been stated more widely. Despite controversy around the appropriateness of the RCT research paradigm for evaluation of a socially complex intervention such as a TC, some have been evaluated using RCTs. The principles of good effectiveness research require that robust assessment measures are used to evaluate change in factors that the treatment is designed to change and that these changes are compared with an appropriate alternative condition. Furthermore, it is desirable that assessment is carried out at a suitable point in time after the end of treatment. Some guidelines for evaluating treatment for personality disorders exist, and reviews suggest areas in which the evidence base needs to be improved. Nonetheless, thus far, the evidence suggests that TCs are an effective approach to reducing both PD features and general symptomatological distress, service usage and costs.

SUMMARY

The development of newer approaches no doubt modified the patient groups who are referred to TCs. However, in spite of having existed in the UK for more than 60 years, TCs remain unusual therapeutic institutions and there remains a place for democratic TCs within the overall treatment armoury. Although there is an evidence base for democratic TCs, part of the preparation and processing of referrals needs to include an assessment of ‘fit’. The referring clinician needs not only to undertake a thorough
(diagnostic and psychodynamic) assessment of the patient and his or her motivation and treatment needs, but also to impart knowledge of the particular TC to the patient. Without this, there is potentially a mismatch between the service user’s capacities and expectations and the service provided, which can be psychologically damaging. It is important that those patients referred understand the nature of the TC’s treatment process, in which they would take part, including why they might need to be assessed by the TC before being accepted. Rejection can be traumatic, and this needs to be borne in mind by the referring clinician, being taken into account as part of the preparation of the patient for referral, so as to minimize the risk of iatrogenic harm. Where the fit is good, the therapeutic impact on outcome has been shown to be significantly beneficial.

KEY POINTS

- TCs represent authentic patient-centred psychiatric services.
- TCs have for a long time viewed their patients as ‘expert’ in their own condition, a view increasingly recognized as important by health systems.
- TCs embody the ethos of patient empowerment, i.e. their involvement in the running of some aspects of hospital organization traditionally the province only of staff.
- TCs function effectively because they are a microcosm of society (in which dysfunction is revealed, leading to insight and experimentation with new coping strategies), and hence what is learned can generalize to life outside.
- TCs are set up to maximize (especially peer group) feedback to the patients so that the effects of their actions or inaction are conveyed clearly and quickly, facilitating insight and learning from such a responsive environment.
- TCs present their patients with the views of other people that challenge their own, even though the ‘new’ relationships with others are initially mistrusted and therefore (sometimes aggressively) tested for their sincerity and strength.
- TCs require clearly stated and robustly and reliably implemented rules that tolerate degrees of deviance, destructiveness and distress but also set and fairly apply strict limits.
- TCs are relatively long-term treatments, usually more than 6 months, and, although applied to a range of different client groups, cater mostly for patients with personality disorder.
- Preparation for the selection, and also for the joining, processes of the TC, is crucially important as is an assessment of the patient’s need for suitable aftercare.
- TCs have a body of research evidence about effectiveness, including health economic benefits.

REFERENCES

INTRODUCTION

Psychological therapy has been defined as ‘an interpersonal process designed to bring about modifications of feelings, cognitions, attitudes and behavior which have proved troublesome to the person who is seeking help from a trained professional’. The psychological therapies are a very diverse set of activities, now including at least seven major classes of approach: (i) psychodynamic psychotherapy, (ii) behavioural and cognitive-behavioural therapy (CBT), (iii) interpersonal psychotherapy, (iv) strategic or systemic psychotherapies, (v) supportive and experiential therapies, (vi) group therapies and (vii) counselling. Each approach provides a model of human behaviour and heuristic foci for interventions.

DETERMINING THE EFFICACY OF TREATMENTS

All psychotherapeutic models provide aetiological formulations, but the evidence base for these is limited. Ideally, as with other medical treatments, the mechanism of therapeutic change entailed in a clinical approach should be understood and tested while simultaneously monitoring the effectiveness of the intervention. The best way to compare these treatments is by randomized controlled trials (RCTs), where variables likely to influence outcome, such as therapist experience and treatment length, are controlled. Studies also increasingly aim to ensure that treatments are carried out in conformity with their theoretical description, for example ensuring that CBT does not include psychodynamic elements and vice versa. To this end, many treatments have been manualized, with the techniques entailed by the therapy pragmatically delineated. Manualization enables reviewers to check whether a treatment was actually delivered in a manner consistent with that advocated by its proponents. There are some limitations to this approach. For example, differences between the groups may occur despite randomization because of small sample sizes. Although the presence of a no-treatment control group would provide an ideal benchmark, it is not ethically viable to withhold treatment in cases other than the very short-term psychotherapies. An increasing number of studies have compared psychosocial interventions with medication or have examined the addition of psychosocial interventions to pharmacological treatment. The criterion used most often to establish the evidence base of a therapeutic approach for a particular condition is the replication of a good-quality RCT with an independent group of investigators testing the same manualized treatment with the same diagnostic group.

Since Hans Eysenck expressed doubts about the overall efficacy of psychotherapy, there have been several meta-analyses of the psychotherapy research literature, as well as narrative reviews, which have examined hundreds of studies measuring the outcome of many forms of therapy. Most studies report a considerable effect size (0.50–0.85) when treatment is contrasted with no treatment, but in most studies other than where a medication arm is used psychotherapy benefits from a placebo effect. The major meta-analyses of therapy outcome have been drawn from rigorously controlled studies (random assignment, careful specification of patient population, use of a treatment manual, raters naive to conditions, statistical power adequate to examine the null hypothesis, and replication by independent investigators).

There is a generally accepted hierarchy of evidence that reflects the degree of certainty with which we can causally attribute observed changes to the treatment under scrutiny. At the top of the hierarchy are RCTs and their aggregation in systematic reviews and meta-analyses. At the second level are controlled trials without randomization and experimental single case designs. At the third level are cohort studies, where groups of patients are allocated to treatments. Ranked below these are case–control studies, where patients with similar outcomes are grouped together and the treatment to which they were exposed is studied retrospectively. At the base of the hierarchy are comparisons across historical times or geographical places, with or without an intervention, alongside the accumulation of professional experience. Finally come descriptive studies.

Although RCTs are at the top of this hierarchy, which is constructed in terms of the clarity of causal inference, RCTs are not without major limitations in the evaluation of
psychological therapies. To be proof against chance findings, RCTs require large samples (often over 100 patients per treatment arm in the case of psychotherapies). The comparison of treated and control groups yields the results of the trial. In drug trials the control is uniform (the placebo pill), but in the case of psychological therapies it can be quite variable. Treatment as usual (TAU) in North America is very different from that in Europe or the UK, and this can yield very different results in RCTs of the same treatment conducted in different places, even if that treatment is well manualized. In trials involving two active treatments, assignment to treatment arms is complicated, as patients are likely to have substantial preferences regarding particular styles of psychotherapeutic interventions. (Interventions can, for example, vary in the extent to which they are oriented towards reflection or how directive they are.)

The sheer number of RCTs of psychological therapies presents a challenge for aggregating evidence. Meta-analysis, the arithmetic aggregation of clinical trials, actually entered the medical field via the psychotherapies. The two most commonly used methods of aggregation are averaging relative risk (the relative proportion of individuals who no longer meet diagnostic criteria) and the standardized mean difference (the difference between treatment and control group means at the end of treatment, divided by the standard deviation of the control group). Both of these statistics can be made more readily applicable by translating them into percentiles indicating the likelihood that a treated client is better off than a control patient or the degree to which the treated client is benefited. These effect sizes are stated with 95 per cent confidence intervals (CI). If the confidence interval does not include a null or negative effect, then the results suggest that the treatment is effective. The level of efficacy is indicated by the size of the coefficient, with 0.2 being considered small, 0.5 medium and 0.8 large. Such data aggregation is clearly desirable but, inevitably, there are complications. Aggregation is possible only across a homogeneous set of studies – that is, studies that address the same research question with the same kind of treatment and the same kind of client group, using comparable measures. The sample of studies may not be representative. There appears to be a bias against publishing negative findings. The effect sizes associated with published studies are significantly larger than those of unpublished investigations, both in psychotherapy and in pharmacotherapy. The allegiance of the researcher is also quite a powerful predictor of outcome.

Measuring the outcome of psychotherapy of course depends on finding an appropriate and generally agreed metric for outcome. There can be no doubt that the metrics we mostly use in evaluating psychological therapy are, to a large extent, arbitrary. There are no absolute scales even to measure depression, let alone more subtle constructs such as wellbeing or marital satisfaction. Most measures are ‘reactive’. In other words, they interact with the treatment modality, such as measuring the impact of CBT in terms of changes in depressogenic cognitions, which is the primary focus of that type of intervention. Because of this, many have called for the use of biomarkers, such as haemodynamic responses to specific types of stimuli in functional magnetic resonance imaging (fMRI) studies, to assess the effectiveness of psychological therapies.

There are a range of other issues and problems associated with the evaluation of psychotherapies. The range of patients who are willing to participate in an RCT may not be representative, either in terms of ethnicity or in terms of severity or complexity. Follow-ups are rarely long enough to assess accurately whether the impact of the treatment will be lasting. Often authors report significant results on one measure but find no significance on another, and there is no widely accepted method for integrating such disparate observations. Treatments are usually considered in relation to particular disorders, but in reality patients rarely come with a single disorder and in clinical work co-morbidity is the routine rather than the exception. Some disorders are far better researched than others, and some therapies lend themselves more readily to manualization and randomization. The economic impacts of psychotherapies are of enormous concern, but the methodology for calculating economic impact is as yet quite limited.

These limitations have to be borne in mind when treatment guidelines such as those developed by the National Institute for Health and Clinical Excellence (NICE) are implemented. They rely on evidence from controlled studies, thus restricting the range of approaches, are conducted in a clinical context that does not reflect real life, deliberately attempt partially to eliminate factors such as variation in therapist quality from the assessment, and are no better able to answer complex questions concerning outcome than are cohort or case–control studies. Recognizing this, many guidelines development groups take quite a sophisticated approach to addressing the limitations of research-based evidence by adding qualitative methodology to the quantitative. Another difficulty is that guidelines often recommend psychological therapies, but therapists with appropriate specific competencies may not be available. NICE guidelines have tended to recommend CBT as an efficacious treatment for a range of mental health problems, but it should be recognized that CBT is a very broad category and effective practitioners require training to address a number of specific diagnostic conditions. Taking into account these reservations, treatment guidelines have been helpful in improving the quality of care across a number of diagnostic entities.

**A GLIMPSE OF THE EVIDENCE BASE**

Space does not permit a review of the empirical status of psychotherapy for all mental disorders, but for a comprehensive review see Roth and Fonagy. To illustrate the
nature of the evidence base, we will consider only briefly the two most prevalent axis I disorders, anxiety and depression, and the most commonly investigated axis II condition, borderline personality disorder (BPD).

The literature on RCTs clearly identifies behavioural and cognitive-behavioural treatments as highly efficacious in the treatment of anxiety disorders. The best effect sizes have been reported for cognitive therapy for panic disorder \( (d = 2.9), \)14,15 cognitive therapy for post-traumatic stress disorders \( (d = 1.3–2.2), \)16,17 cognitive therapy for social phobia \( (d = 2.6), \)18,19 CBT for generalized anxiety disorder \( (d = 1.7), \)20,21 exposure and response prevention for obsessive-compulsive disorder \( (d = 1.6), \)22,23 and exposure for specific phobias \( (d = 2.7). \)24,25 Many of these studies used unstructured supportive treatment as an attention placebo control.

There are a few RCTs of psychodynamic therapies for anxiety,26 but there are some notable trials for depression.27 The National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program is perhaps the most widely cited research programme and set a standard against which other studies could be judged. In this study, patients were randomized to receive one of four interventions: cognitive-behavioural psychotherapy, interpersonal psychotherapy (IPT), imipramine plus clinical management (IMI-CM), or placebo plus clinical management (PLA-CM). Clinical management consisted of a weekly meeting of 20–30 min to discuss medication, side effects and the patient’s clinical status. In addition, and where necessary, support, encouragement and direct advice were also offered. On this basis, it is worth noting that both medication conditions contained psychotherapeutic elements. A total of 250 patients, all moderately to severely depressed, were selected for the trial at three research sites; 239 patients actually entered the trial. Patients were assessed before treatment and at 4, 8, 12 and 16 weeks and then followed up at 6, 12 and 18 months. Post-therapy, the general direction of results was similar on all measures and in all samples,28 with patients who received IMI-CM having the lowest symptomatic scores, those who received PLA-CM the most symptomatic, and the psychotherapies in between and usually closer to IMI-CM. The magnitude of these differences was not large, and pair-wise comparison of treatment conditions revealed no differences between therapies or between therapies and IMI-CM. Patients who received IMI-CM and IPT were significantly more likely to recover than those who had received PLA-CM; a trend toward significance was apparent in the other two patient samples. There were, however, no significant differences between therapies or between therapies and IMI-CM in any patient sample. The lack of significant differences seems attributable to the good performance of PLA-CM (e.g. 62% achieved clinically significant change using the Beck Depression Inventory (BDI) as a measure). For patients with lower levels of depression, PLA-CM (which could be considered a ‘minimal support’ intervention) was as effective as the active thera-
pies. Relapse was defined as the presence of at least 2 weeks of major depressive disorder (MDD)-level symptoms over the 18-month follow-up period. Only 20 per cent of the original sample and 24 per cent of the patients with follow-up data met the criteria for recovery with no relapse. Of those entering therapies, 24 per cent of patients receiving CBT remained recovered without relapse at 18 months, compared with 23 per cent for IPT, 16 per cent for IMI-CM and 16 per cent for PLA-CM. The findings indicate that few patients recover and remain well with 16 weeks of treatment, and a clear conclusion from this study is that interventions of this length are not sufficient to maintain functioning in the majority of patients.

The studies with the most stringent criteria of methodological rigour indicate the efficacy of interpersonal psychotherapy and CBT. In the single trial that contrasted dynamic-interpersonal therapy and CBT, the two modes of treatment were equivalent in their efficacy. This broad equivalence between outcomes from bona fide therapies is an important finding, suggesting as it does that depression may be responsive to a range of psychotherapeutic techniques. Many large-scale careful studies, such as the Helsinki study, found no difference between therapies with different orientations (e.g. no difference was found between psychodynamic psychotherapy and solution-focused psychotherapy, a systemic psychotherapery).28 Overall, the generally observed effect size for the psychodynamic treatment for anxiety is hard to estimate, and for depression the outcomes are comparable to CBT, although both types of therapy have only small to medium effects in the long term.29 In no instance has psychodynamic therapy been shown to be superior to CBT. Most studies compare CBT with drug treatment, and the average effect size across 12 studies \( (n = 1200) \) for comparisons with drug treatment indicates that pharmacotherapy is just as effective (effect size = 0.01; 95% CI −0.1, 0.13). In a meta-analysis of short-term psychodynamic psychotherapy, Abbass and colleagues analysed 23 studies of 1431 randomized patients with common mental disorders.30 These studies covered a range of patient groups, including somatic, anxiety and depressive patients, and patients with social adjustment problems. Moderate effect sizes were obtained in most comparisons, indicating significantly greater improvement in the treatment versus the control groups, which were generally maintained in medium- and long-term follow-up. The findings indicated that short-term dynamic psychotherapy showed modest to moderate gains for a variety of patients, which were mostly sustained. However, there was substantial heterogeneity and variability in treatment delivery and treatment quality, indicating the need for larger studies of higher quality and with specific diagnoses.

For most axis I conditions, various implementations of CBT have the most RCTs, and in general relatively good results are reported. No other therapy has been tested as frequently in trials, but of course we need to remember that the absence of evidence does not imply evidence of the
absence of effectiveness. RCTs for personality disorder are less unequivocal in favouring CBT. Some studies of BPD show CBT to be marginal in effectiveness, and some even reported slight iatrogenic effects.

Dialectical behavioural therapy (DBT), an outgrowth of CBT that was tailored for BPD, was shown to be highly efficacious in treating suicidality and self-harm in borderline women, but not in treating depression. By contrast, a somewhat longer psychodynamic treatment yielded similar effect sizes for para-suicide but also showed improvement for depression and anxiety. Head-to-head comparisons have yielded equivocal results. One 3-year treatment trial apparently favoured a version of cognitive therapy over psychodynamic treatment, but another, better controlled trial showed little difference between DBT, psychodynamic therapy and supportive psychotherapy.

RCTs are the gold standard in evidence-based medicine, but the results of these trials are often hard to apply in the context of a medical practice. A major reason for this is that individuals participating in clinical trials will not always resemble the patients that a clinician would see in psychotherapy. It is reasonably clear that in general, ‘research therapy’ appears more effective than everyday clinical practice. Possible reasons for this include methodological issues, among them the use of focused and structured manualized treatments, careful attention to ensure therapist adherence to protocol, recruitment of participants directly rather than through clinical services, and greater exclusion rates.

COMMON FACTORS IN PSYCHOTHERAPY: SPECIFIC AND NON-SPECIFIC EFFECTS

Psychological treatments work, but by what mechanism? Does it make any difference which method or which theory is the basis for treatment? This issue can be addressed only by conducting comparative trials, in which different forms of treatment are studied head to head.

A number of such studies have been published comparing a wide range of therapies, including psychodynamic, behavioural, cognitive, interpersonal and client-centred methods. The results are surprisingly consistent: with notable exceptions (e.g. the superiority of CBT over interpersonal therapy for the treatment of obsessive-compulsive disorder and other anxiety disorders), research has failed to show that any one method is more potent than the others. For example, an ambitious comparative trial of transference-focused psychotherapy, DBT and supportive psychotherapy for BPD showed little difference between these three forms of treatment after 1 year of therapy. Over recent decades, psychotherapy research has demonstrated repeatedly that a substantial proportion of the variability in therapeutic outcomes across trials is not explained well by differences between formally defined therapeutic procedures, differences between client groups, or (less well examined) the interaction between these two factors. In addition, research has found it hard to show strong correlations between outcome and changes at the level of the mechanism that a particular therapy has postulated as its primary target. For example, in a study of CBT, the extent of focus on ‘parental issues’ turned out to be positively associated with outcome. In a study of psychodynamic psychotherapy process and outcome, Piper and colleagues found that, in sicker patients with whom the therapeutic alliance is shaky, the use of transference interpretations to deal with problems between therapist and patient made the outcome worse, not better. In another study, a negative association has been reported between the number of transference interpretations and therapy outcome, indicating that the overuse of this technique, frequently regarded by clinicians as essential to therapeutic success, may even be iatrogenic. In fact, it is not so much the differences between procedures that indicate the most effective ingredients of psychological treatments, but the similarities. For, if each therapy is successful in its own way, and if each therapy shares common (or ‘non-specific’) factors with all others, then success depends on these non-specific factors, which are so-called because we do not know how to specify them.

A methodological review of child psychotherapy treatment studies between 1995 and 2004 found that recent research did not give adequate attention to non-specific therapeutic factors, including the effects of attention, positive regard and therapeutic alliance, as well as the effects of treatment dose, intensity, and actual processes mediating therapeutic change. In an attempt to identify which interventions lead to progress, Orlinksy and colleagues conducted process research on over 50 different variables describing the process of psychotherapy in relation to its outcome. They concluded that ‘non-specific’ factors are the primary reason behind successful treatment. As a result, they proposed a ‘generic model’ of psychotherapy, which includes the factors common to all methods, from psychoanalysis to behaviour therapy. It is possible that the common factor uniting therapies is simply that therapists help their patients feel hopeful at a time when they are hopeless or demoralized, and that specific theories have little bearing on this matter. Data showing that a good relationship with a therapist is a crucial factor in the outcome of treatment might support this argument. The majority of studies in this area find, unsurprisingly, that therapeutic alliance is impacted by the patient’s attachment style and quality of object relations, although studies also implicate the therapist’s attachment security. It is certainly plausible to argue that those with a secure attachment style approach the therapeutic relationship with greater openness and optimism, which might account for the particularly strong associations found in psychotherapy investigations between pretreatment expectancies and the subsequently observed quality of the alliance. The
paradox is that controlled trials demonstrate repeatedly that
the relationship, if not informed by theoretically coherent
content, is actually of little therapeutic value.\textsuperscript{6,64} It also
appears to be the case that the impact of attachment style
may be strongest at the initial meeting with the therapist,
after which perhaps more subtle processes (arguably still
related to attachment) come to determine the alliance.\textsuperscript{65}
Thus, although all agree that the patient’s relationship with
the therapist is a key catalyst in psychodynamic treatment,
the nature of therapeutic benefit that patients draw from
this new relationship seems yet to be resolved.

**THERAPIST FACTORS IN THERAPY OUTCOME**

Wampold points out that the evidence for common factors
highlights the importance of the therapist and his or her
skill.\textsuperscript{4} The key designs and methods of psychotherapy
research peculiarly owe their origins to the common statisti
cal roots that they share with trial methodology in farm-
ing, education and medicine.\textsuperscript{66} This is understandable, but it
is curious that most studies of interventions have tested the
effectiveness of therapists without paying very much atten-
tion to the role of the therapist.

In Kim and colleagues’ analysis of the NIMH Treatment
of Depression Collaborative Research Project (TDCRP)
dataset, 5–10 per cent of the variance in outcomes was
shown to be associated with therapists.\textsuperscript{66} In more naturalis
tic studies, the effects tend to be larger. For example,
Okishi and colleagues examined variations in patient out-
comes for 91 therapists treating nearly 2000 patients.\textsuperscript{67} The
therapists whose patients showed most improvement had
an average change rate 10 times greater than the sample’s
mean rate. This is consistent with other studies using a
growth curve approach, where as much as 17 per cent of
the variance in rates of patient improvement has appeared
to be attributable to the therapist.\textsuperscript{68} Very large studies, with
datasets of over 5000 patients, consistently report large
effects associated with therapists.\textsuperscript{69}

Some therapists are better than others, but what con
tributes to that quality? Beutler and colleagues carefully
reviewed studies of the impact of therapist characteristics
on outcome.\textsuperscript{44,45} The therapist’s age, gender and ethnicity
appear to have little or no impact on results, and nor are
there significant differences in outcome when therapist and
client are matched on these variables. Assessment of the
impact of therapist personality variables is limited, with
some studies attempting post hoc atheoretical analysis, and
others a more theory-driven approach, with no consistent
or robust findings. There are indications that therapists with
better levels of adjustment may have better outcomes,
although there is some inconsistency across studies.

Contrary to received wisdom, empirical findings suggest
that the therapist’s experience does not help to predict out-
come. Attempts to show the effects of experience have no
conclusive results.\textsuperscript{44,70} Wierzbicki and Pekarik’s meta-
analysis of 125 studies found that there was no correlation
between dropout rate and the therapist’s experience in
years or professional qualifications – although there is
some evidence that experience becomes a more important
predictor of outcome with patients who are more
disturbed.\textsuperscript{71}

**LONG-TERM PSYCHOTHERAPY**

Most psychoanalysts would consider that the aims and
methods of short-term once-a-week psychotherapy are not
comparable to those of full psychoanalysis. What do we
know about the value of intensive and long-term psycho-
dynamic treatment? Here, the evidence base becomes
somewhat patchy and we cannot restrict the review to
RCTs.

The Boston Psychotherapy Study compared long-term
psychoanalytic therapy (two or more times a week) with
supportive therapy for clients with schizophrenia in a ran-
donized controlled design.\textsuperscript{72} On the whole, clients who
received psychoanalytical therapy fared no better than
those who received supportive treatment. In the partial-
hospital RCT, the psychoanalytical arm of the treatment
included therapy groups three times a week as well as indi-
vidual therapy once or twice a week over an 18-month
period.\textsuperscript{37,38} A further controlled trial of intensive psychoana-
lytical treatment of children with chronically poorly con-
trolled diabetes reported significant gains in diabetic
control in the treated group, which was maintained at
1 year’s follow-up.\textsuperscript{73} Experimental single case studies car-
rried out with the same population supported the causal
relationship between interpretive work and improvement in
diabetic control and physical growth.\textsuperscript{74} The work of Chris
Heinicke also suggests that sessions four or five times a
week may generate more marked improvements in children
with specific learning difficulties than a less intensive psy-
choanalytical intervention.\textsuperscript{75}

The Stockholm Outcome of Psychotherapy and
Psychoanalysis Project followed 756 people who received
national insurance-funded treatment for up to 3 years in
psychoanalysis or psychoanalytical psychotherapy.\textsuperscript{76–78} The
groups were matched on many clinical variables. Analysis
four or five times a week had similar outcomes at termina-
tion when compared with one to two sessions of psy-
chotherapy per week. During the follow-up period,
psychotherapy patients did not change, but those who had
had psychoanalysis continued to improve, almost to a point
where their scores were indistinguishable from those
obtained from a non-clinical Swedish sample.

The German Psychoanalytic Association undertook a
major follow-up study \(n = 401\) of psychoanalytical treat-
ments undertaken in that country between 1990 and
1993.\textsuperscript{79,80} Between 70 per cent and 80 per cent of the
patients achieved (average 6.5 years after the end of
Several conclusions can be drawn from the psychotherapy research literature. First, it appears evident that psychotherapy is effective in treating a wide variety of clinical conditions, with results often equal to those for drug-based treatments. Second, the affinity between patient and therapist (the so-called therapeutic alliance) may be a key factor in effective therapy. Third, although therapist skill is important in establishing this relationship, skill is not dependent upon experience. Fourth, level of functioning and the ability to form a therapeutic alliance are better predictors of outcome than mere diagnosis. Fifth, evidence suggests that common factors and not specific interventions are crucial in therapy. Finally, it appears that most patients benefit from psychotherapy within the first 6 months of treatment, and that long-term therapy has no significant advantage over short-term therapy. However, psychodynamic psychotherapy may be associated with so-called ‘sleeper effects’, which means that the full benefit of therapy may not be evident until some months after the termination of the trial.

Research into psychotherapy requires further and significant investigation over the coming years, especially enquiry into the nature of therapeutic alliance, as per the evidence for common factors. Further research may provide evidence supporting specific techniques or prove that psychotherapy can be applied more widely than it is at present. Further investigations might also help to determine whether long-term open-ended psychotherapy is consistently effective for the populations for which it is currently prescribed, including chronic depression, severe personality disorder and bipolar disorder.

Part 5: Approaches to treatment

This page intentionally left blank
This page intentionally left blank
INTRODUCTION

For the purposes of clinical management of patients it is helpful to distinguish non-dependent substance misuse from dependent use. The criteria for the diagnosis of substance problems for both the International Classification of Diseases, 10th revision (ICD-10) and the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) are outlined and discussed in more detail elsewhere in this chapter.

BASIC PHARMACOLOGY AND EPIDEMIOLOGY OF MISUSED SUBSTANCES

The substances discussed in this chapter may be classified according to their psychopharmacological properties into the following groupings:

- **Sedative-hypnotics (central nervous system (CNS) depressants):**
  - Barbiturates
  - Non-barbiturate hypnotics
  - Ethyl alcohol
  - Benzodiazepines (anxiolytic or anti-anxiety)
- **Narcotic analgesics (opiates):**
  - Opiates
  - Opiate derivatives
  - Synthetic opiates
- **CNS stimulants:**
  - Cocaine
  - Amphetamines
  - Nicotine
  - Caffeine
  - Ecstasy
- **Psilocybin and hallucinogens:**
  - Lysergic acid diethylamide (LSD)
  - Mescaline (peyote cactus)
  - Phencyclidine (PCP; ‘angel dust’)
- **Cannabis:**
  - delta-9-tetrahydrocannabinol (THC)
- **Inhalants:**
  - Analgesic and anaesthetic gases
  - Glues, solvents and aerosols.

These substances may also be classified according to their mechanistic properties with regard to their binding sites:

- Drugs that bind to G-protein-coupled receptors (GPCRs), e.g. opioids, cannabinoids, γ-hydroxybutyrate (GHB)
- Drugs that interact with ionotropic receptors or ion channels, e.g. nicotine, alcohol, benzodiazepines
- Drugs that target monoamine transporters, e.g. cocaine, amphetamines, methylenedioxymethamphetamine (MDMA, ecstasy).

EPIDEMIOLOGY

Prevalence

The UK has some of the highest levels of substance misuse in Europe. The situation is dynamic, and it has become well recognized that combinations of substances may be misused, including two of the most commonly encountered substances, alcohol and nicotine. Since the early 1990s, despite a fall in overall prevalence from 45 per cent of the adult population in 1974 to 22 per cent in 2006, the prevalence of cigarette-smoking has been higher among 20- to 24-year-olds than in any other age group in Great Britain. In addition, around 25 per cent of the population drink above safe recommended limits of alcohol, with per capita alcohol consumption not only doubling from 1950 to 2000 but also continuing to rise. Hospital admissions for conditions related to alcohol consumption doubled in the period 1996–2006, while death rates related to alcohol consumption doubled in the period 1991–2005. Admissions to intensive care units in England and Wales for alcoholic liver disease tripled over the 10-year period from 1996 to 2005.

Alcohol

Alcohol problems comprise 4 per cent of the global burden of disease, and alcohol misuse costs the UK £20 billion per
Illicit drugs

Drug misuse costs the UK about £15 billion each year. It is estimated that, of people aged 16–59 years, about 11 million (35%) have used illicit drugs in their lifetime, 3.25 million (10%) have used illicit drugs in the previous year, and 2 million (6%) have used illicit drugs in the previous month. Cannabis is the most likely drug to be used, with 8 per cent of 16– to 59-year-olds reporting use in the previous year. In addition, just over 1 million people aged 16–59 years have used class A drugs in the past year, and the use of class A drugs increased between 1998 and 2007.10

There were almost 196 000 people in contact with treatment services in England in 2006–2007, of whom the majority were primary opioid users, with males comprising over 70 per cent of new cases. Estimates derived from a number of sources in the UK suggest that the prevalence of problem drug use is 9.35 per 1000 of the population aged 15–64 years, with a total drug-using population estimated at 360 811.11 A study of drug use in the younger population of the UK revealed that, among 11– to 15-year-olds, 18 per cent had taken drugs within the past year. The most commonly used drug was cannabis (11%), with 1 per cent reporting the use of heroin and 1 per cent reporting cocaine use.12 The British Crime Survey 2003/2004 showed that 4 million adults in England and Wales have used a class A drug in their lifetime, with over 1 million having used them in the past year and over 500 000 having used drugs in the past month.13

Drug and alcohol problems can present in a variety of settings, including:

- accident and emergency (A&E) units;
- acute hospital settings;
- obstetric and paediatric units;
- mental health wards and clinics.

Prevalence in accident and emergency units

There is an increased risk of traumatic injury among substance users. In a 90-day study, nearly two-thirds of admissions to a trauma centre in the USA were victims of motor vehicle crashes; those who had sustained one traumatic injury were at greatly increased risk of re-injury.14 In a study of drug and alcohol use in road traffic accident victims in the USA, 59.3 per cent of the sample tested positive for either drugs or alcohol. More patients tested positive for drug use (35.5%) than for alcohol use only (15.8%), while 9.9 per cent tested positive for both. Cannabis and benzodiazepines were the most frequently detected drugs.14,15

Screening for drug (or drug and alcohol) use among patients attending emergency or trauma departments in Canada found varying rates of use for a range of different drugs, but overall the studies indicated that about 40 per cent of patients attending these departments were likely to test positive for the use of illicit drugs.16

Prevalence in acute general medical settings

In the UK, a study that identified drug use presenting in an acute medical admission unit used both screening questionnaires and the opinion of the admitting doctor to identify drug and alcohol problems.17 Of the 2988 admissions studied, 609 patients (20%) were found to be misusing drugs or alcohol. The study showed that of the 609 patients with a drug or alcohol problem:

- 437 (72%) had an alcohol problem;
- 116 (19%) were using an illicit drug;
- 56 (9%) were polydrug users.

The most commonly used drug was cannabis.

Prevalence in psychiatric patients

It is well recognized that patients with severe mental illness are especially at risk of substance misuse.18 Studies of primary care populations in England and Wales have indicated that the co-morbidity rate is increasing by about 10 per cent each year and that co-morbid patients are becoming younger. In studies of patients attending mental health services in the UK, 10 per cent of patients treated by Community Mental Health Teams reported problematic use of illicit drugs and 17 per cent reported alcohol problems in the past year. Of patients attending a community drug and alcohol service, 22 per cent reported a severe mental illness and 46 per cent reported some other form of psychiatric disorder.19 A study of the prevalence of dual diagnosis in treatment populations in both mental health services and drug treatment services in the UK showed that around 32 per cent of clients in both services were estimated to have dual diagnosis problems. A study in Scotland has shown that problem use of drugs and alcohol is greater in people with schizophrenia than in the general population. More patients than controls reported problem use of drugs in the past year (22 (7%) v. 5 (2%)) and at some time before then (50 (20%) v. 15 (6%)).20

McCann and colleagues report that approximately 50 per cent of adults with attention deficit hyperactivity disorder (ADHD) have a history of psychoactive substance-use disorders.21 Furthermore, they record that a history of childhood
ADHD has been found in 22–71 per cent of substance-abusing patients. In a sample of patients attending an adult ADHD centre, 33.8 per cent were found to have a positive screen for drug abuse.

A review of the relationship between personality disorder and substance misuse concluded that approximately two-thirds of drug users in treatment have a personality disorder, with antisocial personality disorder being the most common. The review indicated that personality disorder is associated with a range of complications and adverse outcomes in drug users, including psychiatric problems, poor social functioning, dropout from treatment, and increased human immunodeficiency virus (HIV) risk behaviours and infection rates.

**Prevalence in patients attending obstetric and paediatric units**

Pregnant women and parents are another group to be considered. In Dublin, urine testing of 504 first-visit antenatal patients and a separate sample of 515 post-delivery patients found a prevalence of 2.8 per cent, with the most frequently used drug being cannabis. The authors note that their figures are similar to the results from an earlier study in Birmingham, which found that 2 per cent of women tested positive on their first antenatal visit, but lower than figures reported from studies in the USA in the late 1980s.

**Health aspects**

Substances impact on every organ system of the body, on the gastrointestinal, cardiovascular, respiratory, musculoskeletal and endocrine systems, and on the CNS. Some problems, such as intoxication, withdrawal, deliberate overdose, injecting accidents, hypothermia and hyperthermia, dehydration, and choking or suffocating may require urgent medical attention; the training of opiate users in the management of these emergencies, including the use of naloxone, may assist the successful reversal of potentially fatal overdoses.

Poor physical health is correlated strongly with poverty and social deprivation, including accidents, dietary neglect, and failure to access primary care. It is not often possible to attribute cause directly, because many of the risk factors for adverse psychosocial consequences and the development of substance misuse are shared. However, once substance misuse is established, further social problems accumulate and persist, so that the removal of the substance alone will not necessarily reduce the social harm.

Substance users are vulnerable to exploitation, especially if they are homeless, mentally ill or have learning difficulties. Unsafe injecting behaviour, high-risk sexual activity, unwanted pregnancy, sexually transmitted infections and accidental overdose compound drug-taking behaviour. Crack cocaine use, common in sex workers, is linked to hepatitis infection and termination of pregnancy.

Furthermore, pregnant teenage substance misusers are at increased risk not only because of their chaotic patterns of use but also due to physical and emotional violence. Substance misuse is associated with early, unplanned or undesired pregnancy and abortion. Since substance use is often accompanied by amenorrhoea, young women may not realize that there is a possibility of pregnancy and may not be aware of their condition until an advanced stage. This can lead to poor antenatal care, with the associated high risks of miscarriage (3% vs. <1% in a population attending a specialist drug treatment unit compared with the local maternity population), low birth weight (28% vs. 9%) and premature babies (20% vs. 9%).

Substance use, sexual abuse and prostitution have common predisposing factors, including poverty, homelessness, psychiatric illness, and physical and emotional abuse. Cocaine, alcohol and benzodiazepines are commonly used to cope with unmanageable situations. Women involved in prostitution are at risk of sexually transmitted infections, blood-borne viruses and bacterial infections (gonorrhoea, syphilis, chlamydia) that may cause infertility and pelvic disease.

Psychiatric disorders such as depression, anxiety, psychosis, eating disorders and post-traumatic stress disorders are associated with the direct intoxicating effects of acute and chronic substance misuse and withdrawal syndromes, often within a very poor social environment. Treatment of addiction problems in this group must therefore include outreach work, social care, and screening and treatment for sexually acquired infections as part of the spectrum of management. The risk of self-harm and suicide is increased greatly in substance misusers, and strategies to reduce suicide rates necessarily include active management of substance misuse, particularly in high-risk groups such as newly released prisoners.

**Mortality**

Since 2000, the level of drug problems in the UK has stabilized, but at levels that are the highest in Europe, and there is considerable substance-related mortality. In the UK, 40 000 deaths each year are due to alcohol-related disorders and about 2000 are due to illicit drug use. In Scotland, the standardized mortality ratio (SMR) for Scottish drug users is 12 times as high as that for the general population. In a population of drug users treated in a specialist setting, the SMR was 17 times higher for adult female and male heroin users compared with that of the non-heroin-using population. The mortality of excessive drinkers is at least twice, and that of drug users over 20 times, that of the general population.

**Summary**

Overall, these studies demonstrate that drug misusers present to a wide range of services, that their problems are not detected, and that failure to recognize their problem may
result in inappropriate treatment and recurrence of health issues, since at least one associated factor, the drug misuse, is not being treated effectively. This is why assessment is important.

RESTRICTIONS IMPOSED ON DOCTORS BY THE MISUSE OF DRUGS ACT AND REGULATIONS

The Misuse of Drugs Act (1971) and the Misuse of Drugs Regulations (2001) impose restrictions on the possession and supply of a range of drugs, which apply to everyone, including medical practitioners, unless the practitioner is operating under an exemption within the Regulations.

The Misuse of Drugs Act was designed to control the use of drugs that are viewed as having medical applications. It classifies drugs into three categories (A, B, C) and defines the penalties for production, supply and possession of drugs in these categories. The current UK drug classification system is shown in Table 69.1. It should be noted that cannabis and cannabis resin were reclassified from class B to a class C in 2004, when the Criminal Justice Act (2003) amended the Misuse of Drugs Act. This amendment also increased the maximum penalty for trafficking in class C drugs from 5 years’ to 14 years’ imprisonment. In 2008 this decision was reversed due to concerns over the increasing prevalence of super-strength strains of the drug and cannabis was reclassified as class B, despite advice to the contrary given by the Advisory Council on the Misuse of Drugs in 2008.31 Current amendments to the Act are accessible online.32

The Misuse of Drugs Regulations (2001)
The Misuse of Drugs Regulations (2001) apply where there are legitimate medical applications for controlled drugs.33 These Regulations further classify drugs into schedules that reflect the degree of control over possession, use, prescribing and supply. These are summarized in Table 69.2.

LSD, lysergic acid diethylamide.
The General Medical Council (GMC) guidance on prescribing reminds doctors that those with full registration may prescribe all medicines, excluding those in Schedule 1 of the Misuse of Drugs Regulations. Doctors who have provisional or limited registration may prescribe medicines in line with the supervisory conditions of their employment. The introduction of a dual system of registration and licence to practise will mean that, in order to prescribe any medication, doctors would have to be both registered with and licensed by the GMC.34

**Controlled drug prescriptions**

Guidance on writing controlled drug prescriptions is available from a number of sources, including the *British National Formulary*.35

**Notification of drug users**

The requirement to notify the Home Office Addicts Register about drug addicts was discontinued in 1997. However, to enable adequate monitoring of data on people presenting with drug problems, doctors and other workers in the addiction field should ensure that they complete the relevant forms for submitting data to the National Drugs Treatment Monitoring System (NDTMS) when a patient starts treatment for drug misuse of any kind. Unlike the Home Office Register, these databases cannot be used as a check on multiple prescribing for drug addicts, because the data are anonymized.35

---

**CAUSES, CONSEQUENCES AND RECOGNITION OF HEAVY DRINKING**

**The concept of ‘problem drinking’**

Problem drinking incorporates a range of alcohol-related behaviours. The definition of problem drinking has not been standardized; for example, some authors use the term to encompass alcohol dependence, alcohol abuse and hazardous use of alcohol, while others use it to refer to drinking more than the recommended safe level, but short of alcohol dependence.

The use of standardized terms from DSM-IV or ICD-10 avoids such confusion and separates out intoxication from alcohol misuse and alcohol dependence syndrome.

**Intoxication**

Intoxication is diagnosed in ICD-10 using the following criteria:1

A. The following criteria for acute intoxication must be met:

1. There must be clear evidence of recent use of a psychoactive substance (or substances) at sufficiently high dose levels to be consistent with intoxication.

2. There must be symptoms or signs of intoxication compatible with the known actions of the particular substance (or substances), as specified below, and of sufficient severity to produce disturbances in the level of consciousness, cognition, perception, affect, or behaviour that are of clinical importance.

3. The symptoms or signs present cannot be accounted for by a medical disorder unrelated to substance use, and not better accounted for by another mental or behavioural disorder.

B. There must be dysfunctional behaviour, as evidenced by at least one of the following:

1. disinhibition;
2. argumentativeness;
3. aggression;
4. lability of mood;
5. impaired attention;
6. impaired judgement;
7. interference with personal functioning.

C. At least one of the following signs must be present:

1. unsteady gait;
2. difficulty in standing;
3. slurred speech;
4. nystagmus;
5. decreased level of consciousness (e.g. stupor, coma);
6. flushed face;
7. conjunctival injection.

**Alcohol abuse or harmful use of alcohol**

Alcohol abuse (DSM-IV) or harmful use of alcohol (ICD-10) are diagnosed using the criteria outlined in Tables 69.3 and 69.4.

**DSM-IV diagnostic criteria for alcohol abuse**

1. A maladaptive pattern of alcohol abuse leading to clinically significant impairment or distress, as manifested by one or more of the following, occurring within a 12-month period:

   (a) Recurrent alcohol use resulting in failure to fulfil major role obligations at work, school, or home (e.g. repeated absences or poor work performance related to substance use; substance-related absences, suspensions or expulsions from school; or neglect of children or household).

   (b) Recurrent alcohol use in situations in which it is physically hazardous (e.g. driving an automobile or operating a machine).

   (c) Recurrent alcohol-related legal problems (e.g. arrests for alcohol-related disorderly conduct).

   (d) Continued alcohol use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the alcohol (e.g. arguments with spouse about consequences of intoxication or physical fights).

2. These symptoms must never have met the criteria for alcohol dependence.5

DSM-IV, Diagnostic and Statistical Manual of Mental Disorders, 4th edition; ICD-10, International Classification of Diseases, 10th revision.

ICD-10 diagnostic criteria for harmful use of alcohol

A. There must be clear evidence that the substance use was responsible for (or substantially contributed to) physical or psychological harm, including impaired judgement or dysfunctional behaviour, which may lead to disability or have adverse consequences for interpersonal relationships.

B. The nature of the harm should be clearly identifiable (and specified).

C. The pattern of use has persisted for at least one month or has occurred repeatedly within a 12-month period.

D. The disorder does not meet the criteria for any other mental or behavioural disorder related to the same drug in the same time period (except for acute intoxication).²

Components of alcohol dependence syndrome

Alcohol dependence syndrome (ADS) was initially defined as including the following components:¹⁶

- Subjective awareness of compulsion to drink
- Increased tolerance to alcohol
- Repeated withdrawal symptoms
- Relief or avoidance of withdrawal symptoms by further drinking.

Standardized diagnostic classifications have refined the original concept, and the DSM-IV and ICD-10 classifications are summarized below.

DSM-IV diagnostic criteria for alcohol dependence

A maladaptive pattern of alcohol use, leading to clinically significant impairment or distress, as manifested by three or more of the following seven criteria, occurring at any time in the same 12-month period:

ICD-10 diagnostic criteria for alcohol dependence

Three or more of the following manifestations should have occurred together for at least 1 month or, if persisting for periods of less than 1 month, should have occurred together repeatedly within a 12-month period:

1. Tolerance, as defined by either of the following:
   - (a) A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
   - (b) Markedly diminished effect with continued use of the same amount of alcohol.

2. Withdrawal, as defined by either of the following:
   - (a) The characteristic withdrawal syndrome for alcohol (refer to DSM-IV for further details).
   - (b) Alcohol is taken to relieve or avoid withdrawal symptoms.

3. Alcohol is often taken in larger amounts or over a longer period than was intended.

4. There is a persistent desire or there are unsuccessful efforts to cut down or control alcohol use.

5. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol or recover from its effects.

6. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.

7. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the alcohol (e.g. continued drinking despite recognition that an ulcer was made worse by alcohol consumption).²

<td></td>
</tr>
</tbody>
</table>

(2) Impaired capacity to control substance-taking behaviour in terms of its onset, termination, or levels of use, as evidenced by: the substance being often taken in larger amounts or over a longer period than intended; or by a persistent desire or unsuccessful efforts to reduce or control substance use; reduced because of substance use; or a great deal of time being spent in activities necessary to obtain, take, or recover from the effects of the substance; (6) Persistent substance use despite clear evidence of harmful consequences, as evidenced by continued use when the individual is actually aware, or may be expected to be aware, of the nature and extent of harm.1

Physical consequences of alcohol misuse

The physical and metabolic complications of alcohol can affect all systems of the body and may mimic other disease processes.27 In England and Wales alone, around 28 000 people die prematurely each year from physical diseases, accidents and suicides related to alcohol use.38

The physical complications of alcohol use are numerous and are manifested in almost all organs of the body. They relate to the pharmacological effects of alcohol, withdrawal...
and toxicity, deficiency syndromes as a result of chronic abuse, and secondary effects such as domestic violence and injury resulting from drink-driving offences.

Some studies have demonstrated a protective effect of low levels of alcohol intake for some diseases. However, this possibility needs to be balanced against the clear evidence of harm from excessive or prolonged heavy consumption.

Central nervous system
Any level of blood alcohol concentration will produce some impairment of complex psychomotor skills. Acute intoxication with alcohol may lead to coma or death, resulting from CNS depression leading to respiratory depression and cardiovascular collapse. Intoxicated patients are at increased risk of other traumatic and medical pathologies that may precipitate or be exacerbated by head injury, infection or hypoglycaemia, which must be ruled out or treated appropriately.

Alcohol withdrawal syndrome
Alcohol withdrawal syndrome (AWS) can be classified by severity into three categories:

- Mild alcohol withdrawal occurs less than 24 h after stopping or decreasing alcohol intake and may include tremulousness, anxiety, nausea, vomiting, sweating, hyperreflexia and minor autonomic hyperactivity.
- Moderate alcohol withdrawal is an intermediate position along the continuum, with the hallmark of hallucinosis but an otherwise clear sensorium.
- Severe alcohol withdrawal takes place more than 24 h and up to 5 days after stopping or decreasing alcohol intake. It is characterized by disorientation, agitation, hallucinations and severe autonomic derangement and may be precipitated by a variety of circumstances, including:
  - lack of money to purchase alcohol;
  - acute illness or injury, or postoperatively;
  - nausea and vomiting;
  - a decision to stop drinking.

Seizures, hallucinations and delirium tremens are considered major phenomena. Seizures can occur with any severity level of withdrawal but are normally seen 12–48 h after stopping alcohol. Seizures may also be secondary to intoxication or trauma, or as a toxic effect of alcohol. Delirium tremens has a mortality of about 5 per cent, the severity generally being related to a previous history of delirium tremens, heavy alcohol consumption and the presence of physical illness. The condition begins 2–3 days after stopping or decreasing alcohol intake and peaks within about a week.

Standardized rating scales for AWS enable objective monitoring and evaluation of interventions. The Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar) scale is a short, ten-item scale for clinical measurement of the severity of AWS and can be completed in a few minutes by nursing staff. Points are assigned for categories of symptoms and signs, including sweating, anxiety, tremor, agitation, hallucinations, nausea and vomiting, headache, orientation and impaired consciousness.

Neurological nutritional deficiency syndromes
Nutritional deficiency must be considered in alcohol abusers. The initial presentation may be one of peripheral neuropathy and cardiovascular disorder, such as hypotension or high output cardiac failure (e.g. beriberi), in combination with oral inflammation. This is the result of thiamine deficiency.

The most important presentation of nutritional deficiency is Wernicke–Korsakoff syndrome (WKS), which is a consequence of thiamine deficiency. Wernicke’s encephalopathy (WE) and Korsakoff’s psychosis (KP) are both part of this syndrome. This is a medical emergency.

Wernicke’s encephalopathy is a potentially reversible neurological condition, but untreated it is fatal in 17 per cent of cases, with permanent brain damage occurring in 85 per cent of patients who are managed inappropriately. Postmortem findings indicate that a diagnosis of WE is missed in up to 90 per cent of patients. In its classic form, WE is characterized by the triad of ocular abnormalities, ataxia and a global confusional state; this classic triad is found in only 16 per cent of patients, and the onset of the syndrome may be acute or gradual, evolving over several days.

Korsakoff’s psychosis presents as lack of insight, apathy, and anterograde and retrograde amnesia with confabulation. Although originally seen as a distinct syndrome, it is now viewed as part of the progression of WKS and has been shown to share an underlying causation and a common neuropathological basis. Findings from postmortem studies have shown that the most common abnormalities in WKS are in the areas surrounding the cerebral aqueduct and the third and fourth ventricles. The thalamus, mammillary bodies and cerebellum are also affected.

A variety of brain lesions related to alcohol have been defined, including:

- neuronal loss with cerebral dementia;
- alcoholic cerebellar degeneration;
- central pontine myelinolysis;
- Marchiafava–Bignami syndrome.

Liver disease and gastrointestinal disorders
Alcoholic liver disease is a very common cause of morbidity and mortality in the developed world. There is a dose-dependent increase in relative risk for both men and women, with the steepest increase among women. The spectrum of liver disease is not uniform but can be described under three main headings:

- Alcoholic fatty liver: this results from the inhibition of oxidation of fatty acids, combined with an increased
generation of triglycerides. The early stages produce no changes in liver function tests, other than those related to the direct effect of alcohol on liver function. The condition is asymptomatic and can present with right abdominal pain, nausea and vomiting, which resolve on abstinence. The effects can be reversed within a few weeks of abstinence from alcohol.

- **Alcoholic hepatitis:** this results from chronic alcohol abuse. Alcoholic hepatitis produces liver cell necrosis and inflammation and can raise aspartate aminotransferase (AST), alanine aminotransferase (ALT) and bilirubin levels. AST activity is higher than that of ALT in alcoholic hepatitis and Reye syndrome, in contrast to most types of liver disease, where ALT is higher. The clinical presentation involves jaundice, pyrexia, right abdominal pain, ascites and possible encephalopathy. In patients with poor liver function and a prothrombin time prolonged to a degree that precludes liver biopsy, the prognosis is poor, with a third of patients dying in the acute episode. Severe acute alcoholic hepatitis has a poor outcome with standard supportive management. The reported mortality rate of patients with severe alcoholic hepatitis is 35–46 per cent.

- **Cirrhosis:** this involves a permanent loss of liver cells, which are replaced by fibrosis with loss of the normal liver architecture. Liver function tests may be normal until the process is advanced and diagnosis is confirmed by biopsy. Cirrhosis may be asymptomatic or present with gastrointestinal symptoms, ascites, encephalopathy and oesophageal varices, which may cause haemorrhage. Abstinence and good nutrition are mandatory. Prognosis is poor unless alcohol intake ceases; overall, only 25 per cent of patients with cirrhosis survive 5 years from diagnosis.

Other gastrointestinal consequences of alcohol abuse include acute and chronic pancreatitis, and gastritis and peptic ulcers. Over 70 per cent of cases of chronic pancreatitis are caused by long-term heavy alcohol abuse, which may also result in severe weight loss, diabetes and malabsorption syndrome.

**Cancer**

Chronic alcohol consumption is a strong risk factor for cancer in the oral cavity, pharynx, hypopharynx, larynx and oesophagus and is also a major aetiological factor in hepatocarcinogenesis. Alcohol increases the risk of cancer of the colorectum and the breast.

Heavy drinkers are more likely to be heavy smokers, and the increased risk from each substance problem appears to be potentiated by the combination. Men who both smoke and drink are nearly 38 times more likely to develop head and neck cancers than men who do neither. The risk of developing cancer of the oesophagus is 50 times greater in heavy drinkers and heavy smokers than in people who abstain.

**Cardiovascular disease**

The effects of alcohol on the cardiovascular system are well documented and range from the protective effects of light drinking for ischaemic stroke and coronary disease through to the increased risk from heavy drinking for haemorrhagic stroke, cardiomyopathy, hypertension and cardiac arrhythmias.

Other alcohol-related disorders are detailed in Table 69.5.

**WHO USES WHICH DRUGS, AND WHY?**

Drug use is affected by age, gender, fashion, availability, regulations and societal values.

**Reasons for initiating and continuing drug use**

There are a variety of theories used to understand the reasons for initiation and continuation of drug use, which can be classified into three main categories:

- **Biological**
- **Sociological**
- **Psychological**

Table 69.5 Other alcohol-related disorders

<table>
<thead>
<tr>
<th>Alcohol-related disease</th>
<th>Myopathy affects more than 2000 subjects per 100 000 population and, in its chronic form, affects 40–60% of people with alcoholism</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alcohol-related fractures</td>
<td>Common in chronic alcohol misuse. Associated with reduced bone mass and higher incidence of osteoporosis. Poor nutrition and associated smoking habits contribute to the risks of fracture</td>
</tr>
<tr>
<td>Fertility</td>
<td>In premenopausal women with alcoholism, there is an increase in the frequency of menstrual disturbances, abortions, miscarriages and infertility. Uncontrolled studies of men with alcoholism have reported that alcohol consumption may affect spermatogenesis and spermiogenesis. Gonadal atrophy, a direct result of toxicity and suppression of the hypothalamic–pituitary axis, is associated with impotence and diminished fertility</td>
</tr>
<tr>
<td>Fetal effects</td>
<td>Regular consumption of alcohol during pregnancy may affect the fetus. Abnormalities range from growth retardation to fetal alcohol syndrome. There is no evidence on which to base a recommendation of a safe level of alcohol intake in pregnancy</td>
</tr>
</tbody>
</table>
An alternative classification of theory types has also been proposed, which clusters the majority of current theories into five groups:55

- Biological, social or psychological theories
- Theories on the effects of addictive stimuli
- Individual susceptibility theories
- Environmental factor theories
- Recovery and relapse theories.

In reviewing the multiple theories of addiction, West suggested a synthetic theory of addiction, which proposes that addiction is a symptom rather than a unitary disorder and that there are three basic pathologies associated with it:56

- A disorder of the motivational systems unrelated to addiction itself
- An abnormality of the motivational system caused by the addictive activity
- Pathological environments that act on normal motivational systems.

This concept has also been suggested in other integrative models, such as those that include a two-component model of availability-proneness.57,58 These models theorize that drug use occurs when a psychologically prone person is exposed to a high level of drug availability.

Although psychological theories often predominate in the development of interventions for drug addiction, advances in neuroimaging techniques applied to the addiction field could have an increasing impact on available treatments.59

**Recognizing drug use**

A framework for assessing and diagnosing drug problems is provided in the Department of Health’s *Drug Misuse and Dependence: UK Guidelines on Clinical Management*.60 The National Treatment Agency’s (NTA) *Care Planning Practice Guide* provides a summary of the characteristics of a selection of tools that can be used for assessment and outcome measurement in a drug treatment setting.61 The basic principles of the guidelines can be summarized as follows:

- The needs of drug misusers should be assessed in terms of their health, social functioning and criminal involvement.
- A good initial assessment is essential. This may involve a multidisciplinary team.
- Confirmation of drug-taking should be achieved through history, examination and drug testing.
- Any risks to children should be assessed, and child-protection services involved as appropriate.
- Testing for blood-borne infections should be arranged as appropriate.
- A physical and psychological health assessment should be carried out.
- Any ongoing criminal involvement or offences should be determined.
- The drug misuser’s expectations and desire to change should be assessed.
- The degree of dependence and need for substitute medication should be assessed.
- Drug testing can help to monitor compliance and treatment outcome.

**Taking a drug history**

The aim is to elicit as accurately as possible something about past and current drug-taking behaviour and should include the following areas:

- Reason for presentation
- Past and current (past 4 weeks) drug use:
  - Current usage and why patient changed to injecting
  - Supply of needles and syringes
  - Sharing habits, including lending and borrowing injection equipment or paraphernalia
  - Does the patient know how to inject safely?
  - How does the patient clean equipment?
  - How does the patient dispose of used equipment/‘works’?
  - Knowledge of HIV/hepatitis B and C issues and transmission
- Use of condoms
- Has the patient ever thought of or tried other methods of use?
- Previous attempts to reduce or stop taking drugs
- Previous periods of treatment or rehabilitation
- History of injecting and risk of HIV and hepatitis
- Medical history
- Psychiatric history
- Forensic history
- Social history
- Past contact with treatment services
- Drug and alcohol misuse in partner, spouse and other family members
- Impact of drug misuse on other aspects of the patient’s life.

**Examination**

- Assess motivation.
- Assess general health:
  - Signs of drug misuse, e.g. needle track marks, skin abscesses
  - Signs of withdrawal or intoxication
  - Determine the presence of any complications of drug misuse:
    - Viral hepatitis
    - Bacterial endocarditis
    - HIV
    - Tuberculosis
    - Septicaemia
    - Pneumonia
    - Deep vein thrombosis
Patterns of use and dependence on different drugs

Pulmonary emboli
Abscesses
Dental disease

Assess mental health.
Assess social and family situation.

Investigations
- Full blood screen
- Hepatitis B and C
- HIV
- Urine screening for drugs of abuse at the outset and during prescribing
- Hair analysis (where indicated).

Patterns of use and dependence on different drugs

Opiates

Effects of intoxication
Heroin may be smoked, injected, or heated on foil and the fumes inhaled. The short-term effects include a rapid onset of euphoria with a sensation of heavy extremities. The user then experiences alternating wakeful and drowsy states. Heroin is a CNS depressant and has effects on reaction times and ability to concentrate.

Diverted pharmaceutical opiates and opioids may be formulated for injection, oral use or as suppositories. Tablets may be crushed and injected. Dependence can develop rapidly, within weeks. Since tolerance also develops rapidly but diminishes quickly after abstinence, relapse can lead to overdose and death. This is also the case for methadone.

Health complications
Repeated use of heroin induces a state of dependency, with a need for increased doses and increased frequency of use. The occurrence of withdrawal symptoms triggers further use to relieve these symptoms. Repeated injections result in collapsed veins, infection of the heart lining, endocarditis, and skin and muscle infections. Sharing of injection equipment also carries a high risk of blood-borne infections such as HIV and hepatitis C. Opiates and opioids depress coughing, breathing and heart rate, dilate blood vessels, reduce bowel activity and produce constipation. Overdose usually occurs in combination with other drugs.

Signs of opiate intoxication
- Apathy
- Sedation
- Disinhibition
- Psychomotor retardation
- Impaired attention
- Impaired judgement
- Interference with personal functioning
- Drowsiness
- Slurred speech
- Pupillary constriction
- Decreased level of consciousness.

Signs of opiate withdrawal
- Craving
- Sneezing, yawning, runny eyes
- Muscle aches, abdominal pains
- Nausea, vomiting, diarrhoea
- Pupillary dilation
- Goose flesh, recurrent chills
- Restless sleep.

Cannabis

Effects of intoxication
Cannabis is either smoked or eaten. Use is accompanied by distorted time perception, impaired coordination and difficulty in thinking. These effects may persist for over 24 h.

Health complications
Cannabis has effects on physical health, with higher rates of lung and heart disease in cannabis users compared with cigarette-smokers. Cannabis use can lead to depression, anxiety and paranoia. Panic attacks are a feature, and there is controversy as to whether cannabis causes an enduring schizophrenia-like psychosis or simply exacerbates it. Memory and learning are affected. Evidence is accumulating of the risk of lung cancer and cancers of the head and neck in cannabis-smokers.

Signs of cannabis intoxication
- Euphoria and disinhibition
- Anxiety and agitation
- Suspiciousness and paranoid ideation
- Impaired reaction time
- Impaired judgement and attention
- Hallucinations with preserved orientation
- Depersonalization and derealization
- Increased appetite
- Dry mouth
- Conjunctival injection
- Tachycardia.

Signs of cannabis withdrawal
- Anxiety
- Irritability
- Tremor
- Sweating
- Muscle aches.
Stimulants – amphetamines, cocaine and ecstasy (MDMA)

Effects of intoxication
The majority of psychostimulants may be used orally, snorted as a powder through the nose, injected or smoked. Psychostimulants produce an intense euphoric state, which may be accompanied by restlessness and agitation, rapid speech rate and increased wakefulness.

Health complications
The use of psychostimulants may precipitate anxiety states, confusion, convulsions and cardiovascular problems. Acute psychotic episodes are a relatively common presentation in mental health settings. The sharing of injection equipment carries the same risks as for heroin use, but the risk is often underestimated in the stimulant-using population. Use of stimulants may lead to exhaustion, depression and weight loss. A paranoid or confusional state may also occur. Hypertension, cardiac arrhythmias, stroke, hepatic and renal damage, and abscesses are the result of heavy use, especially if the drug is injected. Violent and aggressive behaviour may ensue. Snorting cocaine leads to nasal septal perforation and damage to the nasal passages.

Signs of stimulant intoxication
- Euphoria and increased energy
- Hypervigilance
- Repetitive stereotyped behaviours
- Grandiose beliefs and actions
- Paranoid ideation
- Abusiveness, aggression and argumentativeness
- Auditory, tactile and visual hallucinations
- Sweats, chills and muscular weakness
- Nausea or vomiting
- Weight loss
- Pupillary dilation
- Convulsions
- Tachycardia
- Arrhythmias
- Chest pain
- Hypertension
- Agitation.

Signs of stimulant withdrawal
- Lethargy
- Psychomotor retardation or agitation
- Craving
- Increased appetite
- Insomnia or hypomnia
- Bizarre and unpleasant dreams.

Sedatives – benzodiazepines

Health complications
In the short term, users may experience tiredness, depressed respiration, dizziness and unsteadiness. With other depressants, such as alcohol or opiates, overdose can be fatal. Dependence can develop on low doses, and convulsions occur with withdrawal. Rebound symptoms such as insomnia, anxiety and tension can occur.

Signs of benzodiazepine intoxication
- Euphoria
- Disinhibition
- Lability of mood
- Apathy
- Sedation
- Abusiveness and aggression
- Impaired attention
- Amnesia
- Impaired psychomotor performance
- Unsteady gait
- Slurred speech
- Nystagmus
- Decreased level of consciousness
- Hypothermia.

Signs of benzodiazepine withdrawal
- Confusion and convulsions
- Tremor, postural hypotension
- Nausea and vomiting
- Agitation
- Paranoid ideation
- Tachycardia
- Rebound insomnia and tension.

Sedatives – barbiturates

Barbiturates are classified according to their duration of action:
- Ultra-short-acting
- Short-acting
- Long-acting.

Their effects include relaxation and improved sleep at low levels, but at higher levels they can induce cognitive impairment, lability of mood, and impaired motor behaviour such as slurred speech and slow reaction times.

Signs of barbiturate intoxication
- Apathy
- Sedation
- Abusiveness and aggression
- Impaired attention
- Amnesia
- Impaired psychomotor performance
- Unsteady gait
• Slurred speech
• Nystagmus
• Decreased level of consciousness
• Shallow breathing
• Coma.

**Signs of barbiturate withdrawal**
Signs of withdrawal can occur up to 20 h after the last dose and include the following:

- Irritability
- Increased heart and respiration rate
- Hallucinations and seizures
- Nightmares
- Insomnia
- Coma
- Death.

**Volatile substances**
Volatile substances include petrol, acetone, ether and toluene. They may be found in glues, solvents, lighter fluids, spray deodorants and nail-polish removers.

**Health complications**
The major risks are from the rapid onset of intoxication and method of inhalation. There may be public health and public safety issues where users store large quantities of inflammable solvents in unsafe situations.

**Signs of intoxication with volatile substances**
- Initial euphoria
- Blurred vision
- Impaired psychomotor function
- Delayed reaction time
- Poor manual dexterity and coordination
- CNS depression
- Respiratory arrest
- Unconsciousness
- Death, due to cardiac arrest.

**Signs of withdrawal from volatile substances**
There are no withdrawal effects for this category of drug described in DSM-IV. However, after intoxication has worn off, later effects such as headache, stomach ache, conjunctivitis and cough may last for some days.

---

**SPECIFIC POPULATIONS**

**Adolescents**
There is extensive documentation, mainly from cross-sectional studies, of the association of substance misuse and psychiatric disorder in young people. The major diagnostic groups to emerge are affective disorder (bipolar depression, major depression, anxiety, panic, phobias and post-traumatic stress syndrome), personality disorders (conduct, borderline and antisocial) and attention deficit disorders. Learning disability, for example, has not been studied extensively, though clinical experience suggests an association and where assessment and intervention may yield benefits. Moreover, since psychiatric disorders that begin in childhood may continue into adult life, there is an opportunity to intervene early to prevent or reduce conditions complicated by substance misuse, if access to appropriate services is provided. Longitudinal work is vital in order to explore more fully the patterns of co-morbidity and to implement and evaluate the treatment interventions that might contribute to decreasing morbidity and mortality.

**Cannabis and psychosis in young people**
The possibility of a connection between cannabis use and psychotic symptoms has been the subject of research, and many individual papers have concluded that the connection does, in fact, exist. In a prospective cohort study of cannabis use and its relationship to the development of psychotic symptoms, Henquet and colleagues studied 2437 young people in Europe aged 14–24 years. The study concluded that, at a 4-year follow-up from the baseline, cannabis use has a moderate effect in increasing the risk of psychotic symptoms in young people. This effect was, however, much stronger in young people who showed evidence of a predisposition to psychosis. The study also demonstrated that a predisposition to psychosis at baseline did not predict cannabis use, and the authors concluded that this result could be used to refute the self-medication hypothesis.

A systematic review of general population longitudinal studies was undertaken, which reported the associations between illicit drug use by young people and psychosocial harm. This identified 48 studies, of which only 26 were of a high quality. The review concluded that there were no consistent associations between cannabis use and psychological health problems. Although the evidence did not provide clear support for a causal relationship, it was not robust enough to exclude such a connection, and the authors indicated that better evidence is needed in relation to both cannabis and other illicit substances.

**Attention deficit hyperactivity disorder and substance use disorders in adolescents**
Longitudinal community studies of children with ADHD have shown that they are at risk for a variety of antisocial activities, which are related mainly to co-morbid drug use. In a longitudinal study in the USA, 158 children aged 4–12 years who had been diagnosed with hyperactivity were followed up for a mean period of 20 years. A matched community control group was followed up over the same time period. Children with co-morbid ADHD and substance use disorders were reported to have a higher severity of drug use and worse treatment outcomes than those with ADHD but no substance use disorder.
Wilens highlighted the lack of evidence on the mechanisms by which untreated ADHD increases the risk of drug or alcohol problems, despite the existence of a considerable body of literature concerning their association.\(^6\) The relationship between early substance use and childhood disorders with externalizing psychopathology such as ADHD, conduct disorder and oppositional defiant disorder has been investigated in a longitudinal community-based study of twins.\(^7\) The results suggested that externalizing psychopathology increases the risks for early initiation of alcohol, nicotine and cannabis use. Progression to regular and more serious use of cannabis by the age of 14 years was reported as having the strongest association with externalizing psychopathology (odds ratio (OR) 3.45). ADHD was the weakest predictor of the three externalizing disorders studied, with conduct disorder being the strongest.

Treating ADHD associated with substance misuse disorders with stimulants has been shown to be effective in treating the hyperactivity disorder but has no effect on the drug or alcohol disorder.\(^8\) The possibility that treating young people with ADHD with stimulants might increase the risk of substance use disorders is a concern for clinicians. A meta-analysis of the literature has been performed to address this concern and concluded that, in fact, such treatment reduces the risk of subsequent drug and alcohol problems.\(^9\)

### Anxiety, depression and substance use disorders in adolescents

The relationship between substance use, anxiety and depression in young people is complex, but it reflects many of the general issues that complicate the identification of causal relationships in studies of co-morbidity. A 21-year study of the association between anxiety disorders and substance abuse disorders showed that young people with anxiety disorders are at increased risk of substance use disorders, with ORs between the two disorders in the range of 1.3–3.9.\(^10\) The association is, however, not causal and is dependent on the presence of related confounding factors that are connected with increased risk for anxiety disorder. In constructing the methodology, the authors proposed three possible models: (i) that there would be a common or correlated cause for the disorders; (ii) that self-medication would be confirmed; and (iii) that there would be a causal relationship. The study demonstrated that the first model was the most appropriate.

However, a cross-sectional study that investigated panic attacks, depression and anxiety symptoms, and substance use behaviours during late adolescence demonstrated that ‘panickers’ were significantly more likely to have ever used sedatives, stimulants, opioids and other drugs, but not tobacco, alcohol, cocaine or hallucinogens.\(^11\) Furthermore, in panickers, substance use and psychological symptoms such as depression and anxiety were related. The authors noted that it was not possible to determine causality, but they did conclude that the relationship between panic attacks and substance use appeared to present before the typical age of onset of substance use and panic disorders. Another study of a clinical sample of adolescents with phobic disorders and substance dependence in Finland showed that adolescents with a phobic disorder were almost five times more likely to develop substance dependence than those without a phobia.\(^12\) Over half of the adolescents had developed substance dependence within 3 years of onset of the phobic disorder. This clearly points to the need to screen, diagnose and treat early on.

A longitudinal study examined the effect of age of first substance use and history of psychiatric disorders on the development of substance use disorder by the age of 16 years.\(^13\) This group reported that the risk of transition to substance use disorder increased with age at onset before age 13 years but began to fall after age 14 years. The findings indicated that early substance use was a major predictor of adolescent substance use disorder, even in the absence of conduct disorder. However, past conduct disorder had a strong additive effect at age 13–15 years; boys with a history of depression were at increased risk of substance use disorder; and anxiety increased the risk of substance use disorder in girls at the age of 16 years.

### Pregnant drug users

Pregnancy in a woman who is misusing substances is risky, both for her and the fetus. Pregnant drug users are frequently underweight, anaemic and socially disadvantaged. They are often poor attendees at antenatal clinics, and young users tend to present to maternity services late in their pregnancy. Substance misuse also increases the risk of other conditions, including domestic violence, sexually transmitted diseases, hepatitis B, hepatitis C and HIV. These associated problems can present a significant risk to the pregnant mother and her unborn child, in addition to any effects of the drug use on the growth and maturation of the fetus.\(^14\)

Long-term developmental neurocognitive, physical and psychosocial effects resulting from in utero exposure to opioids and other drugs are poorly understood. Moreover, it is increasingly common for substance misusers to take a combination of different drugs at different times during their pregnancy and, because of the complex psychosocial context in which they use substances, research can face serious methodological problems. However, generally, parental substance misuse poses significant risks for children. Child and adolescent mental health services report that a parent’s long-standing drug or alcohol misuse is a substantial risk factor for poor mental health in children.\(^15\) Children may also be at high risk of maltreatment, emotional or physical neglect or abuse, family conflict, and inappropriate parental behaviour.\(^16\)–\(^18\) Children may be exposed to, and involved in, drug-related activities and associated crimes.\(^19\) They are more likely to display behavioural problems.\(^20\) experience social isolation and stigma,\(^21\) misuse substances themselves when older,\(^22\) and develop problem drug use\(^23\) than other children.
Parents with chronic drug addiction spend considerable time and attention on accessing and using drugs, which reduces their emotional and actual availability for their children. Conflicting pressures may be especially acute in economically deprived lone-parent households and where there is little support from relatives or neighbours. In the long term, children of substance-misusing parents may have severe social difficulties, including strong reactions to change, isolation, difficulty in learning to have fun, and estrangement from family and peers. Despite this, substance misusers should not automatically be stereotyped as poor parents.

**INTERACTION OF DRUG AND ALCOHOL USE WITH PSYCHIATRIC ILLNESS**

**Relationship between drug misuse and mental health problems**

Research shows that substance use, intoxication, harmful use, withdrawal and dependence (addiction) may lead to or exacerbate psychiatric or psychological symptoms or syndromes. Similarly, psychological morbidity and psychiatric disorders may lead to substance use, harmful use and dependence (addiction). Substance misuse is commonly associated with depression, anxiety and schizophrenia, but eating disorders, post-traumatic stress disorders, ADHD and memory disorders also occur. Alcohol problems, for example, are often seen with bipolar disorders, schizophrenia and personality disorders, while concurrent use of other illicit substances is well recognized in opiate dependence.

Interrelationships in dual diagnosis can be classified as follows:

- A primary psychiatric illness may precipitate or lead to substance use, misuse, harmful use or dependent use, which may also be associated with physical illness and alter social ability.
- Substance use, misuse, harmful use or dependent use may exacerbate a mental or physical health problem, for example painful conditions, and any associated social functioning difficulties.
- Substance use, intoxication, misuse, harmful use or dependent use may lead to psychological symptomatology not amounting to a diagnosis and also to social problems.
- Substance use, misuse, harmful use or dependent use may lead to psychiatric illness, physical illness and social dysfunction.

**Co-morbidity**

Co-morbidity may present itself in a range of different combinations and permutations, including the following:

- Substance use – even one dose – may lead to psychological symptoms or psychiatric syndromes.
- Harmful use may produce psychiatric symptoms.
- Dependence may produce psychological symptoms.
- Intoxication may produce psychological symptoms.
- Withdrawal from substances may produce psychological symptoms.
- Substance use may exacerbate a pre-existing psychiatric disorder.
- Psychological morbidity not amounting to a disorder may precipitate substance use.
- Primary psychiatric disorder may lead to substance use disorder.
- Primary psychiatric disorder may precipitate substance use disorder, which may in turn lead to psychiatric disorder.

There is a vast body of literature on this topic. However, it must be stated that there are a variety of methodological issues that comprise the comparability of studies, including definitions, criteria for diagnosis, the different healthcare settings and systems in which studies take place, descriptions of combinations of interventions, and changing prevalence. Nonetheless, despite these differences and inherent difficulties, there can be little doubt that these combined disorders now constitute an important component of a psychiatrist’s day-to-day workload.

Psychoactive substances have differing psychological effects, including those caused by intoxication and withdrawal. Chronic use, intoxication with depressant drugs and withdrawal from stimulants produce symptoms similar to those seen with depressant drugs, while acute intoxication with stimulants and cannabis may mimic a schizophrenic illness. Withdrawal from depressant drugs may result in symptoms of anxiety, panic and even confusional states. These complex interactions have implications in that not only does drug use interfere with emotional, cognitive and social behaviour, but also the combination of disorders results in poorer treatment compliance and worse outcomes in both the short and the longer term.

An association between drug use and psychiatric conditions has been consistently documented in substance-misusing clinical populations, psychiatric populations, the general population, prison populations and homeless populations. Indeed, in the well-known Epidemiological Catchment Area (ECA) study, drug addiction was associated with a 53.1 per cent lifetime rate of an additional mental disorder.

Furthermore, the interrelationships between physical health, mental health and drug misuse are also well documented. Apart from the direct effects of drugs on general health (see below), there are indirect effects such as dietary neglect, impoverishment, trauma, bereavement and loss. Malnutrition, for instance, may emanate from drug-induced...
anorexia, malabsorption or economic deprivation. Liver dysfunction, for example as a result of HIV or hepatitis B or C, produces psychological as well as physical problems.

Psychiatric conditions such as anxiety, depression, post-traumatic stress disorder, drug-induced psychosis, schizophrenia, delirium and dementia may lead to, be a consequence of, or coincide with drug misuse. Withdrawal from barbiturates and benzodiazepines leads to delirium, whereas head injuries and serious infections are associated with dementia. The differing mechanisms and types of relationship demand careful history-taking and judicious interpretation. Depression, dementia, delirium and a heightened risk of suicide are probably the problems most commonly faced by clinicians. Of course, some of these conditions are associated with chronic pain and sleep disorders, which may make patients vulnerable and lead to them seeking relief from prescription and non-prescription medications in a non-compliant fashion. Sleep disorders such as insomnia may precipitate an increased alcohol intake and a consequent negative effect on sleep patterns over a prolonged period of excessive intake.

Since there are effective medications and psychosocial interventions available for many psychiatric conditions, correct diagnosis and treatment or referral have tangible benefits.

Another study of mental health centres and substance misuse services in the UK reported that three-quarters of drug service users and 85 per cent of alcohol service users had mental health problems, mostly affective disorders and anxiety disorders. Approximately one-third of the drug treatment population and half of the alcohol treatment population also had multiple morbidity – that is, the co-occurrence of a number of psychiatric disorders or substance misuse disorders. The costs of caring for service users with dual diagnosis are higher than those for single conditions because of the need for greater service use. In fact, nearly 40 per cent of drug users had not received help for their mental health problems, and just over 40 per cent of mental health service users reported drug use or hazardous or harmful levels of alcohol use in the past year. These individuals were perceived as being more aggressive and chaotic and less compliant with care plans.

Drug users attending treatment also tend to carry a heavy burden of additional health problems. These adversely affect their physical and mental health and are accompanied by high rates of unemployment. Serious physical illness is an additional co-morbidity and one that is, perhaps, overlooked, underrated and undertreated. Physical problems such as pain, infection, injury and cancer may result from substance misuse and may lead to mental illness. If not treated adequately, these conditions not only add to the patient’s suffering but also undermine the treatment provided for substance misuse. As a result, people with multiple conditions often do not access or receive the care they need.

Problems may begin in childhood or adolescence and continue into old age. Child abuse, for example, is known to contribute to the prevalence of co-morbid personality disorder in addiction populations. Women who use substances are more likely than a control group to have been exposed to sexual, physical and emotional abuse as children. They are also more likely to experience emotional distress than a control group of women substance misusers who do not have that background.

The explanation for differing rates of co-occurring disorders depends on many factors, including the following:

- Differences between or lack of standardization of diagnostic classification systems and diagnostic instruments used for mental disorder and substance use disorders
- The setting in which the condition is studied – for example, a clinical setting is more likely to yield high rates than a general population study
- Services may conceptualize and diagnose the same users differently
- An individual’s substance use may fluctuate in type, quantity or frequency
- Time of assessment may influence the result, for example during withdrawal or intoxication
- Mental health presentations may vary, depending on environmental triggers
- Differences between regions in terms of types of presentation and rural or urban communities
- The combination of events that contribute to an individual’s life history.

BASICS OF THE BIOLOGICAL, PSYCHOLOGICAL AND SOCIOCULTURAL EXPLANATIONS OF DRUG AND ALCOHOL DEPENDENCE

Substance use and misuse are best viewed through the framework of a multifactorial biopsychosocial model. Age, role, gender, social group and peer pressure, family, community and occupational environment, and overall cultural values and controls on substance use will all act upon substance-taking behaviour.

The biopsychosocial model of addiction is comprehensive and starts from an assumption of multifactorial causality of addiction, including biological, genetic, psychological and sociocultural factors. Within the population of people with alcohol-related problems, this model would propose that there are a series of subpopulations where specific factors may play a more important role in causation than in other groups. The biopsychosocial model may be used to explain the number of cases of coexisting psychiatric and alcohol problems.

The coexistence of psychiatric illness with alcohol dependence is common; for example, the National Institute of Mental Health Epidemiological Catchment Area Program
reported that, among people with a mental disorder, the lifetime prevalence of an alcohol disorder was 22 per cent, compared with 13.5 per cent for the total population. Among people with an alcohol disorder, 37 per cent had a co-morbid mental disorder. The self-medication hypothesis suggests that the specific pharmacological properties of addictive substances are used to control the symptoms of psychiatric illness. However, although this view has clinical and empirical support, it has not been supported by consistent research evidence.

A literature review of the use of alcohol to control social anxiety reported that attribution of a self-medicating effect to a substance by the user might not align with the reality of the pharmacological and physiological effects of the substance. For example, the review found support for the fact that individuals with social phobia use alcohol to reduce anxiety, but the evidence that alcohol actually reduced social anxiety was less conclusive.

Attempts to change drinking behaviour can be influenced by a range of factors, including:

- genetic make-up;
- personality;
- sense of control;
- sense of efficacy;
- degree of dependence;
- presence of brain damage;
- psychiatric problems;
- internal and external cues or stimuli;
- financial state;
- values of the treatment programme.

**ASSESSMENT AND MANAGEMENT OF DRUG AND ALCOHOL MISUSERS**

Guidelines from the British Association of Psychopharmacology (BAP) summarized the evidence base for the pharmacological treatment of substance misuse and co-morbid conditions. The following findings are drawn from this document.

**Summary recommendations from the British Association of Psychopharmacology guidelines**

**Opioids**

There is considerable evidence for the use of methadone, buprenorphine and \( \alpha_2 \) agonists (clonidine, lofexidine) in the management of withdrawal states. There are differences in choice of medication, depending on the priorities around duration of treatment, adverse effects (bradycardia and hypotension due to \( \alpha_2 \)-adrenergic agonists) and withdrawal severity. The patient’s clinical condition, degree of dependence and preference, and the practitioner’s experience, will determine which drug to use.

Similarly, there is an established evidence base for methadone maintenance treatment and, more recently, for buprenorphine. There is inadequate evidence for treatment with naltrexone and injectable opioids, and for using coercive methods.

**Stimulants**

For stimulant drugs such as cocaine and amphetamine, the guidelines do not recommend the use of dopamine agonists, antidepressants or carbamazepine. Furthermore, there is no clear evidence to support substitute prescription of dexamphetamine. In fact, psychosocial interventions are considered the mainstay of treatment, although the evidence is limited.

**Sedatives and hypnotics**

The guidelines make recommendations for benzodiazepine dependence, whether the benzodiazepines be used licitly on a prescription or illicitly. In early or mild dependence, minimal interventions such as relaxation or general practitioner (GP) advice are suggested. For more severe dependence, graded discontinuation is advised. For illicit misusers, there is no evidence that continued prescribing is beneficial, apart from to reduce illicit use. The above advice is related to an adult population.

**Psychological interventions**

The majority of interventions are based on learning theory models, but there is also the recognition that there are non-treatment routes to improvement. Furthermore, information-based approaches such as health education and information are useful in less complex situations. These might include education about harm minimization, immunization and vaccination.

In the addiction literature, the term ‘counselling’ is used to incorporate brief and intensive interventions, including supportive, directive or motivational counselling, individual, family or group behavioural treatments, and social network behavioural therapy. Counselling may aim to reduce the use of alcohol and drugs, and the associated negative consequences or related problems. The term may encompass assessment, engagement and support, together with the development of therapeutic relationships. The non-judgemental and empathic method of challenging decisions and assumptions in motivational interviewing is included in the gamut of techniques. Important common objectives may include the following:

- **Problem solving**: developing competence in dealing with a specific problem.
- **Acquisition of social skills**: mastery of social and interpersonal skills through assertiveness or anger control.
- **Cognitive change**: modification of irrational beliefs and maladaptive patterns of thought.
- **Behaviour change**: modification of maladaptive behaviour.
• Systemic change: introducing change into family systems.

Counselling is a widely used term and is a form of therapy or intervention that includes a wide range of theoretical models. There are many different definitions, each emphasizing specific aspects of the counselling role and processes practised in a multiplicity of settings. Counselling embodies psychodynamics, cognitive-behavioural and person-centred approaches.

There are various treatment options, the choice of which depends on the nature and extent of the problem and the approach that may appear more appropriate and suitable for a particular drug user. The options include:

- non-directive counselling;
- cognitive-behavioural therapy (CBT);
- family dynamics;
- group therapy;
- motivational enhancement.

Non-directive counselling comprises the following components:

The patient determines the content and direction of the counselling and explores conflict and emotions at the time. While allowing empathic reflection, the counsellor does not offer advice and feedback.

A cognitive-behavioural approach assumes that the patient would like to change and analyses the situations that cause drug use, so that these can be altered. Problem-solving techniques, self-monitoring, anger management, relapse prevention, assertiveness training, the acquisition of social skills, and the modification of irrational beliefs or patterns of thought or behaviour are used. Individual, group and family therapies used in the treatment of addiction problems are often based along cognitive-behavioural lines.

Social network behaviour therapy considers the social environment to be important in the development, maintenance and resolution of substance problems. It maximizes positive social support, which is central to the process. The therapist offers advice and feedback and thereby facilitates change in the patient’s social world. Behaviour is not interpreted, and engagement with significant others is key in bringing about change and achieving goals.

Family therapy involves attempts to understand and interpret family dynamics in order to change the psychopathology. Substance use is perceived as a symptom of family dysfunction and, therefore, altering the dynamics brings about change in the substance misuse. Family members are viewed as contributory to the problem. Behavioural and psychodynamic techniques may be used in family therapy.

Participation in self-help groups is an important feature of many treatment programmes, in which participants receive support from recovering members who often take members back to the negative consequences of substance misuse. A variant of group therapy is the 12-step approach. Central to the 12-steps philosophy is the idea that recovery from addiction is possible only if the individual recognizes his or her problem and admits that he or she is unable to use substances in moderation. Alcoholics Anonymous and Narcotics Anonymous are examples of groups that use the 12-step philosophy, where drug users have to abstain completely.

Recently, the most influential and popular form of treatment has been a brief or minimal intervention, known as ‘motivational interviewing’. This aims to build motivation for change. The focus is on a non-judgemental approach and the patient’s concerns about, and choices regarding, future drug use. The treatment thereby elicits strategies from the patient. Motivational enhancement directs the patient to motivation for change by offering empathic feedback and advice and information and selectively reinforces discrepancies that emerge between current behaviour and goals, in order to enhance motivation for change. Significant others play some role in the treatment, but it is not a central role. It is, by and large, a personal therapeutic situation where the individual’s motivation is seen as vital. It aims to alter the decisional balance so that the patient directs the process of change.

The key characteristics are best described by the acronym FRAMES:\textsuperscript{115}

- Personalized feedback or assessment results detailing the target behaviour and associated effects and consequences on the individual
- Emphasizing the individual’s personal responsibility for change
- Giving advice on how to change
- Providing a menu of options for change
- Expressing empathy through behaviours conveying caring, understanding and warmth
- Emphasizing self-efficacy for change and instilling hope that change is not only possible but also within reach.

Evidence is accumulating with regard to the benefits and cost-effectiveness of this type of intervention.\textsuperscript{116,117}

**Treatment effectiveness**

The first relatively long-term, prospective, observational study on outcome in drug misusers in the UK, the National Treatment Outcome Research Study (NTORS), has been under way since 1995.\textsuperscript{118} This study follows up 1075 drug misusers in two types of residential service (in-patient and residential units) and two kinds of community service (methadone reduction and methadone maintenance). The age range at baseline was 16–58 years, half of whom were responsible for caring for children.

It is important to note that the specific nature of the treatment modalities provided has not been identified or described in any depth or in detail. Opiates, amphetamines, cocaine, non-prescription benzodiazepines and alcohol have been assessed, and the impact of treatment on
psychological health, suicide, mortality and crime has been evaluated. In summary, the study has reported drug use, and injecting and sharing needles, as being reduced. Crime also decreased, with a concurrent improvement in physical and psychological health. However, 20 per cent of the study population continued to use daily, and 40 per cent continued to use once a week. Over a 5-year period, 62 people died, 80 were using two or more illicit drugs and were long-term users, and alcohol use remained at a constantly high level. There was a history of treatment for psychiatric disorder in the 2 years before treatment; in the 3 months before treatment, 30 per cent had suicidal ideation.

NTORS found that over 27,000 acquisitive criminal offences were reported by the cohort examined in the 3 months before starting treatment. Shoplifting was the most common offence. Ten per cent of the sample was responsible for three-quarters of the crimes committed. Frequency of illicit drug use was associated with increased levels of criminal behaviour. Since high-rate offenders were more likely to be regular users of heroin and were three times more likely to have used cocaine regularly, management of this most severely affected group would be important to reduce offending.

At 5 years, 33.3 per cent and 50 per cent of users had achieved abstinence in community and residential services, respectively. However, 20 per cent of users were still using daily. Although 40 per cent used illicit drugs regularly, this had reduced from 66 per cent at intake in the residential services and from 80 per cent in community services. In summary, daily and regular use were found in 20 per cent and 40 per cent, respectively. Likewise, injecting reduced from 60 per cent to 40 per cent, criminal activity halved, and 25 per cent of users were drinking above safe limits. This evidence is encouraging, despite the limitations in the design described above. The study points to some value in the treatment programmes that are being implemented in the UK. This study was on an adult population and so does not include vulnerable groups such as teenagers and older people.

Therefore, despite advances in the effectiveness of pharmacological and psychological treatments for substance misuse, ‘it is not clear that these findings will generalise to comorbid major depression and alcohol dependence’, as evidence for effective psychological treatment for co-morbidity is still limited. Combined treatments (pharmacological and psychological, or two types of pharmacological treatment) are just beginning to be evaluated in substance-misusing and co-morbid populations. A meta-analysis found that only 14 randomized controlled trials (RCTs) have been carried out in people with both depression and alcoholism. This is surprisingly few trials for two such common conditions. Furthermore, the evidence suggests that, although antidepressants may improve mood, it is not clear that there is a commensurate impact on alcohol consumption. Even ‘effective’ treatments are not effective for all those who seek help, and not all who need help will seek it.

The most comprehensive review at the time of writing considered both psychological and pharmacological treatments for substance misuse associated with depression, anxiety, schizophrenia, bipolar disorder and severe mental illness. Fifty-nine studies met the standards for inclusion, of which 36 were RCTs. Although there was no clear evidence of superiority of any intervention over the comparison treatment for both psychiatric disorder and substance misuse, and treatments had not been replicated, the review did demonstrate that effective treatments for psychiatric conditions tended to reduce psychiatric symptomatology, and effective treatments for substance misuse tended to reduce substance use. However, the value of integrated treatment was not substantiated.

Despite the fact that there may be more treatment options and services available, these are not as accessible or available as is required, particularly for some especially vulnerable groups. Since both mental health and substance problems may be chronic conditions, treatment cannot be conceptualized or presented as a ‘cure’, but rather should be considered as support and care that can improve some substance, health and psychosocial outcomes. There is an increasing emphasis on engagement of the service user and carers, on focusing on the community rather than the hospital setting, on continuity, responsiveness and flexibility in care, and on attempting to integrate educational and employment options and accommodation needs, as well as special relationships within the treatment framework. Some of these issues are targeted in models of treatment within the criminal justice system (see below).

DETOXIFICATION PROCEDURES FOR IN-PATIENTS AND OUT-PATIENTS

Opiates

Before embarking on detoxification from opiates, it is advisable to ensure that the patient is fully committed and well informed about the process and is aware of the risk of relapse. Current guidance suggests that the patient should be in a stable supportive social situation or have arrangements in place for this to occur after detoxification. Plans for continuing support should have been finalized.

Guidance on opioid detoxification has been published by the National Institute for Health and Clinical Excellence (NICE), and clinicians should use this as the basis for treatment interventions. In summary, this guidance states the following:

- Methadone or buprenorphine should be offered as a first-line treatment in opioid detoxification, taking into account both the user’s preference and the benefit of starting detoxification with the medication that is already being used.
Addiction psychiatry

- Lofexidine may be suitable for those who do not wish to use either of the above or who want a more rapid detoxification.
- Clonidine and dihydrocodeine should not be used routinely.
- The treatment should last for up to 4 weeks in a residential setting and up to 12 weeks in a community setting.
- Ultra-rapid and rapid treatment should not be offered routinely, and ultra-rapid detoxification under anaesthesia must not be undertaken.
- In-patient detoxification is suitable for patients with complex needs, such as severe physical or mental health problems and concurrent detoxification for alcohol or other drugs. There must be 24-h medical and nursing support.

The management of detoxification for patients with drug problems within a residential setting is seen in the guidelines as a community-based service unless:

- the user has not responded to a community-based detoxification previously;
- there are significant co-morbid physical or mental health problems;
- the user will need complex detoxification, for example where they will need detoxification from a combination of substances;
- there are particular social problems that are a contraindication to a community-based detoxification.

Although rapid and ultra-rapid detoxification have been the subject of some research, with conflicting results, the current guidance is clear that ultra-rapid detoxification under general anaesthesia or heavy sedation carries a high risk of death and must not be offered.

ASSESSMENT AND MANAGEMENT OF NON-SUBSTANCE ADDICTIVE BEHAVIOURS AND RELATED SYNDROMES

The concept of non-substance addictive behaviours has been the focus of much discussion and is currently part of the agenda for the forthcoming revision of the DSM. The application of an addictive behaviour model to activities such as gambling has a long history, although current diagnostic classifications use the concept of an impulse control disorder rather than an addictive model. The advent of the Internet and an exponential increase in access to information and resources has produced the added concept of ‘Internet addiction’. The Internet has been described as ‘both the means and the object of addiction’, and in a wide-ranging review of the concept the authors expressed concern that the proposed development of diagnostic classification based on medical models was premature and lacked an evidence base. Their concern also extended to the use of the concepts in medicolegal cases.

RECOGNITION OF SUBSTANCE MISUSE-RELATED MEDICAL, PSYCHIATRIC AND SOCIAL COMPLICATIONS AND THEIR IMPACT ON PUBLIC HEALTH

Screening and assessment

The aim of screening and assessment measures is to achieve accurate diagnosis and to assist in the development of a relevant management plan. Without rigorous detection, problems will be missed or attributed inappropriately, and the treatment or care response may be inadequate, incorrect or even neglectful as a result. Factors that improve the efficiency of assessment and screening include:

- the experience and environment of the assessment;
- a high index of suspicion;
- a robust assessment process, including taking a thorough history;
- the use of appropriate screening and assessment tools.

This is relevant whether the presentation is to social services or to health, mental health or substance misuse services, and it is important to have a clearly defined and agreed approach in a multidisciplinary context, with continual interaction and collaboration across services. The use of a common assessment framework should be seen as standard good practice. This will reduce the risk of multiple but similar assessments, which are exhausting and unnecessary, and will ensure a common understanding of terminology, definitions, approaches, interventions and outcome expectations. Any improvement in the user acceptability of assessment processed is to be welcomed, particularly as there is evidence that only half of those who require help ask for it.

There are a range of instruments for the screening and assessment of different substances that can be utilized. These range from standardized tools and medical investigations (blood, urine, hair analysis) through to broader evaluation of factors that may affect the life experience and engagement in treatment of the service user, such as:

- occupational capacity;
- social functioning;
- relationship issues;
- readiness to change;
- motivation for change;
- educational and vocational skill assessment.

Social complications

Substance-related problems can have effects in a range of systems, such as health, education and the criminal justice
system. Medication non-compliance, substance abuse and severe mental illness are associated with violence, although violence perpetrated by severely mentally ill people accounts for a small proportion of violent acts in the community.\textsuperscript{134–137} Problems associated with dual diagnosis are associated with a poorer prognosis and greater disability. This includes a greater likelihood of medical, psychiatric and social problems that arise as a result of poor compliance with treatment, unplanned discharge, relapse and rehospitalization.\textsuperscript{138–140} Self-harm (often by overdose) and eventual suicide also have a strong association, as does early mortality. It is recognized, for example, that service users with dual diagnosis, who constitute 27 per cent of suicides, are treated inadequately.\textsuperscript{141–143}

Drug-related violent crime can be divided between violence arising from the effects of the drug, violence associated with the interaction of a psychiatric illness and drug use, violence associated with acquisition of drugs, and violence associated with disputes between drug users, dealers and gangs.\textsuperscript{31} There is evidence to suggest that a combination of psychosis and co-morbid use of drugs results in a higher rate and severity of violence than in a population with psychosis and no co-morbid substance use.\textsuperscript{144} Reviews of heroin users have also indicated that high rates of aggressive behaviour in this group may be independent of their use of heroin and, rather, related to personality factors that are associated with a risk of heroin dependence.\textsuperscript{145}

Substance misuse is commonly associated with a range of social problems, such as:

- homelessness;
- economic deprivation;
- unemployment;
- crime and violence;
- victimization;
- family problems;
- childhood abuse.\textsuperscript{146–149}

As a result of these complications, co-morbid service users present to a range of services, including:

- primary care;
- secondary care;
- general medical services;
- surgical services;
- mental health services;
- social care services;
- education;
- housing;
- employment services;
- social work (child protection and adult services);
- criminal justice system.\textsuperscript{150–153}

It has been noted that the emotional and socioeconomic issues that accompany substance misuse often constitute the major barriers to recovery, both for the individual and for their families.\textsuperscript{154}

**KEY POINTS**

- The UK has among the highest levels of substance misuse in Europe.
- The situation is dynamic, and it has become well recognized that combinations of substances may be misused, including two of the most commonly encountered licit substances, alcohol and nicotine.
- Drug use is affected by age, gender, geographical location, price, fashion, availability, regulations, and cultural and societal values.
- There are a variety of theoretical models that are used to explain initiation and continuation of drug use.
- Substance use and misuse are best viewed through the framework of a multifactorial biopsychosocial model. Age, role, gender, social group and peer pressure, the family, community and occupational environment, and overall cultural values and controls on substance use all act upon substance-taking behaviour.
- Substances impact on every organ system of the body, including the gastrointestinal, cardiovascular, respiratory, musculoskeletal and endocrine systems and the CNS.
- It is well recognized that patients with severe mental illness are especially at risk of substance misuse. In studies of patients attending mental health services in the UK, 10 per cent of patients treated by community mental health teams reported problematic use of illicit drugs and 17 per cent reported alcohol problems in the past year.
- Overall, these studies demonstrate that drug misusers present to a wide range of services, that their problems are not detected, and that failure to recognize their problems may result in inappropriate treatment and recurrence of health issues, since at least one associated factor, the drug misuse, is not being treated effectively.
- There is extensive documentation of the association of substance misuse and psychiatric disorder in young people. The major diagnostic groups to emerge are affective disorder (bipolar depression, major depression, anxiety, panic, phobias and post-traumatic stress syndrome), personality disorders (conduct, borderline and antisocial) and attention deficit disorders.
- Pregnancy in a woman who is misusing substances is risky, both for her and the fetus. Pregnant drug users are frequently underweight, anaemic and socially disadvantaged. They are often poor attendees at antenatal clinics, and young users tend to present to maternity services late in their pregnancies.
- Since both mental health and substance problems may be chronic conditions, treatment cannot be conceptualized or presented as a cure but rather should be considered as support and care that can improve some substance, health and psychosocial outcomes.
- Substance-related problems can have effects in a range of systems, including health, education and the criminal justice system. Medication non-compliance, substance abuse and severe mental illness are associated with violence, although violence perpetrated by severely mentally ill people accounts for a small proportion of violent acts in the community.

ASSESSMENT OF CHILDREN AND ADOLESCENTS

Assessment is conducted in the context of the developmental level of the child or the adolescent and with the appreciation of multiple perceptions and concerns. Most specialist child and adolescent mental health services (CAMHS) in the UK, after receiving a referral, consider it in a multidisciplinary setting. Often the whole family gets invited, as different family members may have different views, and parents and carers are key to the decision-making process.

The assessment interview should be conducted in a child- and family-friendly environment. Who should be present in the meeting may depend on the purpose of the meeting and the age and wishes of the child. For example, young children usually prefer the presence of one or both parents, while teenagers may wish to have an opportunity to talk on their own. It is essential to establish a good rapport with the young person and their carers. An important aspect of any assessment is an understanding of the young person and their family’s strengths, abilities, resilience, coping strategies, and things that are going well.

Assessment interview

The following subheadings act as a useful guide to the areas one should enquire about from parents, the child/adolescent, or both together:

- **Reason for referral:**
  - Presenting complaint

- **Present situation:**
  - Emotional state
  - Cognitive function
  - Sleep
  - Eating
  - Habits of elimination
  - Behaviour
  - Somatic complaints

- **Early developmental history:**
  - Birth and infancy
  - Mother’s health during pregnancy
  - Drug treatment, date, place, mode of birth and birth weight

- **Temperament**
- **Milestones, e.g. age at sitting, walking, first words, first sentences, bowel and bladder control, acquisition of independence with dressing, crossing the road, eating habits**
- **Play**

- **Medical history:**
  - Serious medical illnesses and surgery
  - Medication and other treatments
  - Problems with vision or hearing
  - Past psychiatric/psychological problems

- **Family circumstances:**
  - Draw a family tree
  - Who has parental responsibility?
  - Parents’ (biological and/or step-parents) history, particularly of medical and psychological problems
  - Siblings’ history of medical and psychological problems
  - Parental and other family relationships
  - Other important relationships in extended family
  - Contact arrangements between child and divorced/separated parent if applicable

- **Social circumstances:**
  - Interests, hobbies, structured activities
  - Peer relationships
  - General social functioning
  - Home conditions
  - Family income and financial situation

- **School history:**
  - Behaviour at school
  - Attitude of parents towards school
  - Attitude of child towards school
  - Academic achievement
  - Learning or other academic difficulties
  - Permission to get a school report

**Other agencies involved:**
- Enquire about time, reason and nature of previous contacts
- Social services
- Education, including involvement of educational welfare, educational psychologist or emotional behavioural support service (EBSS)
- Paediatrics
- Other mental health/counselling services
● Other agencies, including voluntary
● Current legal status

**Forensic history:**
● Description of any current or previous offences
● Convictions
● Attitudes to offending
● Contacts with youth justice system

**Interview with the child:**
● Use of play materials, drawings, stories, wishes and so on may be helpful with younger children
● Understanding and perception of the problem
● Motivation for change
● Interests and hobbies
● Friendships
● Child’s ideas on what they would like to achieve therapeutically
● Child’s ideas on how positive change might happen
● Mental state

**Interview with the adolescent:**
● Same as interview with the child, but with further areas for enquiry
● Substance-misuse history
● Psychosexual history
● Identity and self-concept.

### Psychometric assessment

Some clinicians supplement the information gained at interview with a variety of psychometric questionnaires (usually given to the parent or teacher of the child). However, this should be done with caution as, apart from questionnaires designed to measure intelligence, such questionnaires have usually been designed for use in epidemiological and other types of research and are thus of questionable clinical utility. Some of the commonly used instruments include the following:

- Child Behavior Checklist (CBCL)\(^1\)
- Conner’s Rating Scales – Revised\(^2\)
- Strengths and Difficulties Questionnaire (SDQ)\(^3\)
- Wechsler Intelligence Scale for Children, 3rd edition (WISC-III), for measuring intelligence quotient (IQ).\(^4\)

### Assessment of the family and broader context

There are many different schools of family therapy; each has its own approach and attitude towards family assessment:

- **Structural family therapy:** focuses on the structure and power dynamics within a family and examines issues such as generational boundaries, alliances and closeness/distance of family members. The purpose of such assessments is to frame interventions aimed at changing family structure, such as addressing distorted power hierarchies, for example where a child is considered too powerful at home.
- **Systemic therapy:** interested in the dynamics of various systems in which the child is embedded, for example the family, the neighbourhood and the school. The child’s problems may be viewed as, at least in part, being a product of dysfunction in the system, or the collective resources in the system are viewed as something that can be harnessed to solve a problem. Thus, treatment may focus little on changing the child and more on changing the dynamic in the system.
- **Strategic family therapy:** interested in the games people play in their relationships and uses this to devise creative and unique strategies, for example ‘prescribing’ a parent and child who avoid expressing their strong feelings towards each other to practise arguing.
- **Brief solution-focused therapy:** interested in finding out how a young person and his or her family have already solved problems that confronted them. Assessments tend to focus more on what the child and family wish to see change than the presenting problem and its history. Treatment then focuses on goal-setting and using existing problem-solving abilities to find practical ways to achieve these.
- **Narrative therapy:** explores the subjective experience of family members through understanding how each has constructed (individually and together) a set of narratives about themselves, the problem and its relationship to them. Treatment then involves a carefully negotiated process of trying to reshape this narrative away from those aspects that emphasize dysfunction and towards reconnecting with narratives of resilience and coping.

These are just a few of the more well-known schools of family therapy. What this ‘family’ of therapeutic approaches have in common, though, is scepticism towards narrow medical model approaches that locate dysfunction only in the child. Family therapy has its own rich and varied literature, and familiarity with family therapy approaches is an important part of becoming a competent child and adolescent psychiatrist.

Another area where all mental health clinicians are now expected to have knowledge, skill and capability is that of working with children and families from different cultural backgrounds. Assessments must consider families’ cultural beliefs and practices without imposing the values and practices of the dominant Western culture or, conversely, excusing abusive practices as being ‘cultural’. Treatment then involves (but is not limited to) utilizing the family’s existing belief’s, practices and resources to promote positive change in a culturally congruent manner.\(^5\)

### Diagnostic formulation

The place of diagnosis in its narrow sense (i.e. identification by a medical provider of a condition or disease) remains controversial in child and adolescent psychiatry, as practice in this area has changed rapidly in recent years due largely to ideological and cultural changes rather than scientific
advances. In its broader sense, the term ‘diagnosis’ refers to a ‘critical analysis of the nature of something’, and thus a diagnostic formulation avoids the pitfalls of a narrow focus and use of single-word diagnoses. A diagnostic formulation involves a statement about the nature of the presenting problem, identification of risk factors (predisposing/vulnerability, precipitating, maintaining) and protective factors (strengths, resilience, coping) in the child, the family and the broader context, together with relevant aspects of the assessment that will shape the treatment plan (such as those outlined above; see Assessment of the family and broader context).

**EFFECTS OF ADULT MENTAL ILLNESS ON CHILDREN**

The impact of adult (e.g. a parent’s) mental illness or disorder on children is dependent on a variety of factors, such as the nature, severity and duration of the illness, the impact on the adult’s functioning, and the degree to which the illness affects the parent–child relationship. Children may experience frequent separations, uncertain relationships, not being looked after properly, having to look after the parent, being upset, frightened or worried about what may happen to that parent, feeling ashamed, or being teased or bullied by other children. Such children are also more likely to experience other environmental factors associated with increased incidence of child psychiatric disorder, such as parental substance misuse, poverty, poor housing and family instability (see Effects of early and continuing experience on later child, adolescent and adult development and functioning, below). About 175 000 young people in the UK are involved in the care of an adult with mental illness.

**Effect of depression and other psychiatric symptomatology on parental functioning, and the impact of this on child development and functioning**

Neither the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) nor the *International Classification of Diseases*, 10th revision (ICD-10) refers to postnatal mental disorders as formal diagnostic categories; however, mental and behavioural disorders associated with the puerperium are widely recognized in practice and usually start within 6 weeks of birth. Over half of all women feel very emotional in the first week after birth. This is often referred to as the ‘baby blues’ and usually passes away. In more severe or persistent cases, this can progress to postnatal depression. Postnatal depression usually begins within a month of birth, but it can start as late as 6 months after birth. Generalized anxiety disorder has also been found to be higher in postpartum women than in the general population.

Teenage mothers are more likely than older women to have an insecure attachment and are more likely to experience postnatal depression. Women who have experienced early maternal separation and a low level of maternal care have a higher risk of postnatal depression, as do women who have been abused. The extra burden of caring for a sick baby increases the risk of postnatal depression, as do isolation and lack of social support during or after pregnancy.

Postnatal depression can affect the baby in a variety of ways. In severe cases, it contributes to infant abuse, infanticide and suicidal behaviour. It can affect interpersonal communication, emotional expressiveness and responsiveness to the baby. The mother can become hostile and intrusive, or withdrawn and disengaged, resulting in impairment in mother–infant bonding. Social adversity compounds these effects. Sometimes mothers with postnatal depression experience a distressing lack of maternal feeling, irritability, hostility, aggressive impulses, and pathological ideas about and sometimes outright rejection of the baby. Thus, normal infant development is at risk, and the infant may become fussier, vocalize less, make fewer positive facial expressions, and experience growth problems. Postnatal depression can affect breastfeeding initiation and duration, as there is a complex relationship between maternal identity, breastfeeding and psychological distress.

A variety of parenting practices have been found to be associated with parental depression, including not initiating age-appropriate safety and child development practices, and using more harsh discipline practices for toddlers. Psychiatric effects on children of mothers with maternal postnatal depression include behaviour disturbance, physical ill-health, insecure attachments, depressive symptoms, poor attention, sleep disturbance, eating problems, social problem-solving deficits and poor intellectual development. Male children appear to be more vulnerable than female children. The association between behaviour problems in the child and maternal depressive symptoms has been found to vary according to social support available to the mother and the amount of involvement others have in the care of the child.

**Puerperal psychosis**

Puerperal psychosis is a more serious condition that usually starts within days or weeks of birth and affects approximately 1 in 500 mothers after birth. There are rapid and extreme changes of mood, withdrawal or overactivity, severe sleeplessness, delusions or unusual experiences. It is more likely if there is a past history or family history of serious mental illness. Puerperal psychosis can manifest as any of the three main psychotic disorders – mania, depression or schizophrenia. It is associated with a higher risk of adverse outcomes for children, including infanticide.

**Cultural variations in aetiology and management**

The UK government has come to view developing cultural competence in mental health services as a priority.
However, the development of services that have a comprehensive understanding of cultural variations in beliefs and practices and their implication for clinical work remains in its infancy. Greater knowledge and appreciation of cultural diversity also create opportunities for learning about different beliefs, practices and social organizations that can potentially help children and families from a variety of backgrounds.28

For example, the prevalence and impact of postpartum depression varies cross-culturally.29 Although postpartum depression occurs in 10–20 per cent of women in the UK and the USA, it is considered rare in Chinese populations, Fiji and some African populations.30 Structured social supports after childbirth are described in groups of women with low rates of postpartum depression.30 In traditional Chinese society, women’s bodies are considered weak in the month after childbirth, and the mothers are prohibited from working and visiting. Extra help is brought in: often, the woman’s mother or mother-in-law helps with domestic duties, looks after the family and offers advice. Studies in Hong Kong show lower levels of depression at 3 months in women who have this support, although this is dependent to some degree on who offers the support and whether this leads to conflict with the mother.31

With regard to psychosis, studies have shown consistently that outcome from schizophrenias is routinely better in developing world settings, a difference that becomes apparent during the initial 2 years of illness.32 Although extended families can be tyrannical as well as supportive, and most are living in conditions of greater poverty than in developed countries, family involvement, engagement and low criticism appear to be important positive factors contributing to a positive outcome, casting doubt on the stereotype that mental illness is associated with greater stigma in the developing world.32 It is likely, therefore, that even severe mental illness in a parent may have a less detrimental impact on children in developing countries, particularly where positive family support is available, although this issue has not been investigated adequately.

One of the most widespread adversities is the experience of parental discord and divorce. The divorce rate varies internationally, with North America and northern Europe having the highest rates globally. Based on annual statistics of marriages and divorce in the USA, it is anticipated that about 50 per cent of first marriages for people under age 45 years may end in divorce.34 The divorce rate in the UK has been relatively stable for the past couple of decades, at 12–14 divorces per 1000 married couples per year.35

Poverty is associated with behaviour problems and poorer cognitive functioning. Parental alcoholism, antisocial behaviour and mental illness (such as schizophrenia and major depression) are associated with slower child development and child psychiatric disorders such as conduct disorder, attention deficit hyperactivity disorder (ADHD) and childhood depression.33 Many of the risks associated with adversities co-occur (e.g. poverty, parental psychopathology, marital discord), further increasing the loading for the development of emotional and behavioural problems in the offspring.

Long-term implications of early insecure attachment

Attachment theory was first developed by the British psychoanalyst John Bowlby.36 Attachment theory provides a framework for understanding not only the emotional development of children from birth to adolescence and into adulthood but also the development of a variety of mental health problems and a psychotherapeutic framework for working with children and their caregivers.37 Attachment refers to an intense emotional relationship between two people that endures over time, with any prolonged separation leading to distress.18 Development of distress in infancy, and the interpersonal mechanisms by which it can be regulated through attachment relationships, has received significant theoretical consideration. According to attachment theory, early interactions become internalized into an inner working model shaping perceptions, thought and behaviour. A secure attachment helps with the regulation of internal states (e.g. affect, arousal) within an interpersonal context. Adults’ representations of their early attachment relationships are believed to predict patterns of parenting and attachment in the next generation (i.e. between them and their offspring).

Three specific patterns of infant–caregiver attachment – secure, insecure–ambivalent and insecure–avoidant – were originally identified based on reactions to the ‘strange situation’ laboratory task. The ‘strange situation’ entails observation of infant behaviour during a series of separations and reunions with the caregiver.39 The original studies using the strange situation with infants found that about 70 per cent of infants demonstrate a secure attachment to their main caregiver, 15 per cent an avoidant (insecure) attachment and 15 per cent an ambivalent (insecure) attachment.39 Insecure attachment by itself does not mean that the child will necessarily develop psychopathology but

A substantial body of research has found that rates of emotional and behavioural disturbance in children and young people are associated strongly with environments that create persistent stress for the young person or their family. The most notable of these chronic adversities are poverty, parental psychopathology, parental death, interparental discord, community violence, child maltreatment, entry into the care system (such as foster care) and persistent or chronic medical illness.31
leads to an increased vulnerability to psychopathology in the presence of environmental stress.

Many studies demonstrated associations between ambivalent infant attachment and later mental health problems. According to this research, ambivalently attached infants are prone to develop chronic levels of anxiety later in life. This may be due to unpredictable and irregular responsiveness of the caregiver, leading to a fear of separation or abandonment in the infant, which in turn creates a coping strategy centred on chronic vigilance. This may then continue throughout childhood and adulthood and lead to the development of anxiety or behavioural disorders.

There are three broad criticisms aimed at the idea of attachment and its implications of maternal deprivation leading to psychopathology. The first is that Bowlby overstated his case. The studies on which he based his conclusions involved almost complete lack of maternal care, and it was unwarranted to generalize from this that lesser degrees of separation in the first 3 years of life would be damaging. The idea of exclusive care or exclusive attachment to a preferred figure rather than a hierarchy thus places too high an emotional burden on the mother. Second, Bowlby’s theory viewed through a historical perspective can be seen as idealizing motherhood and family life after the traumas of the Second World War. Third, Bowlby’s theory derives primarily from observations in a nuclear family culture. Thus, it is argued that anthropology has shown that it is normal for childcare to be shared by a stable group of adults, of which maternal care is an important but not exclusive part. Studies attempting to deal with these critiques have provided support for both attachment theory and its critics, for example finding that children who spent their early years in institutions have more emotional and behavioural problems, but also that early loss of the main attachment figure does not necessarily lead to psychopathology that persists into adulthood. However, considerable scepticism remains as to the generalizability of attachment theory, particularly in non-Western and non-nuclear family contexts.

Although attachment insecurity has been found to be a risk factor for later development of psychopathology, its predictive value is poor. However, the more recent proposal for a fourth category of attachment – disorganized attachment – has, some authors argue, increased the potential clinical relevance of attachment theory. Disorganized attachment has been found to have a base rate in low risk families of about 15 per cent but up to 80 per cent in high-risk groups. Disorganized attachment refers to a pattern in which the proximity-seeking behaviour of the infant or child can become disguised, indiscriminate, disorganized and even hostile or violent.

Under the category of ‘Disorders of social functioning with onset specific to childhood and adolescence’, ICD-10 includes two subcategories that explicitly refer to attachment. ‘Reactive attachment disorder of childhood’ has an onset before 5 years of age; the clinical features include strongly contradictory or ambivalent social responses that extend across social situations (but may show variability from relationship to relationship), lack of emotional responsiveness, withdrawal reactions, aggressive responses to the child’s own or others’ distress, and fearful hypervigilance that does not respond to comforting (frozen watchfulness). The clinical features of ‘disinhibited attachment disorder of childhood’ include attention-seeking and indiscriminately friendly behaviour, poorly modulated social interactions with unfamiliar people and peers, lack of normal tendency to seek comfort from others when distressed, and lack of selectivity in the people from whom comfort is sought. There is often a history of frequent changes in caregivers or institutional upbringing from infancy, resulting in unstable attachment figures during the first 5 years of life.

**Short- and long-term effects of other negative life events on development and functioning**

**Maternal loss**

The loss of a parent by death poses a significant developmental challenge on the dependent child. Rates of exposure to parental loss during childhood vary across the world. This affects the meaning attached to parental death and the coping mechanisms that develop to deal with it. For example, in parts of the world where death of a parent is more common, families often have well-developed social networks and extended family support allowing for not only an increase in the availability of other carers to take on child-rearing of a youngster well known to them but also the development of more complex identities in carers who may see their own and other extended family members’ children as their direct responsibility.

In Western countries, 1.5–4 per cent of children are orphaned of at least one parent during childhood. Studies of Western populations show that disruption of early attachment through death increases the risk of the child developing an attachment disorder, anxiety, depression and other emotional disorders of childhood and adolescence.

**Child abuse**

The consequences of experiencing abuse depend upon a variety of variables, such as the nature of the abusive act, its frequency, intensity and duration, the relationship between the child and the abuser, the characteristics of the child, others’ response to the abuse, and other associated factors. Consequences of abuse include:

- hypothalamic–pituitary axis dysregulation;
- physical harm, including death, life-threatening injuries, long-term physical impairment, or from Munchausen by proxy syndrome, where a parent (about 95% female) feigns, exaggerates or induces illness in the child;
- psychological consequences, such as aggression, anxiety, depression, attachment disorders, post-traumatic stress, substance abuse and psychosis;
• social consequences, such as family disruptions, entering the care system and excessive hospitalization.

The degree of impact of the abuse on the child’s life and development is mediated by the degree to which daily functioning is affected and the availability of positive supportive relationships in the child’s life. In addition, different types of abuse produce different challenges. For example, sexual abuse can result in a complex interaction between traumatic sexualization, sense of betrayal, sense of powerlessness, guilt, self-blame and self-loathing, behavioural problems, deliberate self-harm, genital/anal injury, sexually transmitted disease, unwanted pregnancy, sexualized behaviour, prostitution, peer relationship problems, educational underachievement, and entry into the care system. In adulthood, such a history can lead to anxiety, depression, self-harm, drug and alcohol abuse, poor sexual functioning, difficulty with maintaining intimate interpersonal relationships, distrust, eating disorders and problems with being a parent.

Child abuse is also discussed below (see Child protection).

Chronic or life-threatening illness
Chronic illness and disability are associated with increased prevalence of psychiatric disorders. Approximately 30–40 per cent of children with a severe paediatric illness also have a co-morbid psychiatric disorder. Illnesses affecting the brain have a stronger association with subsequent and concurrent psychiatric disorders compared with physical illness that does not affect the brain. In Rutter and colleagues’ classic Isle of Wight study, rates of psychiatric disorder were 44 per cent among children with structural brain disorders, 29 per cent among children with idiopathic epilepsy, 12 per cent among children with non-cerebral physical disorders and 7 per cent among children free from physical disorders.

CLASSIFICATION AND EPIDEMIOLOGY OF CHILD AND ADOLESCENT PSYCHIATRIC DISORDERS

Classification
The two main systems currently used for classifying child and adolescent psychiatric disorders are ICD-10 and DSM-IV. These versions are more similar in their approach to classifying child and adolescent psychiatric disorders than previous versions. Both adopt a multi-axial classification system, although the extent to which this is used in clinical practice is variable.

International Classification of Diseases, 10th revision
ICD-10 is divided into blocks of diagnostic groupings. Blocks F80–F89 (disorders of psychological development) and F90–F98 (behavioural and emotional disorders with onset usually occurring in childhood and adolescence) cover disorders that are specific to childhood and adolescence. A number of disorders placed in other categories can occur in people of almost any age and so can be used for children and adolescents when required. Examples are disorders of eating, sleeping and gender identity. Disorders categorized elsewhere and more commonly found in people over 18 years of age, such as schizophrenia and obsessive-compulsive disorders, can also be used for such presentations in people under 18 years of age.

ICD-10 recommends that clinicians should follow the general rule of recording as many diagnoses as are necessary to cover the clinical picture. When recording more than one diagnosis, ICD-10 advises giving one precedence over the others by specifying it as the main diagnosis and labelling any others as subsidiary or additional diagnoses.

The main ICD-10 categories relevant to child and adolescent psychiatry are as follows:

- F70–F79 Mental retardation:
  - F70 Mild mental retardation
  - F71 Moderate mental retardation
  - F72 Severe mental retardation
  - F73 Profound mental retardation
  - F78 Other mental retardation
  - F79 Unspecified mental retardation

- A fourth character may be used to specify the extent of associated behavioural impairment:
  - F71.x.0 No, or minimal, impairment of behaviour
  - F71.x.1 Significant impairment of behaviour requiring attention or treatment
  - F71.x.8 Other impairments of behaviour
  - F71.x.9 Without mention of impairment of behaviour

- F80–F89 Disorders of psychological development:
  - F80 Specific developmental disorders of speech and language
    - F80.0 Specific speech articulation disorder
    - F80.1 Expressive language disorder
    - F80.2 Receptive language disorder
    - F80.3 Acquired aphasia with epilepsy (Landau-Kleffner syndrome)
    - F80.8 Other developmental disorders of speech and language
    - F80.9 Developmental disorder of speech and language, unspecified
  - F81 Specific developmental disorders of scholastic skills
    - F81.0 Specific reading disorder
    - F81.1 Specific spelling disorder
    - F81.2 Specific disorder of arithmetical skills
    - F81.3 Mixed disorder of scholastic skills
    - F81.8 Other developmental disorders of scholastic skills
    - F81.9 Developmental disorder of scholastic skills, unspecified
Classification and epidemiology of child and adolescent psychiatric disorders

Part 6: Clinical specialties

- F82 Specific developmental disorder of motor function
- F83 Mixed specific developmental disorders
- F84 Pervasive developmental disorders
  - F84.0 Childhood autism
  - F84.1 Atypical autism
  - F84.2 Rett's syndrome
  - F84.3 Other childhood disintegrative disorder
  - F84.4 Overactive disorder associated with mental retardation and stereotyped movements
  - F84.5 Asperger's syndrome
  - F84.8 Other pervasive developmental disorders
  - F84.9 Pervasive developmental disorder, unspecified
- F88 Other disorders of psychological development
- F89 Unspecified disorder of psychological development
- F90–F98 Behavioural and emotional disorders with onset usually occurring in childhood and adolescence:
  - F90 Hyperkinetic disorders
    - F90.0 Disturbance of activity and attention
    - F90.1 Hyperkinetic conduct disorder
    - F90.8 Other hyperkinetic disorders
    - F90.9 Hyperkinetic disorder, unspecified
  - F91 Conduct disorders
    - F91.0 Conduct disorder confined to the family context
    - F91.1 Unsocialized conduct disorder
    - F91.2 Socialized conduct disorder
    - F91.3 Oppositional defiant disorder
    - F91.8 Other conduct disorders
    - F91.9 Conduct disorder, unspecified
  - F92 Mixed disorders of conduct and emotions
    - F92.0 Depressive conduct disorder
    - F92.8 Other mixed disorders of conduct and emotions
    - F92.9 Mixed disorder of conduct and emotions, unspecified
  - F93 Emotional disorders with onset specific to childhood
    - F93.0 Separation anxiety disorder of childhood
    - F93.1 Phobic anxiety disorder of childhood
    - F93.2 Social anxiety disorder of childhood
    - F93.3 Sibling rivalry disorder
    - F93.8 Other childhood emotional disorders
    - F93.9 Childhood emotional disorder, unspecified
  - F94 Disorders of social functioning with onset specific to childhood and adolescence
    - F94.0 Elective mutism
    - F94.1 Reactive attachment disorder of childhood
    - F94.2 Disinhibited attachment disorder of childhood
    - F94.8 Other childhood disorders of social functioning
    - F94.9 Childhood disorder of social functioning, unspecified
  - F95 Tic disorders
    - F95.0 Transient tic disorder
    - F95.1 Chronic motor or vocal tic disorder
    - F95.2 Combined vocal and multiple motor tic disorder (de la Tourette’s syndrome)
    - F95.8 Other tic disorders
    - F95.9 Tic disorder, unspecified
  - F98 Other behavioural and emotional disorders with onset usually occurring in childhood and adolescence
    - F98.0 Non-organic enuresis
    - F98.1 Non-organic encopresis
    - F98.2 Feeding disorder of infancy and childhood
    - F98.3 Pica of infancy and childhood
    - F98.4 Stereotyped movement disorders
    - F98.5 Stuttering (stammering)
    - F98.6 Cluttering
    - F98.8 Other specified behavioural and emotional disorders with onset usually occurring in childhood and adolescence
    - F98.9 Unspecified behavioural and emotional disorders with onset usually occurring in childhood and adolescence.

Diagnosis of each condition is based on a judgement that the emotions or behaviour being categorized lie outside the usual range found for age and sex of the child/young person and that personal functioning or development is impaired.

ICD-10 employs a multi-axial framework for child and adolescent psychiatric disorders:

- Axes I: clinical psychiatric disorders
- Axes II: specific disorders of development
- Axes III: intellectual level
- Axes IV: medical conditions
- Axes V: abnormal psychosocial conditions
- Axes VI: global social functioning.

Diagnostic and Statistical Manual of Mental Disorders, 4th edition

DSM-IV is a categorical classification system. The categories are ‘prototypes’, and a patient with a close approximation to the prototype is said to have that disorder. DSM-IV states that there is no assumption that each category of mental disorder is a completely discrete entity with absolute boundaries. Qualifiers are sometimes used, for example mild, moderate or severe forms of a disorder. For nearly half the disorders, symptoms must be sufficient to cause clinically significant distress or impairment in social, occupational or other important areas of functioning.

DSM-IV organizes each psychiatric diagnosis into five levels (axes) relating to different aspects of disorder or disability:

- Axes I: clinical disorders, including major mental disorders, and developmental and learning disorders
- **Axis II:** underlying pervasive or personality conditions, and mental retardation
- **Axis III:** medical conditions and physical disorders
- **Axis IV:** psychosocial and environmental factors
- **Axis V:** global assessment of functioning.

Under ‘Disorders usually first diagnosed during infancy, childhood or adolescence’ the following are found:

- **Mental retardation:**
  - 317 Mild mental retardation
  - 318.0 Moderate mental retardation
  - 318.1 Severe mental retardation
  - 318.2 Profound mental retardation
  - 319 Mental retardation, severity unspecified

- **Learning disorders:**
  - 315.00 Reading disorder
  - 315.1 Mathematics disorder
  - 315.2 Disorder of written expression
  - 315.9 Learning disorder not otherwise specified (NOS)

- **Motor skills disorders:**
  - 315.4 Developmental coordination disorder
  - 315.31 Expressive language disorder
  - 315.32 Mixed receptive–expressive language disorder
  - 315.39 Phonological disorder
  - 307.0 Stuttering
  - 307.9 Communication disorder NOS

- **Pervasive developmental disorders:**
  - 299.00 Autistic disorder
  - 299.80 Rett’s disorder
  - 299.10 Childhood disintegrative disorder
  - 299.80 Asperger’s disorder
  - 299.80 Pervasive developmental disorder NOS

- **Attention–deficit and disruptive behaviour disorders:**
  - ADHD
  - 314.01 Combined subtype
  - 314.01 Predominantly hyperactive–impulsive subtype
  - 314.00 Predominantly inattentive subtype
  - 314.9 Attention–deficit hyperactivity disorder NOS
  - Conduct disorder
  - 312.81 Childhood onset
  - 312.82 Adolescent onset
  - 312.89 Unspecified onset
  - 313.81 Oppositional defiant disorder
  - 312.9 Disruptive behaviour disorder NOS

- **Feeding and eating disorders of infancy or early childhood:**
  - 307.52 Pica
  - 307.53 Rumination disorder
  - 307.59 Feeding disorder of infancy or early childhood

- **Tic disorders:**
  - 307.23 Tourette’s disorder
  - 307.22 Chronic motor or vocal tic disorder
  - 307.21 Transient tic disorder
  - 307.20 Tic disorder NOS

- **Elimination disorders:**
  - Encopresis
  - 787.6 Encopresis, with constipation and overflow incontinence
  - 307.7 Encopresis, without constipation and overflow incontinence
  - 307.6 Enuresis (not due to a general medical condition)

- **Other disorders of infancy, childhood, or adolescence:**
  - 309.21 Separation anxiety disorder
  - 313.23 Selective mutism
  - 313.89 Reactive attachment disorder of infancy or early childhood
  - 307.3 Stereotypic movement disorder
  - 313.9 Disorder of infancy, childhood, or adolescence NOS

**Epidemiology**

**Classic studies**

Rutter and colleagues’ Isle of Wight study on 10- and 11-year-olds found that:

- 6.8 per cent had a diagnosable psychiatric disorder;
- 4 per cent had a conduct disorder and 2.5 per cent had an emotional disorder;
- the ratio of boys to girls among those with a psychiatric disorder was nearly 2:1;
- 2.5 per cent had an IQ below 70;
- 5.7 per cent of the children had a physical disorder, with higher rates of psychiatric disorder found in those with a physical disorder.

A study with similar methodology in inner London found twice the rate of psychiatric disorders among 10- and 11-year-olds than in the Isle of Wight.

Richman and colleagues’ study of 3-year-olds in Waltham Forest, London, found that:

- behavioural problems were common, including bedwetting (37%), daytime wetting (17%), poor appetite (17%), regular night-time waking (14%), difficulty settling at night (13%), soiling (13%), strong fears (13%) and overactivity (13%);
- 7 per cent were classed as having moderate to severe behaviour problems;
- prevalence was roughly equal in boys and girls;
- associated factors (with behavioural problems) included speech and language delay, maternal depression, poor parental relationship and psychosocial adversity.

**More recent studies**

Based on an international literature review, the prevalence of mental disorder in community surveys is reported to be around 20–30 per cent of school-age children, but this figure drops to 12–15 per cent when only moderate to severe (clinically significant) diagnoses are considered.
In a study by the Office for National Statistics of 5- to 15-year-olds, a rate of around 10 per cent for all mental disorders was found. About 5 per cent had a conduct disorder, 4 per cent an emotional disorder and 1 per cent a hyperkinetic disorder. Less common disorders such as autism and eating disorders occurred in about 0.5 per cent. Psychiatric disorders were more common in lone-parent families, reconstituted families, families with more than five children, children of unemployed parents, families in social class V, and families where the parents were social sector tenants.

In the New Zealand child survey, by 11 years of age the prevalence for any psychiatric disorder was found to be approximately 18 per cent. At 15 years of age, approximately 25 per cent of young people met DSM-IV criteria for one of the main mental disorders. At 18 years of age, 45 per cent met criteria for one or more disorder.

These large international variations highlight the difficulties of interpreting the findings due to differing methodologies and variations in the way mental disorders are defined and categorized.

**AETIOLOGY OF CHILD PSYCHIATRIC DISORDERS**

Knowledge about aetiology is hampered by several factors, including lack of physical or psychological markers for any of the major psychiatric disorders of childhood; differing definitions and categorization; differing interpretations of clinical significance and impairment; cultural relativity and the social construction of diagnostic categories; lack of international studies; differences in meaning attributed to different symptoms by different communities; and the cultural nature of developmental frameworks. One problem is that definitions of disorder rely on definitions of normality; however, cross-disciplinary literature demonstrates that our concepts of childhood, parenting and child development vary enormously cross-culturally and even within Western culture (particularly over time), and thus any system that attempts to impose a universal definition of ‘normality’ (and thus, by implication, mental disorder) is going to encounter difficulties.

However, a number of factors that increase the risk for emotional and behavioural problems in children and adolescents have been found and replicated. These factors include poor-quality family relationships, school experiences and community environments, and poor physical health. These factors are also associated with poorer treatment outcomes. These and other potential associations of possible aetiological significance can be subdivided into biological and psychosocial risks.

**Biological risks**

There is little replicated and undisputed evidence to confirm that common child psychiatric disorders are genetic or related to some form of neurodevelopmental dysfunction or chemical imbalance in the brain. Space does not permit a wider discussion of these complex issues; however, a brief discussion on genetic evidence will give a flavour of the nature of the controversies.

For disorders that child psychiatrists are likely to be asked to assess and manage, hyperkinetic disorders, autism-spectrum disorders (ASD), schizophrenia and anorexia nervosa are the disorders for which evidence for having strong heritability and thus a genetic basis are most frequently claimed. The basis of the evidence comes from familial, twin and adoption studies. All these types of study suffer from numerous methodological problems. Because of the greater methodological problems associated with familial and adoption studies, the main source of information for estimating the relative genetic contribution to heritability comes from twin studies. In twin studies, the difference in the degree to which monozygotic (MZ) twins share a diagnosis compared with dizygotic (DZ) twins forms the basis for estimating the genetic contribution for that particular diagnosis. As MZ twins have all their genes in common whereas DZ twins on average share half their genes, the greater the similarity in MZ than DZ twins, the stronger the genetic contribution. However, for this statement to be true, one has to assume that MZ and DZ twins share the same environment. This is termed the ‘equal environment assumption’ (EEA). It is accepted that EEA does not hold, as research has demonstrated that being an MZ twin produces psychosocial differences (e.g. MZ twins report more sharing, are more likely to have the same friends, are more likely to be dressed alike, report more identity confusion, and so on, compared with DZ twins). Critics thus contend that twin studies are, as a result, no better than other studies (e.g. family studies) at separating out genetic from environmental factors. Supporters of the twin study method retort that we can still use this method if the violation of EEA is not in the traits or disorder under study. Critics in turn respond by arguing that, when it comes to psychological and behavioural features, it is not possible to speak of ‘trait-specific EEA’, as psychosocial life does not conform to linear causality, and thus all one needs to prove is that EEA does not hold, and therefore twin studies cannot be used to discover genetic contributions to psychiatric disorders unless a reliable physical marker is found. (For a more detailed overview of these arguments, see the books by Jay Jospeh and Michael Rutter). In addition to these limitations, the lack of identifying consistent genetic linkages to any child psychiatric disorder means that, at present, genetics is of little clinical relevance to the child psychiatrist.

As outlined above (see Chronic or life-threatening illness, physical illnesses, particularly those affecting the brain, increase the risk for comorbid psychiatric disorders. In addition, children with low IQ and children with specific learning difficulties show increased co-morbid psychiatric disorder (see Mental handicap and developmental disorders, below).
Gender as a risk (with boys being at higher risk of childhood psychiatric disorders, particularly externalizing disorders such as ADHD, conduct disorder and autism) remains a relatively and surprisingly unexplored area. We simply do not know whether the higher rates of diagnosis of these behavioural disorders reflect biological differences or societal attitudes and in what way these two factors interact.60

Psychosocial adversity

As outlined above (see Effects of early and continuing experience on later child, adolescent and adult development and functioning, above), a range of adversities, including poverty, parental discord, parental psychopathology, disrupted attachments and violence, are associated with an increased likelihood of developing a psychiatric disorder. In addition, other factors that may increase the likelihood of subsequent psychiatric disorder include environmental factors such as living in an urban setting, poor social networks, going to a school with high rates of behavioural problems, and bullying. Some cross-cultural research finds considerable differences in prevalence rates, with children in politically stable developing countries appearing to have lower rates of child psychiatric disorders;65,64 however, urbanization and modernization may be associated with an increase in the prevalence of behavioural disorders in these populations.65

CHILD PROTECTION

The changing needs of developing children

Concepts of what a child needs at different stages are highly dependent on the model of child development being applied. Our beliefs about what ‘normal’ child development looks like have continued, and continue, to change over time in Western cultures;66 in addition, important differences are apparent in different traditions’ beliefs and practices about children and their development.43,67,68 For example, one study found that Indian social work professionals, more than American social work professionals, considered a wider range of adult sexual behaviours and media images to be seriously abusive to children. However, these Indian professionals did not consider physical ‘mal-treatment’ to be as seriously abusive as their American counterparts did.69 Another example relates to the use of physical punishment on children: Sweden, which has made physical chastisement of children a criminal offence, is often cited as a positive example; however, examination of various morbidity and mortality figures shows Swedish children to be somewhere in the middle of league tables for rich countries.70 For example, rates of death from child maltreatment in Sweden at 0.6 per 100 000 children are much higher than those in countries that fare best in these tables, namely Spain (0.1/100 000) and Greece and Italy (0.2/100 000), which have not outlawed corporal punishment but which, interestingly, have family-oriented cultures.71

The question of how to draw up an ethical framework that provides adequate protection to all children and is able to encompass a proper respect and understanding of this cultural diversity remains an emotive and challenging one. Who has the power and authority to set standards and decide what is acceptable morbidity becomes a loaded issue.72 Western cultures have a framework that emphasizes rights of the child, and many non-Western cultures also emphasize the responsibilities of the child.28 Adolescence in many Western cultures is characterized by conflict and the striving for independence, but in many other cultures it is characterized by ambivalence and an exchange of loyalty for protection.66 There are many other examples of significant cross-cultural differences in the needs of children at different ages, from birth to adulthood. Although it is imperative that every clinician understands, adheres to and explains to families the child protection laws in the country in which they work, every child and family also deserves a competent understanding of this cultural variation in order to properly understand the intentions behind the actions of those in authority towards children, and children towards those in authority.
