Adam Zeman DM FRCP
Professor of Cognitive and Behavioural Neurology, Peninsula Medical School, Exeter, UK
Among the many demands on modern psychiatrists is keeping up to date with the ever-increasing pace of the development of psychiatric knowledge in recent years, both in the biological and psychosocial spheres. The basic sciences of psychology, neuroanatomy, neurophysiology, neuroendocrinology, neuroimaging, neuropathology, genetics, biochemistry, pharmacology, neuroscience, epidemiology and social sciences have now led to a better understanding of the basic mechanisms underlying clinical disorders. Sub-specialties of psychiatry have rapidly developed and the practice of psychiatry has increasingly moved from institutions to the community. Clinicians are now under pressure to deliver high quality cost-effective patient-focused care based upon the best evidence available.

The aim of this volume is to provide an up-to-date, solid, evidence-based text. Many of our contributors are acknowledged international leaders in their respective fields, have often been centrally involved at the forefront of shaping psychiatric research and practice and have, as a result, a first-hand feel of the evidence base of their contributions. The strength of the evidence base does still vary widely in different fields of psychiatry, but with the development of national guidelines, systematic reviews and meta-analyses, individual, sometimes idiosyncratic, clinical practices of the past are now no longer acceptable unless based on evidence. Thus, even if not entirely evidence based, psychiatry should always be evidence informed. Psychiatrists who increasingly work in multidisciplinary teams and whose practice is now increasingly challenged by other professionals, managers and, indeed, patients, now have to be able to defend the evidence base to their practice, if they are to maintain their medical leadership role in psychiatric practice.

In this book, we aim to comprehensively describe the basic sciences and clinical disorders and their treatments – using the UK and Ireland MRCPsych syllabus as a guide – while emphasising the evidence underlying theory and practice for the topics covered. However, we believe that this book will cater not only for trainee psychiatrists studying for the MRCPsych examinations, but also for trainees elsewhere and, indeed, will provide a valuable resource for psychiatrists who have completed their training and other professionals who work in psychiatry.

To facilitate the aim of this project, the book is divided into major sections and 79 chapters in a carefully considered order. Chapters have been standardised and cross referenced and include important and up to date references and generous use of tables, figures, boxes and pictures. At the end of each chapter major learning points are identified. While the book strives to provide an integrated overview of current knowledge through its sections and chapters, chapters have also been designed to stand alone, which inevitably implies some overlap in content between chapters which we hope has been kept to an acceptable minimum.

We hope this book will achieve wide acceptance through its succinct, user-friendly approach and its recognition of the importance of a solid evidence base for psychiatric practice. While a text book alone does not make a good psychiatrist, we hope this one will provide the sound foundation of evidence-based theoretical knowledge required for the competent practising clinician of today.

Basant K Puri
Ian Treasaden
We would like to warmly thank our contributors for their excellent contributions, delivered often on tight deadlines. We would also like to thank our publishers Hodder, including the Commissioning Editor, Philip Shaw, and the Project Editors, Amy Mulick and Joanna Silman, for their encouragement and always helpful assistance. We also wish to thank our Publisher, Caroline Makepeace. We would additionally like to thank Susan Oxlade for her administrative and secretarial assistance.
PART 1

The foundations of modern psychiatric practice
INTRODUCTION
Psychiatric illness seems intrinsic to – and a necessary part of – being Homo sapiens, so it is not surprising that there are descriptions of abnormal behaviour, and even of symptoms resembling schizophrenia, in the earliest written fragments of Egypt, India and Babylon. Some evolutionary theorists consider psychosis to be inextricably linked to the genetic mutation(s) for our enlarged frontal lobe, with its unique capacity for memory and imagination. A history of psychiatry has to understand therefore how ‘mental’ symptoms – presentations of madness, sadness, foolishness, strangeness – were understood in all societies and accepted, or not, and what was done, or not, to help the sufferers.

There is thus a long history of mental illness consisting of 3000 years of random descriptions (in religious writings, legal documents, diaries, histories, romances and plays), and a shorter and more technical/medical history of practical psychiatry, in terms of professionalized attempts to understand, diagnose and treat mentally ill people. The long history precedes even the Bible and Classical Greece, while the short history starts some 200 years ago (at least in European terms), a product of the scientific advances of the Enlightenment, industrialization and city life. Supernatural ‘apparitions’ become secularized ‘hallucinations’, and psychopathology begins to erode the varieties of religious explanation.

HISTORIOGRAPHY – i.e. WHAT’S BEEN WRITTEN ABOUT IT
This chapter concentrates on the past two centuries as being essential to understanding what drives modern psychiatry. Just as taking a history is the key to psychiatric diagnosis, so knowing how and why we are at our present state of knowledge and organization helps us to make sense of our current work. In itself, the topic ‘the history of psychiatry’ has undergone a radical change in the past 30 years, from the obscure jottings of retired psychiatrists to a thriving subspecialty of modern historical research. It has its own quarterly journal, History of Psychiatry (first published in March 1990), its own European Association and a body of dedicated academic historians. The standard heavyweight tomes, such as The History of Psychiatry by Alexander and Selesnick (1966), have been replaced by more svelte versions, such as Edward Shorter’s (1997) A History of Psychiatry: From the Era of the Asylum to the Age of Prozac, and diagnosis-based compilations such as A History of Clinical Psychiatry: The Origin and History of Psychiatric Disorders (Berrios and Porter, 1995). There has also been a series of reprints of core psychiatric textbooks and careful descriptions of whole eras of change, for example Andrew Scull’s (1979) Museums of Madness, subtitled The Social Organisation of Insanity in Nineteenth Century England. Details of the most substantial histories of psychiatry, and the most influential secondary texts and textbooks (or versions thereof) are given in Tables 1.1–3.

Most importantly, there has been a prolonged, sometimes bitter but generally creative debate since the rise of the so-called ‘anti-psychiatry movement’ of the 1960s and 1970s as to what is even meant by a ‘history of psychiatry’ or a ‘history of insanity’ or of ‘madness’, and so on. Traditionally it had been the recording of notable forms of mental illness, whether in literature (e.g. Shakespeare’s King Lear or Othello) or medical writings, accompanied by outlines of new diagnostic or treatment approaches, with admiring biographies of the leading doctors (not always medical) who had tried to help or even ‘cure’ the afflicted mad folk. This so-called ‘meliorist’ history – things getting better, in terms of more accurate diagnoses, more thoughtful doctors (and attendants/nurses) and more humane treatments – was challenged in the writings of social theorists such as Michel Foucault and Andrew Scull (see Table 1.2).

Foucault postulated a ‘Great Confinement’ in the seventeenth and eighteenth centuries, whereby the world of free-thinking and imaginative ‘unreason’ had been corralled by the mechanistic warriors of reason and social control. Psychiatrists and the psychiatric enterprise were even seen as a kind of thought police of this dark Enterprise. Mental illness was theorized as ‘socially constructed’, a means of rounding up the deviants and low life in society rather than a genuine part of medical practice dealing with real diseases. This debate goes on, has involved historians, psychologists, anthropologists, lawyers, sociologists and even a few psychiatrists, and has now swung back to some degree
towards a general acceptance that there, probably, is such a thing as mental illness.

The key research has been into archival sources such as asylum records (going back to the mid-nineteenth century and sometimes earlier), the casebooks of individual doctors, for example the famed eighteenth-century ‘mad-doctor’ and physician to Bethlem (‘Bedlam’) Hospital, John Monro (1715–91), the writings of psychiatric patients themselves, and Table 1.1 Ten histories of psychiatry

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tuke DH (1968; reprint of 1882 edn)</td>
<td><em>Chapters in the History of the Insane</em>, Amsterdam: Bonset</td>
<td>The original heroic nineteenth-century history, written as a celebration of Victorian achievement in building asylums and rescuing ‘lunatics’ from the neglect and abuse of whips, chains and supernatural beliefs.</td>
</tr>
<tr>
<td>Zilboorg G, with Henry GW (1941)</td>
<td><em>A History of Medical Psychology</em>, New York: Norton &amp; Co.</td>
<td>Zealously pro-Freudian (‘the second psychiatric revolution’), this is written in the classic ‘great men’ style of history but has good details and nice photographs. Psychoanalysis is seen as the cure for all mental illness and more.</td>
</tr>
<tr>
<td>Alexander FG, Selesnick ST (1966)</td>
<td><em>The History of Psychiatry</em>, New York: Harper &amp; Row</td>
<td>The standard of its time but also in awe of Freud, more than half being devoted to the ‘Freudian Age’. Much material from classical/medieval times, but unreliable in details. For example: ‘It does not seem probable that pharmacological and biological methods will throw more light upon the complex phenomena of interpersonal relationships and replace psychological methods of treatment’</td>
</tr>
<tr>
<td>Jones K (1993)</td>
<td><em>Asylums and After: A Revised History of the Mental Health Services – From the Early Eighteenth Century to the 1990s</em>, London: Athlone Press</td>
<td>Describing how services developed, this is the best analysis of the rise and fall of the asylums, with special insight into the social, legal and political influences on psychiatry, including the deinstitutionalization of the past 50 years. Very critical of the weaknesses of ‘care in the community’.</td>
</tr>
<tr>
<td>Scull A (1993)</td>
<td><em>The Most Solitary of Afflictions: Madness and Society in Britain 1700–1900</em>, New Haven, CT, and London: Yale University Press</td>
<td>An updated version of the author’s groundbreaking <em>Museums of Madness</em> (1979), which introduced a radically new take on psychiatry as representing social power and social control, thus reinforcing the status quo via an often doubtful construct of ‘mental illness’. A challenging way of looking at history, even if you disagree.</td>
</tr>
<tr>
<td>Berrios G, Porter R (eds) (1995)</td>
<td><em>A History of Clinical Psychiatry: The Origin and History of Psychiatric Disorders</em>, London: Athlone</td>
<td>A multi-author volume reviewing the clinical and social history of our understanding of the major mental disorders (e.g. dementia, schizophrenia, anxiety), including neuropsychiatric conditions and the epilepsies. Not for reading through, but it is well referenced, and individual topic chapters (e.g. post-traumatic shock disorder, shell shock) are fascinating.</td>
</tr>
<tr>
<td>Fuller Torrey E, Miller J (2001)</td>
<td><em>The Invisible Plague: The Rise of Mental Illness from 1750 to the Present</em>, Piscataway, NJ, and London: Rutgers University Press</td>
<td>A spirited and informative outline concentrating on the theory that severe schizophreniform mental illness represents a modern epidemic due to industrialization and urbanization. Diet, toxins, infectious agents (related to vaccination?) and even pet cats are among the postulated aetiological agents. Or is this retrospective history gone too far?</td>

and court records dealing with, for example, insane murderers. If you are prepared to hunt around in medieval documentation – and that is hard work, in terms of finding and even reading the material, which is often in Latin – and in dusty library records, a much more nuanced picture of how madness has been dealt with through the ages can be extracted, albeit often in bits and pieces, like the shards of pottery from an archaeological dig.

For example, if we consider how people deemed to be ‘mad’ or ‘lunatic’ were dealt with in Shakespeare’s time (1564–1616), whether in his plays or in the plays of his contemporaries, it is not a lot different from today. Recognizing

<tbody>
<tr>
<td>Pinel P (1801)</td>
<td><em>A Treatise on Insanity</em> (trans. DD Davis), New York: Hafner Publishing</td>
<td>An outline of ‘maniacaal disorders’, including an attempt at classification and numerous case histories. A humane, detailed and easy-to-read masterpiece – the first modern textbook with delightful descriptions of treatments, theatrical(s), and moral and physical approaches to managing very disordered people.</td>
</tr>
<tr>
<td>Maudsley H (1867)</td>
<td><em>The Physiology and Pathology of the Mind</em>, London: Macmillan</td>
<td>A much admired textbook outlining the physical basis of mental disease as opposed to the ‘metaphysical’ theorizing that tended to dominate public discussion. Maudsley was a bluff Yorkshireman with a sarcastic tongue, but he was widely read in the French and German literature. Although much quoted, it was probably not practically used by working psychiatrists of his time.</td>
</tr>
<tr>
<td>Freud S (1900)</td>
<td><em>The Interpretation of Dreams</em> (trans. J Strachey 1976), London: Pelican Books</td>
<td>The classic Freud text on his theory of the unconscious, dreams being considered essential to understanding one’s inner mental life. From this he moved on to developing his highly influential theories of childhood sexuality and the ‘Oedipal complex’ of character development. Lots of examples, but not ‘scientific’, although claimed as such.</td>
</tr>
<tr>
<td>Kraepelin E (1904, 1905, 1912 – very popular)</td>
<td><em>Lectures on Clinical Psychiatry</em> (ed. T Johnston), London: Bailliere, Tindall and Cox</td>
<td>Summarizing the classic and groundbreaking textbook – Kraepelin in fact produced eight editions of his Lehrbuch from 1886 to 1924, which first described dementia praecox as a distinct psychotic disorder. His distinction between dementia praecox/schizophrenia and manic-depressive insanity continues to dominate diagnostic categories today.</td>
</tr>
<tr>
<td>Sargant W, Slater E (1944)</td>
<td><em>An Introduction to Physical Methods of Treatment in Psychiatry</em>, Edinburgh: Livingstone</td>
<td>The (wartime) classic of biological psychiatry, trumpeting the use of insulin therapy, electroconvulsive therapy (ECT), chemical sedation, malaria treatment and prefrontal leucotomy, as opposed to psychotherapy, to which the authors barely paid lip service. Biology red in tooth and claw, claiming mental disorders as ‘dependent on physiological changes’.</td>
</tr>
</tbody>
</table>
mental illness was based on people's behaviours, what they said and what they perceived (e.g. Lady Macbeth's recurrent and obsessional hand-washing), doctors are called to attend them (e.g. Dr Caius in The Comedy of Errors), and disordered brains are seen as part of the problem ('canst thou not minister to a mind diseased ... raze out the written troubles of the brain ...', asks Macbeth of his physician). Confinement in madhouses, or 'dark houses' (e.g. Malvolio in As You Like It), or somewhere out of the way, is a common resort. We even have, in the character of Tom O'Bedlam in the play King Lear a vivid description of someone pretending to be mad. This is the eventual hero, Edgar, who in order to avoid entrapment and murder hides out half-naked, gibbering to himself and expressing a range of symptoms that today are entirely consistent with what we call 'schizophrenia'. If that is what early-seventeenth-century play-goers recognized as mental illness, then it seems reasonably indicative of the persistence of what we call schizophrenia, over some 400 years or more, rather than it being (as some have postulated) a relatively new disease of the industrial age of the nineteenth century and beyond (see especially Fuller Torrey, in Table 1.1).

TREATING MENTAL ILLNESS: WHERE, HOW, WHO?

The past 200 years have seen the rise and fall of a standard approach to mental illness – the asylum. Founded as a vehicle for delivery of what was essentially a structured psychosocial intervention, namely the 'moral treatment', the asylum has dominated psychiatric practice since the mid-nineteenth century – throughout the world – and only in the past 30 years has it become subservient to the notions of 'community care'. In fact the asylum arose because of the failures of community care – troubled souls wandering the countryside and dying of starvation, or being chained up in cellars or attics (à la Rochester's wife in the 1847 novel Jane Eyre) or unreliable private madhouses. The combination of Quaker concern, evangelical Christianity and the bricks-and-mortar solution of Victorian industrialization demanded that the 'pauper insane' be placed in large sanctuaries, i.e. the asylums, rather like medieval lepers in leprosaria. The rise of modern risk management and the medium-secure unit (MSU) are merely a replication of this process under a new guise. 'Normal' folk distrust (and exploit) 'mad' folk – thus the unique role of the psychiatrist in negotiating the relationship.

There is also during this period the development of a specialist profession, from a few scattered individuals, good-hearted clergymen looking after people in their houses, to the organization of medico-psychological associations and the first regular journals (e.g. The Asylum Journal in 1854, now the British Journal of Psychiatry). The troubled story of the development of psychiatry reflects another essential theme, namely stigma, the fear of the insane, and the difficulties their case has met in terms of resources, trained staff, research-based treatments and integration back into 'normal' society. Even today many doctors and nurses qualify, all over the world, without having partaken in any genuine psychiatric training or practice.

Yet psychiatry, one of the first true specializations in medicine, actually spawned the subspecialty of neurology and is the branch of medicine most outward-looking in terms of its relationship with sociology, psychology, criminology, the law, architecture, and social and working life. It has its heroes and its villains of course, more of the former than the latter, and has been cruelly mocked, not least in modern cinema (e.g. Hannibal Lecter in The Silence of the Lambs in 1991) and for indulging in what are termed 'desperate remedies' such as lobotomy and electroconvulsive therapy (ECT). But much retrospective criticism, which rarely comes from mainstream historians, often fails to understand how difficult it always has been to cope with chronic, unremitting, progressive psychosis.

The journey from essentially social and institutional treatments (e.g. asylums) to various psychological approaches (e.g. Sigmund Freud and friends), and on to the 1950s rise of psychopharmacology, is full of iconic stories. Philippe Pinel (1745–1826), the father of French psychiatry, unchaining the insane in 1792, in the middle of the chaos of the French Revolution (a battalion of soldiers hiding round the back of the hospital in case all hell broke loose); John Conolly (1794–1866) introducing, against mocking scepticism, non-restraint to the enormous Hanwell asylum (his monograph on non-restraint was published in 1856); the unravelling of 'general paralysis of the insane' (GPI) as in fact an infectious disease, tertiary syphilis, and its response to malaria therapy researched and developed by Julius Wagner-Jauregg (1857–1940), psychiatry's first Nobel Prize winner; the shell shock debate during and after the First World War (was it physical, a form of brain damage, or nervous, or cowardice even?), and the million or more war pensions generated; the transformed acute wards of the 1950s and the reported great interest of the nursing personnel when chlorpromazine, a 'neuroleptic', was introduced. These are mainly true, and some of the key historical themes are outlined in Table 1.4.

THE WORLD OF BEDLAM PRE-1800

Biblical and classical writings give many descriptions of people going mad, mainly kings and heroes such as Saul, Nebuchadnezzar and Ajax (who ran amok and slaughtered a herd of sheep). The long-influential Greco-Roman physician Galen (c. AD 129–200) reinforced the Hippocratic doctrine of the humoral theory – the four humours (i.e. visible bodily secretions) being phlegm (tears or sweat), blood, yellow bile (choler) and black bile (= ‘melancholia’ in Greek), imbalances of which were seen as the basis of all
disease, physical or mental. Most of the latter came under the terms ‘mania’ and ‘melancholia’, people being overexcited by too much blood/choler or slowed down by too much phlegm or black bile. In the West the rise of Christianity led to the elaboration of supernatural and later witchcraft theories, mental illness even being seen as a punishment for wickedness, despite Jesus Christ ‘casting out devils’ from madmen, as regularly reported in the four Gospels.

From the fall of Rome to the Renaissance, such notions became a fixed part of approaches to treatment. The agrarian poor looked to holy shrines, magic potions, wise women or necessary beatings. The ‘furious’ mad were tied up in cells or driven from parish to parish. Suicide was a sin – with a loss of possessions – and thus coroners’ juries increasingly tried to establish a non-compos mentis verdict, medicalizing the deed in order to avoid penalizing the family. Physicians might be sought for the wealthy (Henry...
VI, king of England from 1422 to 1461, when he heard ‘voices’ saw a learned doctor), with the use of laxatives (‘purging’) or bleeding as the standard approaches (to get rid of the excess humours).

With the Renaissance came a questioning of accepted ideas, with witchcraft trials (some 50,000 executions during the sixteenth and seventeenth centuries) providing one battleground. This European ‘witch-craze’ was fuelled by challenges to papal authority, for example by ‘Protestant’ preachers such as Martin Luther (1483–1546) or by scientists, such as Galileo Galilei (1564–1642) demonstrating that the earth went round the sun (not the other way round). Reactionary work appeared, famously Malleus Maleficarum (1486) written by two monks, Kraemer and Sprengler. A kind of handbook for witch-finding, this ‘Hammer of Evil-Doing’ was like a modern National Institute for Clinical Excellence (NICE) guideline, and it took a brave German physician, Johannes Weyer (1515–88), to produce the sceptical counterblast. His De Praestigiis Daemonum (‘The Devil’s Signs’) of 1563 suggested that mental illness, with its ravings and imaginings, was often and easily mistaken for witchcraft.

Were these disordered women – and they were mainly women – dangerous witches, needing to be burnt at the stake, or brain-sick lunatics? Regular physicians such as William Harvey (1578–1657), discoverer of the circulation of the blood and physician to King Charles I, had another role as detectors of witchcraft, advising courts on what was illness and what was not. His contemporaries included Richard Burton, author of the Anatomy of Melancholy (1621), an enormous compendium of exemplary cases – troubled minds, not necessarily ‘depressed’, in all their different lifestyles and presentations – and Richard Napier (see Table 1.2), an astrologer-cum-psychotherapist who gained a reputation for helping mentally ill people and whose notebooks still survive.

By about 1700 most of Europe was over its witch beliefs, and during the seventeenth and eighteenth centuries a rising demand for sympathetic treatment rather than incarceration demonstrated the swing from religious supernaturalism to rationalist and early scientific explanations. Now come the first medical writings on mental illnesses and the beginnings of the ‘mad-doctoring’ business. William Battie (1703–76), with his Treatise on Madness (1758) and a famous debate with John Monro (1715–91) as to the real basis of mental illness (deluded imagination or impaired judgement?), and George Cheyne (1671–1743), with his 1733 description of The English Malady, were the most famous of their time, doing very well for themselves in a seemingly lucrative trade. The better-off English middle classes had discovered neurosis.

Apart from a 1744 Vagrancy Act, however, the first law passed ‘for the better maintenance and care of Lunatics’ was in 1808, fear of mental illness creating shame and family cover-ups. When George III went mad in 1788, putting the constitution itself at peril, psychiatry was represented by a self-made Lincolnshire reverend/therapist, Francis Willis. The king was ‘knocked flat as a flounder’ via a behavioural regime that eventually brought him back to his senses, and he was even ‘cured’. Treatment of disease rather than punishment for sins gradually became the standard approach. Contemporary descriptions of Parkinson’s disease (in 1817), delirium tremens (in 1813) and the brains of post-mortem syphilitics (in 1822) demonstrated the physical basis of some (but not most) disordered behaviours.

**THE RISE OF THE ASYLUM 1800–1900**

The early private madhouses have few records, as privacy was required, but business flourished in the rising prosperity and urbanization of the eighteenth century. There had always been St Mary Bethlem (founded in 1247) – home of the Tom-of-Bedlams, wandering madmen, of myth and Shakespeare – and from the 1750s new charitable institutions (e.g. St Luke’s in London, the Bethel in Norwich) were set up. A flourishing area for private madhouses was around Shoreditch, Bethnal Green and Hackney in east London, some of them family businesses (‘Mr Balme’s House’) with lurid reputations. Concerns about maltreatment (patients left tied up in filthy, faeces-coated cots, and especially the death of Hannah Mills, in the York Hospital, led the local Quakers to set up, for their ‘brethren’, ‘the Retreat’, which became a European model. Not least this reputation was thanks to the masterly public relations of the 1813 Description of the Retreat by Samuel Tuke, outlining a form of treatment called ‘moral therapy’ based on kindness, reason, behavioural limits, exercise and activities, a family atmosphere and setting a good example.

In the year of the Battle of Waterloo (1815), there was also a widely reported Inquiry into Bethlem Hospital, detailing abuses and negligence, for example keeping one notorious patient in a metal contraption and chains for over 7 years (Figure 1.1). Especially scapegoated was the apothecary John Haslam, whose case study (1810) of Bethlem inmate James Tilly Matthews, Illustrations of Madness (see Table 1.3), is often quoted as the first description of a full-blown schizophrenia-type illness, with delusions, hallucinations and a bizarre range of other symptoms, including the patient’s belief in an infernal air loom machine, run by a dangerous gang, that could do things such as ‘thigh-talking’, ‘thought-making’ and ‘cutting soul from sense’. The ignorance of such disorders among the medical profession was a particular target of Haslam, since two prominent society physicians actually tried to have Tilly Matthews released, on the grounds that he was perfectly sane.

The resultant evangelical reform movement, led by the long-lived Lord Ashley, seventh Earl of Shaftesbury (1801–84), based on the principles of moral therapy, unchaining the insane (as Philippe Pinel in revolutionary Paris) and the
central role of the medical profession, created a specific therapeutic device for curing madness. This was the asylum, where ‘lunatics’ could be taken away from the hurly-burly of modern life (deemed to be driving them mad) and restored amidst fresh air, nice views, clean water and regular exercise. By 1845 every county in England had a statutory duty to build one (the Asylums Act). Such ring-fencing of money, for a particular specialty, has even been considered a kind of precursor to the start of the National Health Service (NHS), and over 120 asylums were eventually constructed in Britain (Figure 1.2), amidst a relentless rise in people deemed officially to be insane.

The psychiatric profession, throughout Europe, developed alongside the new asylums. Journals were founded, reports were published, posts were created and formal legal powers (certification) were introduced. Still readily stigmatized as ‘mad-doctors’ – hence the increasing fears about sane people being locked up for nefarious reasons (e.g. in novels such as *The Woman in White* by Wilkie Collins (1860) and *Hard Cash* by Charles Reade (1863)) – this new breed of ‘alienists’-cum-‘medical psychologists’ wrote and held meetings and lobbied Parliament, but treatment approaches remained basic. Apart from the traditional purging, bleeding, confinement and exercise, they had to resort to devices such as whirling chairs, mustard baths (hot and cold), leeches and even early forms of electricity. Laying open the scalp, filling the wound with various herbs and ointments, and letting it suppurate for a week or two was practised by Dr Prichard, author of the much admired *A Treatise of Insanity*, published in 1835. For sedating medication they
had only opium/morphine, chloral hydrate and, of course, cannabis indica and brandy (Table 1.5).

But these first-generation psychiatrists and asylum superintendents did have one advantage. They could watch diseases evolve as the lunatic asylums grew larger and larger (see Figure 1.2), and they could start to classify the diseases more clearly. From the hordes of deranged, crippled, feebly-minded, epileptic and dementing inmates that filled up every new asylum, and each newly built asylum extension, doctors began to sort out different conditions, psychiatric, neurological, metabolic (e.g. hypothyroidism) and nutritional. Every leading alienist would publish his system, with new words, new diagnoses and new theories of causation. Abandoning the basics of ‘mania’ and ‘melancholia’, they created moral insanity, neurasthenia, catatonia, hebephrenia, lactational insanity and numerous others. By 1892 Daniel Hack Tuke, from the same family of Quaker Tukes that had founded the Retreat 100 years earlier, was able to publish his two-volume Dictionary of Psychological Medicine. This defined and discussed several thousand terms and phrases used by his zealous European-wide colleagues (including 200 legal cases).

But the asylums themselves, with their crowded 100-bed wards, their poorly paid and often untrained attendants, their handful of ‘medical men’ – perhaps four or five for two or three thousand patients – and their farms, drains and outbreaks of dysentery and typhoid, became less and less therapeutic and more and more just ‘museums of madness’. Energetic superintendents burned themselves out trying to activate, morally treat, feed and semi-medicate their shuffling collections of ‘chronic dements’. Paperwork and certificates dominated their days and nights, and ruthless magistrates imposed admissions and economies. Doctors could not refuse admissions, since all ‘lunatics’ were certified by the courts and simply sent in without warning. Formal inspections, unpleasant sounds and smells (incontinence was rife), and even random assaults dominated their day, although by the 1900s football matches and cricket leagues were well established. The good and bad of asylum life is summarized in Table 1.6.

Even worse news was that the numbers of insane people were rising faster than the population was growing, leading to fears of ‘degeneration’ – a theory first espoused by BA Morel (1809–73), a leading French asylum physician – and even a qualitative decline of the human race. Further classifying people as ‘feebly-minded’ led to more building (the Binet-Simon tests of intelligent quotient (IQ) appeared in 1905) of ‘colonies’ (i.e. very large asylums) of ‘pauper imbeciles’ designed to segregate the degenerate and to stop them overbreeding. In the early twentieth century some countries even sterilized large numbers of the ‘mentally deficient’, with certain American states such as California leading the way. The rise of eugenics (i.e. the theory of selective breeding of healthy genes) and the 1930s Nazis’ attitudes to psychiatric patients, eliminating them as a precursor to the Holocaust, were the dark outcome of these developments.

The most positive effect of the asylums was the work of first-class researchers such as Emil Kraepelin (1856–1926). Using a computer-like system of library cards, he classified symptoms and followed their course, separating out dementia praecox (DP), a progressive, deteriorating psychotic disorder, from which patients seemed to recover. This distinction, despite many attempts at redefinitions, remains at the heart

*A twentieth-century term describing the effects on the individual of living in a controlled environment, with food, activities, contacts, clothes and time completely regimented by the needs of the institution.*
of modern diagnosis, despite the term ‘schizophrenia’ replacing ‘DP’ as the standard terminology by the 1950s, probably because of its connotations of understandable treatability.

THE TWENTIETH CENTURY: I – THE BIOMEDICAL MODEL

Research advances in the late nineteenth century, especially in bacteriology, even started to pay dividends for psychiatry. Some 10 per cent of inmates of asylums had GPI, namely syphilis of the brain. When Noguchi and Moore discovered the syphilitic organism in 1913 (the brain abnormalities of syphilis had been known since the 1820s), it was the first clear connection of a mental illness to a disease process. Linked in with nineteenth-century knowledge of the effects of trauma to the brain, nutritional deficiencies, thyroid disease (‘cretinism’), and the association between forms of epilepsy and types of hallucinations, a stronger line of research developed as to mental illness having a physical basis. Forget moral theories, ‘religious excess’ and the supernatural; here was cerebral disease generating crazy behaviours. Unfortunately this concentration on brain disorder did not generate much in the form of a biochemical marker or an effective treatment. Critics, often psychologists and psychotherapists, used the mocking term ‘brain mythology’.

The pre-1950s asylums were full of chronic psychotics (schizophrenics and manic depressives), but the neuroses such as anxiety, depression, obsessionality and sexual perversions also had their proposed physical associations. A range of drugs, operations and shock therapies, of varying scientific reliability, ensued. Numerous records, photographic and written, graphically describe what happened. These unfortunately mainstream remedies may seem comic or gothic, for example excising colons or adenoids in search of ‘focal infection’, or giving injections of monkey gland cells to boost libido, but they reflect the desperation of patients, patients’ families and physicians. The asylums had become enormous, crowded ‘Private Worlds’, as illustrated by Phyllis Bottome’s 1932 novel of the same name and by the 1948 Warner Brothers movie The Snake Pit. In 1944, the textbook Physical Methods of Treatment in Psychiatry (Sargent and Slater) included insulin treatment, convulsion therapy (i.e. ECT), chemical sedation with drugs such as bromides and stimulation via Benzedrine (amphetamine), narcotherapy, malarial treatment (for GPI: give the patient malaria and a high fever and kill off the bugs before killing off the patient) and prefrontal leucotomy.

In the 1950s the discovery of chlorpromazine, other antipsychotics and a range of antidepressants led to the psychopharmacological revolution (Tables 1.7 and 1.8) and even new diagnoses to fit the new formulations available. The rise of the international drug companies in the 1970s and 1980s, pushing products such as Prozac, became a stock market phenomenon. Such approaches also enabled the gradual closure of the asylums, towards what has been called ‘community care’, and an increasing sense of neglect in that the sanctuary provided by the old asylums was no longer available. The continued failure, despite billions of dollars spent, to establish a clear biological marker for schizophrenia, depression or any other mental illnesses (although some brain imaging techniques are showing promise) has created a semi-mythical feeling about the need for ‘counselling’. But the drugs do work, thus the now vociferous user movement and a rising anti-stigma campaign.

THE TWENTIETH CENTURY: II – PSYCHOLOGICAL APPROACHES

The asylums and classifications of the nineteenth century also led to a richer language of psychological description and a rising interest in psychological methods of treatment. Dominant personalities (among many) were Sigmund Freud (1856–1939) and Pierre Janet (1859–1947), the former’s Interpretation of Dreams being published (but largely unsold) in 1900. For reasons that are hard to understand – although playing the sex card helped? – Freudian psychoanalysis swept aside many of its rivals. Like the Bolsheviks
Part 1: The foundations of modern psychiatric practice

in revolutionary Russia, the diehard commitment of Freud’s followers created a new language of ‘id’, ‘ego’, ‘transference’ and ‘Oedipus complex’, loved by intellectuals and fitting the zeitgeist of post-First World War Europe. The shell shock of tens of thousands of previously ‘normal’ young men also helped to strengthen beliefs that mental illness was not due to heredity or degeneration, but rather was the understandable effects of a hellish environment, trench warfare. The treatment of the poet Siegfried Sassoon by the British psychoanalyst WHR Rivers (1864–1922), at Craiglockhart Hospital, is especially well documented.

Although basing his theories upon some half a dozen famous cases, such as the Wolf Man (Serge Pankaev, who died in 1979 having wandered around Europe, uncured, looking for help from many other therapists), Freud’s approach to individual psychotherapy became the shibboleth of the cultured middle classes, especially in the USA. Despite schismatic alternatives developing under the leadership of Carl Jung (1875–1961) – the founder of analytical psychology and theories about archetypes – and Alfred Adler (1870–1937) – inventor of the inferiority complex, elaborated in *The Nervous Character* (1912) – the notion of the psychiatrist as a German Jewish professorial figure who put you on a couch while listening silently became the standard image. Even so, an undercurrent of – often misinformed – critical attitudes towards psychoanalysis persisted in mainstream medicine, not helped by some of the cruder approaches about childhood sexuality made by Freudian disciples such as Ernest Jones, who had to go off to Toronto to get away from the paedophilic taint. Scepticism also met the Freudians’ beliefs that they could even ‘cure’ serious psychoses such as ‘schizophrenia’. Given the looseness of that diagnostic term (i.e. the mistaken notion of a ‘split’ mind, like Dr Jekyll and Mr Hyde), this was not surprising. It took several decades of careful worldwide research to develop a reliable ‘operational’ system of diagnosing schizophrenia during the 1960s and 1970s, helped by the rise of effective antipsychotics, the need to counter the criticisms of anti-psychiatry and the new brain scanning techniques, such as magnetic resonance imaging (MRI).

In those same decades, however, radical psychology (e.g. RD Laing, Thomas Szasz), alongside alternative anti-establishment cultures, reached its pinnacle. This became the dominant mode of understanding the world, was critical of hidebound, asylum-bound, biology-bound ‘straight’ psychiatry, and scored notable victories. Diagnostic categories

were seen as loose or corrupt (e.g. the Russian KGB’s term ‘latent schizophrenia’ for political dissidents), and mental illness was seen as caused by parental impositions (e.g. the 1971 film *Family Life*; Table 1.9), social injustice and restrictive mores. Therapeutic drug experience using lysergic acid diethylamide (LSD) was even mooted as the real breakthrough. Increasingly influential, however, were the behavioural psychologists, developing sophisticated theories of – and treatments for – anxieties and phobias, and moving on to cognitive behavioural therapy (CBT) and cognitive analytical techniques. Linking the psychoanalytical and behavioural approaches were group therapies, family therapies and patient-centred approaches such as Alcoholics Anonymous (AA) and an increasingly vociferous user movement.

Psychiatrists, from being asylum keepers in the nineteenth century to being proto-neurologists in the first half of the twentieth century, were now trying to be eclectic – that is, doctors-cum-therapists-cum-psychopharmacologists, with sophisticated interpersonal and therapeutic skills and an enhanced awareness of social and legal constructions. The organizations, publications and legislation psychiatry in Britain are summarized in Tables 1.10 and 1.11.

### WHAT NOW?

By the 1990s, the ‘talking therapies’, although intellectually established in terms of art criticism and literature, had run into a series of debates as to effectiveness, cost–benefit and the nature of ‘distress’. Why talk à la Woody Allen to a shrink three times a week for 15 years, when Prozac could make you feel alright within a month? Newly recognized,

though still controversial (vis-à-vis their aetiological role), conditions such as child sex abuse and post-traumatic stress disorder were rife, but talking about them didn’t necessarily help. ‘Counselling’ research in primary care showed limited evidence of making you feel better or even happier; CBT has become almost a panacea.

By the end of the twentieth century, therefore, psychiatric practice had become an embattled profession. Still enmeshed in stigma, and beset by homicide inquiries, risk management and a rising demand for public safety, psychiatrists are seen by many as poodles of corporate power (the drug companies) failing to deliver enough talking therapy or real understanding of user problems. Their own history has even been subverted by historical sociologists, who view its so-called ‘advances’ as nothing more than a cover-up for Orwellian social control and the medicalization of unhappiness. Ever the war zone of conflicting attitudes to the normal and the mad, psychiatry therefore continues to find itself fighting for the neglected Cinderellas of society, nowadays the prison-housed thousands yearning for understanding (asylum and prison populations tend to relate inversely, the one rising as the other falls, and vice versa). Key themes of this historical process are outlined in Table 1.4.

This ‘history of psychiatry’ is merely one version of a complex series of events, discoveries, social movements and intellectual developments. It has barely touched upon the philosophical basis to modern psychopathology, the numerous Parliamentary committees generating legislative change, the popular books and articles informing public attitudes, or even the individual case histories that have influenced clinical practice. There is a rich range of sources still awaiting thoughtful research, and some degree of cynicism as to, for example, why doctors became the agreed experts on managing mental illness. But one theme is constant: psychiatrists are in demand because of their unique combination of clinical and personal skills. History enables us to know what those mean and how they can work.

INTRODUCTION

It is hard to argue with the principle that decisions should be informed by the best available evidence. However, since the early 1990s, evidence-based medicine (EBM) has evoked fierce debate. This debate has focused essentially on two questions: what is the best available evidence for clinical decision-making, and what role should this evidence play?

In this chapter, I use the term ‘evidence-based medicine’ to refer to decision-making in the care of an individual patient. Other terms in common use are ‘evidence-based healthcare’ (EBHC) and ‘evidence-based practice’ (EBP). EBHC relates to decision-making about groups of patients or populations. The generic descriptor EBP is often used to embrace both EBM and EBHC.1

EBM grew out of the need to improve the effectiveness and efficiency of medical education. It offers clinicians, mindful of their limitations, a strategy for recognizing and managing clinical uncertainty and information overload. With over two million articles published in 20,000 biomedical journals each year, it is impossible for busy clinicians to keep up to date without competence in EBM.

THE BEST AVAILABLE EVIDENCE

EBM proposes a paradigm shift in clinical decision-making. Instead of relying on reasoning from basic sciences, EBM demands that clinical decisions are informed by the best available clinical research data. In other words, evidence showing that a drug does work in clinical practice is valued above inferences from basic sciences that a drug should work.

Implicit in this paradigm shift is the principle of a hierarchy of evidence. Just as clinical trial data trump reasoning from basic sciences when considering what drug to prescribe, a systematic review of two or more randomized controlled trials (RCTs) will typically provide more convincing evidence than an individual RCT, which again provides more convincing evidence than an individual cohort or case–control study. Recognizing the inherent strengths and weaknesses of different study designs for different types of question is essential for the efficient identification of the best available evidence. The development of electronic databases has made searching for and retrieving research data much easier.

As a reader of the biomedical literature, you will be aware that publication in a scientific journal is no guarantee of study quality. The EBM revolution serves to equip all healthcare practitioners with the opportunity to question received wisdom and constructively, yet critically, appraise research findings in order to determine whether they are valid, important and applicable to the specific clinical situation. Critical appraisal requires a working knowledge of the possible pitfalls in scientific research.

Having identified the best available evidence, what role should it play in decision-making?

THE ROLE OF EVIDENCE IN CLINICAL DECISION-MAKING

Dave Sackett, one of the earliest advocates, defined EBM as ‘the conscientious, explicit, and judicious use of best evidence in making decisions about the care of individual patients’;2 Critics of EBM have drawn attention to the limitations of using research evidence alone when making clinical decisions. Approaches such as values-based medicine and ‘the expert patient’ have challenged traditional models for the doctor–patient relationship.3,4 As these models have evolved, so has the philosophy of EBM. Perhaps EBM can be best understood as a component of clinical expertise that is ‘the ability to integrate research evidence and patients’ circumstances and preferences to help patients arrive at optimal decisions’.5 This model for patient decision-making is illustrated in Figure 2.1.
Evidence-based practice and clinical expertise

Evidence-based practice and clinical expertise

Part 1: The foundations of modern psychiatric practice

EVIDENCE-BASED PRACTICE AND CLINICAL EXPERTISE

Competence in EBM should help us empower patients to make optimal decisions. Helping patients to arrive at optimal decisions requires new and enhanced skills. These skills include the ability to use electronic databases, to critically appraise clinical research and data, and to communicate effectively with patients and other colleagues. Books and courses can help us develop our knowledge base, but the most effective way of developing competence in EBM is through reflective practice – that is, learning embedded in clinical practice.

Drawing upon the public health disciplines of epidemiology and biostatistics, EBM seeks to simplify the process of accessing, appraising and applying research evidence. The EBM components of clinical expertise can be broken down into five steps:

1. Translation of uncertainty to an answerable question.
4. Application of results in practice (empowering patients to make clinical decisions).

The knowledge, skills and attitudes underpinning each of these five steps are summarized in Box 2.1.

It is clearly impractical to systematically retrieve and critically appraise the primary literature for every question that emerges in clinical practice. Meta-resources present pre-appraised summaries addressing some of the more common clinical questions, while evidence-based guidelines are becoming increasingly common. The art of EBM is judging, in partnership with patients, which questions are addressed adequately through guidelines, meta-resources and those that require appraisal of systematically retrieved primary evidence.

Whatever the source of the evidence, the critical step in this process is the last one: the assessment of performance. This is easier to describe than to practise, but as we strive to improve patient safety and care we must not only evaluate our fidelity to the EBM process but also assess whether patients have been helped. The evaluation of performance remains the greatest challenge to truly practising EBM. Why? – because it requires a "culture that is free of blame and encourages an open examination of error and failure."

INTRODUCTION

The psychiatrist and neuroscientist Nancy Andreasen has pointed out that a crucial characteristic of psychiatry as a research-led clinical discipline is the unique way in which it combines some of the most challenging scientific questions with equally challenging conceptual problems. Andreasen argues that the conceptual difficulties that we face have been driven increasingly to the top of psychiatry’s practical agenda by the recent rapid pace of advances in the neurosciences. These conceptual and empirical difficulties are evident in a wide range of contexts; examples include (i) disputes around the current revision processes for both the International Classification of Diseases (ICD) and the American Psychiatric Association’s Diagnostic and Statistical Manual; (ii) the contested shift in the UK and in many other countries in service delivery from psychiatry to a more multidisciplinary approach; and (iii) growing pressure for a move away from professional-led mental health and social care services to a more equal partnership between professionals and service users and carers.

In this chapter we set the conceptual difficulties surrounding current challenges of this kind in their historical context, with the aim of illustrating the extent to which the history and philosophy of science provide both context and direction for responding to the issues that we face today. It is natural to think of history and philosophy as perhaps subordinate to science as resources for improving service delivery in psychiatry. What we hope this chapter will illustrate is that the uniquely challenging nature of psychiatry, as a research-led clinical discipline, demands the resources of rigorous historical and philosophical work alongside, and as a full partner to, equally rigorous empirical methods.

Clearly, in a chapter of this length, we will not be able to cover the history and philosophy of science as it relates to psychiatry in any way comprehensively. Rather than giving an overview, therefore, we will adopt a case-study approach, exploring in some depth one particular strand in the history and philosophy of psychiatry that we believe is particularly relevant to current challenges. This strand concerns the role of both meanings and values as a complement to the brain sciences. The key protagonists that we will be considering are, respectively, one of the fathers of modern descriptive psychopathology, Karl Jaspers, and the Kantian philosopher of science Wilhelm Windelband, both writing around the start of the twentieth century.

The first section of this chapter focuses on Jaspers’ work and in particular on his attempt to reconcile meaningful understanding with causal explanations in psychiatry. The second section examines Windelband’s work, which focuses on the role of values in understanding individuals. Finally, we bring the story right up to date with recent developments in the counterparts of Jaspers’ and Windelband’s work, respectively phenomenology and what has become known as ‘values-based practice’. This concluding section illustrates how these developments build on philosophical and empirical sources to provide practical approaches to decision-making in psychiatry that are directly complementary to the resources of the sciences.

JASPERS ON THE ROLE OF UNDERSTANDING MEANING IN PSYCHIATRY

Karl Jaspers was born in 1883. He studied first law and then medicine at university, graduating as a doctor in 1908 when he started to work as an assistant in the department of psychiatry in the University of Heidelberg. Kraepelin’s influential textbook of psychiatry was in its eighth edition at this time. As a young man, Jaspers read widely, studying not only medicine but also psychology and philosophy, and it was the depth of his philosophical understanding that equipped him to make his unique contributions to psychiatry.

Jaspers and psychiatry’s first biological phase

Jaspers was working at a time in the development of psychiatry very similar to our own, in that there were dramatic advances in the neurosciences of the day: the period has indeed become known as ‘psychiatry’s first biological phase’. Jaspers’ professor in the Heidelberg department of psychiatry was Franz Nissl, a neurohistologist who discovered the dye that allowed the structure of nerve cells to be
clearly seen for the first time. Using this technique, he had shown that the neurohistological changes in general paralysis were different from the changes described by Alois Alzheimer in dementia. General paralysis was a degenerative dementia that had swept Europe after the wars of the late nineteenth century. It was shortly to prove to be a form of neurosyphilis. These were dramatic discoveries, therefore, and the young Jaspers was impressed with Nissl as a scientist. But when it came to clinical work, however, Jaspers was considerably less impressed.

Psychiatry at the turn of the century in Germany had moved out of the large institutions into university clinics. There was considerable resentment among the institutional psychiatrists that their discipline had been taken over by academic neuroscientists, whose knowledge of clinical psychiatry was scant, and whom they perceived as being under the spell of a crudely natural scientific model, epitomized by the German psychiatrist Wilhelm Griesinger’s famous aphorism ‘Mental illnesses are brain illnesses’. Psychiatric researchers at the time, such as Griesinger, Alzheimer, Nissl, Carl Meynert and Theodor Wernicke, were actively searching for the neuropathological changes by which they believed the major psychoses could be characterized. And, given their success with general paralysis, hopes were high. Jaspers shared these hopes. But he believed that the underlying biological approach had been pushed too far. ‘These anatomical constructions, however, became quite fantastic (e.g. Meynert, Wernicke) and have rightly been called “Brain Mythologies”’.5

Jaspers met Max Weber in 1909. He was invited to join Weber’s elite intellectual circle, and he quickly became one of Weber’s key intellectual antagonists. Jaspers thought of Weber as the ‘Galileo of the human sciences’.6 Although Weber believed that the human sciences involved a distinctively natural-scientific approach to psychiatry were driven by his understanding of the philosophical debates about psychology in the late nineteenth century, the so-called Methodenstreit. This concerned whether the human sciences (Geisteswissenschaften) should try to emulate their far more successful cousins the natural sciences (Naturwissenschaften) or whether they should go their own methodological way. ‘Positivists’, including John Stuart Mill in England and both Auguste Comte and Emile Durkheim in France, argued that the human sciences were different from the natural sciences. Others argued that the human or cultural sciences were different from the natural sciences, in terms of either the nature of their subject matter or their methodology, or both. The latter, in Germany, included Heinrich Rickert, Wilhelm Dilthey and Wilhelm Windelband, to whom we will return in the next section. Crucially for Jaspers, the German philosopher and sociologist Max Weber was among the latter camp.

Jaspers and the Methodenstreit

Jaspers’ reservations about what he perceived as the excessively natural-scientific approach to psychiatry were driven by his understanding of the philosophical debates about psychology in the late nineteenth century, the so-called Methodenstreit. This concerned whether the human sciences (Geisteswissenschaften) should try to emulate their far more successful cousins the natural sciences (Naturwissenschaften) or whether they should go their own methodological way. ‘Positivists’, including John Stuart Mill in England and both Auguste Comte and Emile Durkheim in France, argued that the human sciences were different from the natural sciences. Others argued that the human or cultural sciences were different from the natural sciences, in terms of either the nature of their subject matter or their methodology, or both. The latter, in Germany, included Heinrich Rickert, Wilhelm Dilthey and Wilhelm Windelband, to whom we will return in the next section. Crucially for Jaspers, the German philosopher and sociologist Max Weber was among the latter camp.

Jaspers was among the latter camp.

Jaspers and general psychopathology

Jaspers regarded psychopathology as Weber regarded sociology. It lay both within the natural sciences, pursuing abnormalities of brain functioning, and within the human sciences, pursuing the experiences, aims, intentions and subjective meanings of its patients. Of course, at a time when psychiatry was dominated by the ‘brain mythologists’, Jaspers’ major aim was to bring psychiatry back within the ambit of the human sciences. He wanted to balance things up. In Weber’s work, therefore, which in turn had drawn on the work of Dilthey, Windelband and Rickert, Jaspers saw things falling into place, and much of Weber’s social theory – interpretation/understanding, Evidenz, ideal types and so forth – was to find its way into Jaspers’ psychopathology. Some time later he wrote:

My article of 1912 and this present book (1913) were greeted as something radically new, although all I had done was to link psychiatric reality with the traditional humanities. Looking back now, it seems astonishing that these had been so forgotten and grown so alien to psychiatry. In this way within the confines of psychopathology there grew a methodological comprehension of something which had always been present, but which was fading out of existence and which appeared in striking reverse, ‘through the looking-glass’ as it were, in Freud’s psychoanalysis – a misunderstanding of itself. The way was clear for scientific consciousness to lay hold on human reality and on man’s mental estate, his psychoses included, but there was an immediate need to differentiate the various modes of understanding, clarify them and embody them in all the factual content available to us.5

The period 1909–13 was a time of high output for Jaspers. He wrote papers on homesickness, hallucinations, pathological jealousy, phenomenology, and the need for both ‘causal’ (natural scientific) and ‘understandable’ (human scientific) connections in psychic life. We will discuss two papers published in this period below: ‘The phenomenological approach in psychopathology’ and ‘Causal and “meaningful” connections between life history and psychosis’. But the culmination of this burst of output was that, in 1911, he was commissioned by the publisher Springer to write a textbook of psychopathology. It was thus that his General Psychopathology (Allgemeine Psychopathologie) appeared in its first edition in 1913.

Jaspers on subjective and objective

In ‘The phenomenological approach in psychopathology’, Jaspers sets out his account of the role within psychopathology for a phenomenological approach. As we will explain shortly, phenomenology is, in Jaspers’ view, a form of static understanding by contrast with what he calls...
genetic understanding (see below). But both forms of understanding have in common that they are attempts to explore subjective, as opposed to objective, symptoms. What is the distinction between subjective and objective? Jaspers describes objective symptoms as follows:

Objective symptoms include all concrete events that can be perceived by the sense, e.g. reflexes, registrable movements, an individual’s physiognomy, his motor activity, verbal expression, written productions, actions and general conduct, etc.; all measurable performances... It is also usual to include under objective symptoms such features as delusional ideas, falsifications of memory, etc., in other words, the rational contents of what the patient tells us. These, it is true, are not perceived by the senses, but only understood; nevertheless, this ‘understanding’ is achieved through rational thought, without the help of any empathy into the patient’s psyche.7

The distinction between what is available to rational thought and to empathy is important and one to which we will return. It helps to form a broader conception of what is objective than would generally be accepted today. But this in turn gives rise to a correspondingly narrower sense of ‘subjective’:

Objective symptoms can all be directly and convincingly demonstrated to anyone capable of sense-perception and logical thought; but subjective symptoms, if they are to be understood, must be referred to some process which, in contrast to sense perception and logical thought, is usually described by the same term ‘subjective’. Subjective symptoms cannot be perceived by the sense-organs, but have to be grasped by transferring oneself, so to say, into the other individual’s psyche; that is, by empathy. They can only become an inner reality for the observer by his participating in the other person’s experiences, not by any intellectual effort.7

Jaspers complains that a purely objective psychology leads ‘quite systematically to the elimination of everything that can be called mental or psychic.’ In order to illustrate what he means, Jaspers refers to the assessment of a patient’s fatigue through measurable performances where ‘it is not the feeling of fatigue but “objective fatigue” which is being investigated.’ This suggests a contrast between objective and measurable aspects of physiology and the subjective aspect of what it is like to be or to feel fatigued. Assessing such subjective symptoms requires a kind of imaginative transference or empathy, which, thus, lies at the heart of psychopathology.

**Jaspers on phenomenological understanding**

Having drawn this distinction between subjective and objective, Jaspers goes on to characterize the aims of phenomenological psychopathology in the following terms:

What then are the precise aims of this much-abused subjective psychology? ... It asks itself – speaking quite generally – what does mental experience depend on, what are its consequences, and what relationships can be discerned in it? The answers to these questions are its special aims... So before real inquiry can begin it is necessary to identify the specific psychic phenomena which are to be its subject, and form a clear picture of the resemblances and differences between them and other phenomena with which they must not be confused. This preliminary work of representing, defining, and classifying psychic phenomena, pursued as an independent activity, constitutes phenomenology.7

Thus, the key aim of phenomenology, or static understanding, is to identify the specific psychic phenomena that are to be its subject and to form a clear picture of the resemblances and differences between them and other phenomena. How does it set about this task?

We should picture only what is really present in the patient’s consciousness; anything that has not really presented itself to his consciousness is outside our consideration. We must set aside all outmoded theories, psychological constructs or materialist mythologies of cerebral processes; we must turn our attention only to that which we can understand as having real existence, and which we can differentiate and describe. This, as experience has shown, is in itself a very difficult task. This particular freedom from preconception which phenomenology demands is not something one possesses from the beginning, but something that is laboriously acquired after prolonged and critical work and much effort – often fruitless – in framing constructs and mythologies.7

A key aspect of the task of getting a very clear picture of psychological phenomena is thus to attempt to strip away theoretical descriptions or constructs and to get back to the things themselves, to use a slogan of the philosophical phenomenologist Edmund Husserl (1859–1938) (the precise nature of whose influence on Jaspers is contested). Of course, from a modern perspective, the aim of a theory-free approach has echoes of the aetiological-theory-free approach of the glossary to ICD-8 and its successors in both the ICD and DSM series of classifications. Quite how successful a genuinely theory-free approach can be in the face of arguments as to the essential theory-ladenness of data is a matter of debate (see Fulford et al.7).

So far, Jaspers’ discussion has presented the difficulties of the phenomenological method rather than offering specific guidance as to how it is to be achieved. The most concrete account offered of that in this essay runs as follows:

How then do we proceed when we isolate, characterise and give conceptual form to these psychic phenomena? We cannot portray them, or bring them before our eyes in any way that can be perceived by the senses. We can only guide ourselves by a multiple approach. We have to be led, starting from the outside, to a real appreciation of a particular psychic phenomenon by looking at its genesis, the conditions for its appearance, its configurations, its context and possible concrete contents; also by making use of intuitive comparison and symbolization, by directing our
observations in whatever ways may suggest themselves (as artists do so penetratingly) …

The phenomenologist can indicate features and characteristics, and show how they can be distinguished and confusion avoided, all with a view to describing the qualitatively separate psychic data. But he must make sure that those to whom he addresses himself do not simply think along with him, but that they see along with him.7

**Jaspers on genetic understanding**

As remarked above, Jaspers distinguishes between two legitimate forms of understanding (of subjective phenomena): static understanding, which he also calls phenomenology, and genetic understanding. In ‘The phenomenological approach in psychopathology’, he characterizes the differences thus:

‘Genetic understanding’ [is] the understanding of the meaningful connections between one psychic experience and another, the ‘emergence of the psychic from the psychic’. Now phenomenology itself has nothing to do with this ‘genetic understanding’ and must be treated as something entirely separate.7

What then is genetic understanding? A fuller discussion is given in another essay from this period, ‘Causal and “meaningful” connections between life history and psychosis’.8 Again, an important clue comes from the distinction mentioned above between rational connections and those that require empathy. Taking the case of understanding a speaker and understanding what the speaker has said, Jaspers comments:

The first important differentiation was made by Simnel, who showed the difference between the understanding of what has been said from understanding the speaker. When the contents of thoughts emerge one from another in accordance with the rules of logic, we understand the connections rationally. But if we understand the content of the thoughts as they have arisen out of the moods, wishes, and fears of the person who thought them, we understand the connections psychologically or empathetically. Only the latter can be called ‘psychological understanding’. Rational understanding always only enables us to say that a certain rational complex, something which can be understood without any psychology whatever, was the content of a mind; empathic understanding, on the other hand, leads us into the psychic connections themselves. Whereas the rational understanding is only an aid to psychology, empathic understanding is psychology itself.8

This fits the earlier quotation in which the rational content of what a patient reports was characterized as an objective symptom. Equally, the rational interconnection between reports, their implications and so forth are also outside the domain of subjective psychology. But if empathy, in the service of genetic understanding, does not chart the logical or rational connection between one thought and another, then what is the basis of such psychological understanding? Jaspers’ answer is not entirely clear. He says: ‘We experience immediate evidence which we cannot reduce further nor base on any kind of other evidence… Meaningful connections are ideally typical connections. They are self-evident.’8

In other words, when there is a self-evident connection between one state and another, a connection that is typical although perhaps not always realized in practice, genetic understanding of it, through empathy, is possible. Realizing that one has won the lottery and thus solved all one’s financial problems might lead, ideally and typically, to a state of happiness. Normally, to explain someone’s sudden happiness, we might simply and sufficiently say that they have just heard that they have won the lottery. But, of course, in some unusual cases, that might not be a reason for happiness. The normal connection is basic – no more needs to be said – but it need not hold in all cases. It is ideally typical.

Thus, the relationship between static and genetic understanding is like this. The former articulates and vividly presents what it is like, for example, to have a sudden realization or what it is like to be in a state of happiness. It makes these kinds of state clear for further enquiry before the imposition of psychological theory. Genetic understanding adds to this the connection of how one state arises – ideally and typically – from the other. Such connections are shared empathically by psychological subjects, including psychiatrists and their patients.

Jaspers’ characterization of static understanding has echoes in a more recent debate within the philosophy of mind between ‘theory theory’ and ‘simulation theory’ accounts of knowledge of other people’s minds.9 According to theory theory approaches, access to, and thus knowledge of, other people’s minds is mediated by possession of a theory of mind. The theory is a body of deductively structured generalizations about the unseen causes of observable (speech and other) behaviour. This approach to the epistemological problem of how we can know about other minds thus dovetails with what are called ‘functionalist’ approaches to the ontological problem of what sort of things mental states are. Functionalism characterizes mental states in causal and functional terms, mediating between perceptual inputs and behavioural outputs. In other words, according to functionalism, mental states are akin to software states running on the brain as a computer. By characterizing types of mental state in second-order terms, functionalism aims to answer the problem of relating minds and bodies without simply reducing mental states to brain states. Theory theory approaches deploy broadly functionalist characterizations of what mental states are to explain, in addition, how we can have knowledge of them (in the case of other people).

Simulation theory, by contrast, explains knowledge of other minds not by possession of a theory of minds but merely by possession of a mind itself. The idea is that it is possible to have knowledge of another person’s mental
states by imaginatively putting oneself into his or her predicament. One ‘runs’ one’s deliberative processes ‘offline’, as it were. Simulation theory is thus a form of empathy. But, unlike Jaspers’ account, there is no restriction to non-rational patterns of thoughts emerging from one another. Indeed, one of the key arguments for simulation theory and against theory theory is that rational connections lie at the heart of mental phenomena but are not reducible to or codifiable in any set of principles of good thinking that could thus form part of a theory of mind.11,12

The limits of understanding

Despite its centrality in Jaspers’ conception of psychopathology and thus psychiatry, understanding has limits. One kind of limit is quite general and concerns its scope by contrast with natural scientific explanation. In a section of ‘Causal and “meaningful” connections between life history and psychosis’ called ‘The limits of understanding and the universal application of explaining’, he says:

The suggestive assumption that the psychic is the area of meaningful understanding and the physical that of causal explanation is wrong. There is no real event, be it physical or of psychic nature, which is not accessible to causal explanation...

The effect a psychic state may have could in principle lend itself to a causal explanation, while the psychic state itself of course must be phenomenologically (statically) understood. It is not absurd to think that it might one day be possible to have some rules which could causally explain the sequence of meaningfully connected thought processes without paying heed to the meaningful connections between them...

It is therefore in principle not at all absurd to try to understand as well as to explain one and the same real psychic event. These two established connections, however, are of entirely different kinds of validity.8

The thought here seems to be this: Understanding and explanation do not have two distinct subject matters. Rather, the difference between them is one of method or of the kind of intelligibility that they deploy. As applied in psychiatry, they share the same subject matter: ‘real events’ or ‘thought processes’, in Jaspers’ terms. These can in principle be charted in either way: either by looking to the law-like causal relations between them or by looking to the meaningful relations between them.

The idea that neural events might be susceptible to two distinct patterns of intelligibility was articulated by the US philosopher of mind Donald Davidson (1917–2003). On his model of the mind, Anomalous Monism, the very same events that comprise mental events and that – according to Davidson – stand in essentially rational relations also comprise physical events and can be subsumed under nomological or law-like causal explanations.13 When described in mental property terms, however, there are no laws that fit them. Hence - qua instantiations of mental properties – they are anomalous. But there are laws that fit them that use their physical or neurological properties.

Given this broad view of the relation between understanding and explanation, one might expect the following asymmetry between them. Although every mental event is also a physical event, not every physical event is a mental event. There were no mental properties in the event of comet Shoemaker Levy 9 colliding with Jupiter in 1994, for example. That collision was not a mental event. Thus, one might expect Jaspers to say that, although every event that can be understood can also be explained, not every event that can be explained can also be understood. It is rather curious, therefore, that he actually says: ‘there is no event which cannot be understood as well as explained’.8

Although he does not recognize that plausible general limitation on understanding – that non-mental events can only be explained, not understood – Jaspers does suggest a more specific local limit in the case of psychopathology. He believes that ‘primary delusions’ cannot be understood. To unpack that claim, we will now outline his taxonomy of delusions.

Jaspers suggests that delusions fall into two kinds: primary and secondary, or delusions proper and delusion-like ideas. Primary delusions fall into four further kinds. The first is mentioned in General Psychopathology almost in passing: delusional atmosphere. He says:

with this delusional atmosphere we always find an ‘objective something’ there, even though quite vague, a something which lays the seed of objective validity and meaning...Patients feel as if they have lost grip on things, they feel gross uncertainty...5

To a person with schizophrenia, the world as a whole can seem subtly altered, uncanny, portentous or sinister. This general transformation prompts Jaspers to say elsewhere: ‘We observe that a new world has come into being’.5 There are then three further forms of primary delusion:

Delusional perceptions. These may range from an experience of some vague meaning to clear, delusional observation and express delusions of reference...

Delusional ideas. These give new colour and meaning to memory or may appear in the form of a sudden notion – ‘I could be King Ludwig’s son’ – which is then confirmed by a vivid memory of how when attending a parade the Kaiser rode by on his horse and looked straight at the patient...

Delusional awareness. This constitutes a frequent element particularly in florid and acute psychoses. Patients possess a knowledge of immense and universal happenings, sometimes without any trace of clear perceptual experience of them...5

In each of these cases, there is a deep change in the experience of the significance of features of the world. In the case of delusional perceptions, an experience is transformed. In the case of delusional ideas, the significance of a memory is transformed. In delusional awareness, a delu-
sional idea springs unbidden. But in all cases: ‘All primary experience of delusion is an experience of meaning’.

The experiences of primary delusion are analogous to this seeing of meaning, but the awareness of meaning undergoes a radical transformation. There is an immediate, intrusive knowledge of the meaning and it is this which is itself the delusional experience.

The key feature of primary delusions, however, is that they are un-understandable. While secondary delusions or delusion-like ideas are, in principle, understandable in the context of a person’s life history, personality, mood state or presence of other psychopathology, primary delusions have a kind of basic status. We can distinguish two large groups of delusion according to their origin: one group emerges understandably from preceding affects, from shattering, mortifying, guilt-provoking or other such experiences, from false perception or from the experience of derealisation in states of altered consciousness etc. The other group is for us psychologically irreducible; phenomenologically it is something final. We give the term ‘delusion-like ideas’ to the first group; the latter we term ‘delusions proper’.

As Andrew Sims says in a contemporary introduction to descriptive psychopathology:

When we consider the middle aged schizophrenic spinster who believes that men unlock the door of her flat, anaesthetize her and interfere with her sexually, we find an experience that is ultimately not understandable. We can understand, on obtaining more details of the history, how her disturbance centres on sexual experience; why she should be distrustful of men; her doubts about her femininity; and her feelings of social isolation. However, the delusion, her absolute conviction that these things are happening to her, that they are true, is not understandable. The best we can do is to try and understand externally, without really being able to feel ourselves into her position (genetic empathy), what she is thinking and how she experiences it [Sims 1988: 85].

Thus, although Jaspers places empathic understanding (both static and genetic) at the heart of psychopathology and thus psychiatry, he also argues that some of the key phenomena that characterize psychopathology cannot be understood. They are un-understandable. If Jaspers is correct, then psychiatry has a fundamental limitation. We return to this point later, when we bring the story up to date with developments in modern phenomenology.

WINDELBAND ON THE ROLE OF UNDERSTANDING VALUES IN PSYCHIATRY

In this section, we consider a second strand of conceptual work from psychiatry’s first biological phase, namely the role of values, which as a complement to the neurosciences has particular relevance to psychiatry today. As noted earlier, although Jaspers had important things to say about the role of meanings, he was less interested in the role of values. In the following passage, for example, he distances his conception of understanding meaning from forming or understanding value judgements:

It is a fact that when dealing with meaningful connexions as such we inevitably tend to value positively or negatively, while everything meaningless we merely value, if we do so at all, only in relation to something else. Thus the emergence of moral demands from resentment we may value as something despicable, whereas we value memory merely as a tool. In the science of psychology, however, we must strictly refrain from any such value judgement. Our task is merely to grasp the meaningful connexions as such and to recognize them.

Thus, Jaspers separates understanding meanings from the kind of evaluation that properly involves the assessment of values. But another European philosopher of science, Wilhelm Windelband, did wish to stress the importance of values for a properly rounded scientific account. He did this via an account of idiographic understanding, which, as we will outline later, is itself at the forefront of contemporary thinking about psychiatry.

Windelband and idiographic understanding

Wilhelm Windelband was a Kantian philosopher of science. He first introduced the distinction between ‘idiographic’ and ‘nomothetic’ in his rectorial address of 1894. Key components of the distinction between them are that it is a distinction of method not of subject matter, that it concerns treating events as unrepeatable, and that it is a reaction against an overreliance on an essentially general conception of knowledge.

Windelband contrasts his own methodological distinction with one of substance, between natural sciences (Naturwissenschaften) and sciences of the mind (Geisteswissenschaften): ‘I regard the dichotomy as unfortunate. Nature and mind is a substantive dichotomy ... not equivalent to a dichotomy based on modes of cognition.’

Such a distinction of substance is a hostage to the fortune of a metaphysical distinction of kind between mind and the rest of nature. In psychiatry, the interplay of both broadly psychological methods and neurology makes drawing such a distinction premature and unhelpful.

Windelband proposes, instead, a distinction that places psychology (as he understands it) and other natural sciences on one side and other disciplines, which in Germany at the time were called ‘sciences of the mind’ but which have a distinct method, on the other. This gives rise to a characterization of what he goes on to label ‘idiographic’, as follows:

The majority of the disciplines that are usually called sciences of the mind have a distinctively different purpose: they provide a complete and exhaustive description of a single, more or less...
The commitment to the generic is a bias of Greek thought, perpetuated from the Eleatics to Plato, who found not only real being but also real knowledge only in the general. From Plato this view passed to our day. Schopenhauer makes himself a spokesman for this prejudice when he denies history the value of a genuine science because its exclusive concern is always with grasping the specific, never with comprehending the general... But the more we strive for knowledge of the concept and the law, the more we are obliged to pass over, forget, and abandon the singular fact as such...16

**Unique individuals and values**

This raises a question – which arguably Windelband never answered satisfactorily – as to the nature of this individualistic understanding. What is it to understand an individual in essentially non-general terms? But he did give an important clue as to why he thought there was need for idiographic understanding. What we value when we value people or events is tied to their individuality, he argues.

In opposition to this [general, nomothetic] standpoint, it is necessary to insist upon the following: every interest and judgment, every ascription of human value is based upon the singular and the unique... Our sense of values and all of our axiological sentiments are grounded in the uniqueness and incomparability of their object.16

Examining value judgements helps to reveal the fundamental importance of particular cases as opposed to general kinds in judgements. It suggests that there is an important role for clinical judgement aimed at reflecting the nature of individuals and their experiences. Windelband himself seems to have taken this to imply the need for a particular kind of individualistic judgement in which there is no implicit comparison – as there is with any general concept – with other cases. Such a judgement would be essentially particular or individualized.

Windelband’s fellow neo-Kantian Heinrich Rickert also argues that there can be essentially particular or individualized judgements and that these are exemplified by value judgements. Unlike nomothetic accounts of, for example, the forces acting on bodies, which are described and explained in general terms, judgements about the value of things are individualized judgements.

*We are concerned here with the connection of objects with values; for a generalizing approach the objects are free of value-connection, they are exemplars, replaceable... This is what happens when we free the object of all connection with our interests – it becomes a mere exemplar of a general concept. An individualising approach is necessarily connected with the value-bound grasp of the object [mit der wertverbindenden Auffassung der Objekte]...16*

But although Windelband’s discussion supports the suspicion of subsuming individuals under categories and the role, instead, of a kind of individualized judgement, he does...
not offer a very clear account of what form such an idiographic judgement might have. How precisely is a judgement supposed to reject an historical overemphasis on the general? In fact, there is reason to be suspicious of the suggestion that reflecting individuals needs a special kind of individualistic judgement.19,20

Thus, the lasting importance of Windelband’s discussion is this: he reminds us of the importance of the individual as well as the general. He suggests that judgement aimed at understanding individuals in their own terms rather than instances of generalities can be an important aspect of a scientific understanding, albeit one that contrasts with essentially general statistical or law-like explanation. And he suggests that understanding of individuals can be importantly connected to value judgements. In the final section of the chapter, we will outline a more recent approach to reflecting the values of individuals that avoids Windelband’s reliance on the contested notion of ‘individualising judgement’.21

MEANING AND VALUES IN PSYCHIATRY TODAY

In this section we outline current developments in psychiatry as they reflect respectively meanings (phenomenology and related disciplines) and values (values-based practice), both of which are philosophically derived resources for clinical practice that are complementary to the resources of the sciences. Again, we are unable to cover either of these in detail, but we include a list of suggested further reading at the end of the chapter.

Phenomenology and related disciplines

Although not prominent in much of Anglo-American psychiatry, there was a strong continuing tradition of work in phenomenology and related disciplines in continental Europe through much of the twentieth century. This tradition was indeed one of a number of important sources of the remarkable resurgence of cross-disciplinary work between philosophy and psychiatry that began in the 1990s in parallel with the dramatic advances in the neurosciences of that period.22

As a rich theoretical discipline, phenomenology has continued to develop strongly along with other disciplines broadly within the ‘philosophy of mind’, very much in partnership with research in the neurosciences; see, for example, a number of papers in the double special issue of Philosophy, Psychiatry, and Psychology, edited by Christoph Hoerl.23 As in Jaspers’ day, it has been crucial in this respect that careful analysis of the subjective content of experience is available as a complement to the findings of empirical disciplines, such as functional neuroimaging and behavioural genetics. Equally important, though, has been the clinical impact of phenomenology, and related disciplines such as hermeneutics and existentialism, through improved understanding of the subjective experience of mental disorder. We return in a moment to a particular application of phenomenology to the problem of understanding as raised by Jaspers’ work. Examples of other clinical applications of this area of philosophy include the work of the Dutch philosopher Guy Widdershoven on improved decision-making in old-age psychiatry;24 of the American philosopher and psychologist Steven Sabat on interpretation of language difficulties in Alzheimer’s disease;25 and of the Oxford philosopher of mind Katherine Morris on body dysmorphic disorders.26

Returning, then, to the problem of understanding as raised by Jaspers, recent work by psychiatrists and philosophers alike has challenged the assumption that this rules out meaning-laden understanding as an aim, at least. The Italian psychiatrist and phenomenologist Giovanni Stanghellini, for example, treads a middle ground between explaining and understanding schizophrenia. In his book of essays Disembodied Spirits and Deanimated Bodies, he has argued that some understanding of the experiences of sufferers of schizophrenia is possible on the hypothesis that they experience a threefold breakdown of common sense.26 This involves a breakdown of three distinct areas: the ability to synthesize different senses into a coherent perspective on the world (coenaesthesia); the ability to share a common world view with other members of a community (sensus communis); and a basic pre-intellectual grasp of, or attunement to, social relations (attunement). Stanghellini says: ‘The philosophical kernel of my proposal is to show how all these dimensions of the phenomenon of common sense (coenaesthesia, sensus communis, and attunement) are related to each other’.26

But Stanghellini does not attempt to use these ideas to step wholeheartedly inside the world view of subjects with schizophrenia. Rather, breakdowns of these are postulated as clues to interpret the strange things that people with schizophrenia report. But a basic phenomenon remains: the inaccessibility of experiences and thoughts:

Listening to a person affected by schizophrenia is a puzzling experience for more than one reason. If I let his words actualize in me the experiences he reports, instead of merely taking them as symptoms of an illness, the rock of certainties on which my life is based may be shaken in its most fundamental features. The sense of being me the one who is now seeing this sheet, reading these lines and turning this page; the experience of perceptual unity between my seeing this book, touching its cover and smelling the scent of freshly printed pages; the feeling that it is me the one who agrees or disagrees with what I am reading; the sense of belonging to a community of people, of being attuned to the others and involved in my actions and future; the taken-for-granted of all these doubtless features of everyday life, may be put at jeopardy.

Although my efforts to understand, by suspending all clinical judgement, allow me to see these person’s self-reports as a pos-
sible configuration of human consciousness, I must admit that there is something incomprehensible and almost inhuman in these experiences, something that makes me feel radically different from the person I am listening to.28

This suggests that understanding is an ongoing and ultimately unfinished task. The clinician has to make a series of interpretative judgements taking broad account of the life of the sufferer from, for example, schizophrenia. Such judgements can help towards at least a partial understanding of the person as a whole while at the same time taking account of the vividly alien quality of their psychopathological experiences.

On this approach, interpretative judgements presuppose that, as it were, the basic unit of meaning is the life of the whole person. Attempts at individual interpretation of specific delusions can be guided by a more general framework that takes schizophrenia, for example, to involve a breakdown of common sense. But such an approach goes only so far and, once they have given out, the interpretation of individual experiences has to be replaced by a sometimes partial and shifting understanding of the person as a whole based on contextual judgements. As in other areas of psychiatry, there is no quick route to bypass the need for good and sensitive judgement and hence to the irreducible role of the individual. It is the link between the general and the individual as mediated by values that is illustrated by recent developments in values-based practice outlined below.

Values and values-based practice

As described earlier, although Jaspers rather dismissed values, it was the particular contribution of Windelband during psychiatry’s first biological phase to show their importance in relation to the uniqueness of individual people. As with phenomenology, then, values have sprung back into prominence in recent years as part of the new philosophy of psychiatry, alongside and as a complement to developments in the neurosciences. The most familiar aspect of the new prominence of values is of course ethics; but other examples of emerging disciplines include health economics (e.g. Brown et al.39) and decision analysis (Hunink et al.26).

Values-based practice is distinctive theoretically in that it is derived from both philosophical and empirical sources. At a practical level, it is the closest to Windelband’s work in providing a complement to the generalized sciences:

- in the emphasis it places on the importance of the diversity of individual values, including the values of clinicians, researchers and managers as well as those of patients and carers; and
- in relying on a number of elements of good process, in particular specific and learnable clinical skills, to support balanced decision-making where values conflict.

It is because it is process-rather than outcome-based that values-based practice is most directly complementary to the sciences as a resource for clinical decision-making. Values-based practice, as we describe further below, is indeed in this respect directly complementary to evidence-based practice.29 In this section, we describe briefly (i) the theory and empirical base of values-based practice, including its philosophical roots, and (ii) illustrative examples of recent policy, training and service development initiatives in values-based practice in the UK and internationally.

The theory and empirical base of values-based practice

The theory underpinning values-based practice is based on work in linguistic analytical philosophy of the ‘Oxford school’ in the middle decades of the twentieth century, on the meanings of key value terms, such as ‘good’, ‘ought’ and ‘right’. Exemplar work from this period includes RM Hare’s The Language of Morals,10 Freedom and Reason11 and Descriptivism,22 in which he explored the logic of value terms. Although not drawing directly on the work of Windelband and others in the Methodenstreit, Hare can be understood as being concerned with broadly the same issues, namely how factual terms are related to value terms. Hare’s line on this was that there is always a logical distinction (i.e. a distinction of meaning) to be made between these two kinds of term: this is essentially because to evaluate something as good or bad always means something more than merely describing it. Thus, in one of Hare’s examples, an eating apple that is (i.e. can be described as) red and crisp happens to be, for most people, a good eating apple; but to actually call such an apple a ‘good eating apple’ means more than merely describing it as red and crisp—it also commends it.

Hare’s work did not go uncontested, of course: alternative views were put forward, for example by another Oxford philosopher, GJ Warnock, in his The Object of Morality.13 The debate between Hare and Warnock was itself set in a tradition of analytical philosophy running through much of the twentieth century,14 and also back to the work of the British empiricist philosopher David Hume.35 The debate indeed continues to this day; see, for example, the 2002 collection by the American philosopher Hilary Putnam.36

Nonetheless, work in this tradition, and in particular Hare’s disentangling of descriptive and evaluative meaning, provides a powerful set of insights that, although not developed originally with medicine in mind, can help us to understand the relationship between facts and values in healthcare. Fulford applied these insights to the meanings of medical terms such as ‘illness’, ‘disease’, ‘disability’, ‘function’ and ‘dysfunction’ in his Moral Theory and Medical Practice (Fulford, 1989)37. As a contribution to the ongoing debate about the meanings of these medical terms as they are used particularly in psychiatry, it is Fulford’s work, in Moral Theory and Medical Practice together with a number of subsequent articles,38–40 that provides the key theoretical underpinnings for values-based
practice. We do not have space here to go into the theory of values-based practice in detail, but among the practical implications of the theory are clear ways of articulating the relationships between values-based practice and both ethics- and evidence-based practice.29

Values-based practice also builds on empirical work on values guided by the philosophical theory just outlined. Thus, a key prediction of the theory of values-based practice is that the implicit values driving medical decision-making are often far more diverse than is generally recognized. This prediction has been tested by the British social scientist Anthony Colombo in a major study of the models of disorder (including values and beliefs) guiding decisions in the management of people with long-term schizophrenia in the community.41 The study combined empirical methods from the social sciences with the analytical philosophical theory just outlined and was innovative in a number of respects.42 The results of the study were widely disseminated in both research and non-governmental organizations (NGO) journals (e.g. in the house journal of MIND), and the methods developed in this study became the basis for one of the main areas of skills training for values-based practice (see below).

Policy, training and service development initiatives in values-based practice

As noted above, values-based practice starts from the diversity of individual values and relies on good process to support balanced decision-making in practice. In its reliance on good process, rather than preconceived correct outcomes, values-based practice is very much a partner to evidence-based practice: evidence-based practice provides a process for effective healthcare decision-making where the relevant evidence is complex and possibly conflicting; values-based practice provides a different but complementary process for effective healthcare decision-making where the relevant values are complex and possibly conflicting.

Again, we do not have space here to describe the process of values-based practice in detail. Ten key principles of the process of values-based practice have been set out by Fulford, together with a detailed case history of a patient with manic–depressive disorder, showing how each of these principles interweaves in practice with evidence-based approaches.29 The ten principles have been applied in mental health and social care as the basis of a series of policy, training and service development initiatives. This work has been carried out in partnership with both service users and service providers and with institutional support from NGOs, including the Sainsbury Centre for Mental Health (SCMH), the Mental Health Foundation (MHF) and Turning Point in London, and the World Psychiatric Association, and from government departments, in particular the UK Department of Health. Internationally, corresponding developments have been included in the World Psychiatric Association’s Institutional Program on Psychiatry for the Person.43,44 Examples of these developments are described below.

Policy

The National Institute for Mental Health in England (NIMHE), as the body responsible for mental health policy implementation in England and Wales, published a framework of values that was based explicitly on the approach of values-based practice (Box 3.1).45 This in turn guided a range of subsequent policy developments, including a generic skills programme,46 as the basis of moves towards more multidisciplinary and person-centred approaches to service delivery.3 The approach has also been applied in a number of specific areas of policy development, including delivering race equality47 and the introduction of community development workers.48

Training

The first training manual for values-based practice was developed in a partnership between the Sainsbury Centre for Mental Health and Warwick Medical School, with the support of NIMHE. Published as Whose Values?,49 the training manual was launched at a conference in London by the minister Rosie Winterton and, together with the NIMHE values framework, supported the policy initiatives noted above. A further application of values-based practice has been in the training materials produced to support the amended Mental Health Act in England and Wales. These training materials combine evidence-based resources with an innovative values-based approach to using the guiding principles defined by the code of practice (Table 3.1) as a framework of values guiding the application of the general provisions of the Act to individual cases (Figure 3.1).50

Figure 3.1 The guiding principles as a framework of values. Reproduced with permission from Ref. 50
Respect for diversity within mental health is also:

- user-centred: it puts respect for the values of individual users at the centre of policy and practice;
- recovery-oriented: it recognizes that building on the personal strengths and resiliencies of individual users, and on their cultural and racial characteristics, there are many diverse routes to recovery;
- multidisciplinary: it requires that respect be reciprocal, at a personal level (between service users, their family members, friends, communities and providers), between different provider disciplines (such as nursing, psychology, psychiatry, medicine, social work), and between different organizations (including health, social care, local authority housing, voluntary organizations, community groups, faith communities and other social support services);
- dynamic: it is open and responsive to change;
- reflective: it combines self-monitoring and self-management with positive self-regard;
- balanced: it emphasizes positive as well as negative values;
- relational: it puts positive working relationships supported by good communication skills at the heart of practice.

NIMHE will encourage educational and research initiatives aimed at developing the capabilities (the awareness, attitudes, knowledge and skills) needed to deliver mental health services that will give effect to the principles of values-based practice.

CONCLUSIONS

The period around the start of the twentieth century was one of great progress for biologically based neuroscience. It was a time of great promise for the science of psychiatry.
Table 3.1 Guiding principles in the code of practice for the new Mental Health Act (England and Wales)

| Purpose | Decisions under the Act must be taken with a view to minimizing the undesirable effects of mental disorder, by maximizing the safety and wellbeing (mental and physical) of patients, promoting their recovery and protecting other people from harm |
| Least restrictive alternative | People taking action without a patient’s consent must attempt to keep to a minimum the restrictions they impose on the patient’s liberty, having regard to the purpose for which the restrictions are imposed |
| Respect | People taking decisions under the Act must recognize and respect the diverse needs, values and circumstances of each patient, including their race, religion, culture, gender, age, sexual orientation and any disability. They must consider the patient’s views, wishes and feelings (whether expressed at the time or in advance), so far as they are reasonably ascertainable, and follow those wishes wherever practicable and consistent with the purpose of the decision. There must be no unlawful discrimination |
| Participation | Patients must be given the opportunity to be involved, as far as is practicable in the circumstances, in planning, developing and reviewing their own treatment and care in order to help ensure that it is delivered in a way that is as appropriate and effective for them as possible. The involvement of carers, family members and other people who have an interest in the patient’s welfare should be encouraged (unless there are particular reasons to the contrary) and their views taken seriously |
| Resources (effectiveness, efficiency and equity) | People taking decisions under the Act must seek to use the resources available to them and to patients in the most effective, efficient and equitable way, to meet the needs of patients and achieve the purpose for which the decision was taken |

Nevertheless, two figures of great importance for psychiatry realized that the science of natural laws and general mechanisms needed to be complemented by distinct approaches. As we have shown, Jaspers argued that the very nature of the subject matter of psychiatry called for an understanding of the meanings of and meaningful connections between subjects’ experiences. Windelband argued that understanding the values that we place in and are held by individuals required a different approach from general nomological or nomothetic science.

As with any other area of research, their suggestions were not without problems, and there has been genuine progress in developing their key ideas. Jaspers’ claim that key aspects of psychopathology are both genuinely mental phenomena and yet brutally ‘un-understandable’ has prompted attempts to explain simultaneously how there can be at least shifting and partial understanding of still difficult phenomena. We have mentioned work drawing on a phenomenological tradition, but equally the US psychologist Brendan Maher’s suggestion that delusions are an understandable response to abnormal experiences can be seen as a reaction to Jaspers’ work. Similarly, Windelband’s idea that value judgements require a special kind of individualistic judgement has been replaced by an approach, values-based practice, that is derived from analytical philosophy and relies on ‘good process’, in particular learnable clinical skills, as a basis for balanced decision-making where complex and conflicting values are in play.

Our aim in giving this brief outline of the work of Jaspers and Windelband, as two key figures in the history and philosophy of science, together with their modern counterparts, has been to indicate the extent to which resources derived from philosophy can contribute alongside the sciences to improving mental health care. Phenomenology and values-based practice, furthermore, it is important to add, are themselves set within a new and rapidly expanding international field of cross-disciplinary work between philosophy and psychiatry. As Box 3.3 shows, this is a rapidly expanding field, and there are other potentially important practical developments, notably in relation to tacit knowledge (the basis of professional skills) and individual judgement (as in clinical judgement).

It might seem surprising to some that there should have been this expansion of philosophy and psychiatry over the past two decades, in parallel with dramatic developments in the neurosciences underpinning psychiatry. The history of ideas outlined in the first two sections of this chapter not only makes sense of these parallel developments but also helps us to see their likely future direction. Then, as now, there were dramatic (actual or anticipated) advances in the sciences underpinning psychiatry; and these advances, far from reducing the need for careful conceptual work alongside empirical studies, actually increased it. There are several reasons for this: the challenge of applying generalized scientific knowledge to particular individual human beings, but also theoretical challenges
Box 3.3 Developments in the new philosophy of psychiatry

- 43 New academic and research groups around the world
- Special sections in the WPA and AEP
- Establishment of the International Network for Philosophy and Psychiatry (INPP), launched Cape Town, South Africa, 2002
- Annual international conferences in different parts of the world
- New professorial chairs in Italy, Netherlands, South Africa and the UK
- Training and research programmes, including a recently launched Oxford DPhil
- The international journal Philosophy, Psychiatry, and Psychology (PPP) now in its fourteenth year, from Johns Hopkins University Press
- Several book series, including International Perspectives in Philosophy and Psychiatry (IPPP) from Oxford University Press
- Establishment of the Institute for Philosophy, Diversity and Mental Health (IPDMH) at the University of Central Lancashire in the UK, with over £1 million funding
- Philosophy into practice, e.g. values-based practice (see text).

within the sciences themselves – we noted at the start of this chapter Nancy Andreasen’s claim that advances in the neurosciences have driven many of the deepest problems of traditional philosophy to the top of our practical agenda.

Jaspers’ work in the early twentieth century represented one clear response to these challenges. Naive models of empirical science, he believed, would reduce the sciences of the day to mere scientism (you will recall that he called such models ‘brain mythologies’); and his response was to argue that we needed to find ways of working with meanings alongside and in parallel with scientific work on explanatory causes. Windelband’s work on values represents a different response to scientism – one built on values in so far as these are distinct from meanings. What is shared by these approaches, then, is a recognition of the need to bring together in one way or another the findings of generalized science with the uniqueness of individual human beings.

The need to reconcile generalized science with individual human beings is perhaps particularly acute at the present time, with growing pressure to base service delivery on a narrow model of evidence-based practice that Jaspers would perhaps have characterized as scientific. Yet, again as during psychiatry’s first biological phase, the dangers of a scientific use of evidence-based practice have been most evident to those who have been at the very forefront of developing this approach. As David Sackett puts it, in his seminal training manual on evidence-based practice, it is only when best research evidence is combined with clinical skills and, importantly, patient values that ‘clinicians and patients form a diagnostic and therapeutic alliance which optimises clinical outcomes and quality of life’. There is no better statement of the need for combining rigorous empirical methods with equally rigorous philosophical approaches in developing a psychiatry for the twenty-first century that is both fully science-based and genuinely patient-centred.

KEY POINTS

- Jaspers divides symptoms between subjective and objective. Another person’s objective symptoms can either be detected by one’s senses (such as by sight or hearing) or by merely rational understanding. To be sensitive to another’s subjective symptoms requires that one imaginatively puts oneself into their predicament in a way that goes beyond merely rational understanding. The distinction between objective and subjective corresponds to a distinction between explanation and understanding.
- Jaspers distinguishes between two forms of (subjective) understanding. Static understanding, also called phenomenology, concerns what mental states feel like. Genetic understanding, also called empathy, concerns the way one mental state, ideally and typically, arises from another.
- Jaspers believes that some forms of apparently mental phenomena nevertheless cannot be understood. Primary delusions are, he claims, ‘un-understandable’.
- Windelband distinguishes between idiographic and nomothetic sciences. Nomothetic sciences concern law-like and general phenomena. Idiographic sciences concern one-off events or processes. The most obvious need for an idiographic approach, according to Windelband, concerns judgements about values.
- Values-based practice is a new skills-based approach to working with complex and conflicting values that has been developed from philosophical value theory to stand alongside evidence-based practice as a support tool for clinical decision-making in mental health.

WEBSITES AND FURTHER READING

Fulford and others have examined the links between values-based practice and a number of specific areas of medicine including Child and Adolescent Mental Health Services (CAMHS), management, spirituality and other aspects of the medical humanities, ethics, diagnosis and
neuroscience. See Warwick Medical School website http://www2.warwick.ac.uk/fac/med/study/cpd/subject_index/pemh/vbp_introduction/.

Teaching and learning materials on values-based practice have now been published in a wide range of professional journals and textbooks. See the Warwick Medical School website noted above, and also the Royal College of General Practitioners’ 2005 Curriculum Statement: Ethics and Values Based Medicine at www.rcgp.org.uk/gpcurriculum/pdfs/ethicsAndVBPspRCGPcouncilDec2005.pdf.

Details of Jaspers’ work and of other important figures in the early development of psychiatry are given in ‘History of ideas’ in The Oxford Textbook of Philosophy and Psychiatry (Fulford KWM, Thornton T, Graham G (2006) Oxford: Oxford University Press). Section 3 of this same book covers modern developments in the philosophy of science, Section 4 covers values-based practice and ethics, and Section 5 covers phenomenology and the philosophy of mind. The Oxford Textbook includes a series of readings (on a CD-ROM) and includes detailed guides to further reading and key learning points.

References

INTRODUCTION

In this chapter we review study designs and statistical techniques commonly used in psychiatry, focusing on the requirements of the MRCPsych examination. For reasons of space, we have not included details of all tests and definitions, but where appropriate we have given one or two key references. General texts that would be very useful to consult are: Bland (2000),1 for a comprehensive guide to methods; Petrie and Sabin,2 an excellent handbook covering all the standard statistical tests, including examples; and Everitt,3 for concise definitions. Some useful articles can be found in the journals Bandolier and BMJ Teaching.

Psychiatric data: a typical scenario

We introduce here a typical scenario that will be used as an example throughout the rest of the chapter. A medication training package is offered to nurses, who each care for a caseload of patients. Each nurse willing to participate in a trial of this package is randomized to receive the training or be placed on a waiting list to receive training later, after the trial. Two patients are chosen at random from each nurse’s caseload for assessment of patient outcomes. Outcomes are at two levels: a knowledge test for nurses, before and after the trial has taken place, and a global assessment of functioning (GAF) for patients. This is fairly typical of psychiatric data because it involves comparing groups at different levels within the same study, which leads to ‘clustering’ of data (because patients of a particular nurse are likely to be more similar to each other than patients of different nurses).

We shall use output from the package Stata to illustrate the results of analysing various types of data. Another package that is widely used is SPSS. Both programs are very comprehensive, but Stata has particularly good facilities for the types of data encountered in psychiatry. A good introduction to statistics using Stata is Dupont.4 First we discuss some aspects of study design and general concepts such as precision and bias.

Classification of data types

The type of data being analysed determines which statistical methods are appropriate. In Table 4.1 we have given some examples of types of data that may be encountered in psychiatry and how they are classified.

Apart from the clustering feature mentioned above, psychiatric data have other characteristics that make them somewhat distinct from medical data in general. One of

these is the widespread assessment of patient outcomes from questionnaires. Establishing validity and reliability is particularly important for such data, as are issues concerned with combining responses to several individual questions (or items) into an aggregate score. Before describing the design and analysis of collected data, we first consider some aspects of scale development.

**SCALE DEVELOPMENT**

**Measurement scales**

Measurement involves the estimation of a quantity relative to some standard. Measurements usually need a measuring instrument, such as a measuring tape. The type of unit on which something is measured is called the scale (e.g. metre, second, kilogram) of the measuring instrument. In psychiatry, typical measurement problems involve identifying and assessing the severity of a disorder and evaluating the outcome of a treatment. However, many traits, such as abilities, attitudes, quality of life and personality, are difficult to measure, since they are unobservable and subjective. Psychometrics is concerned with the theory and technique of measuring such psychological phenomena, which are called constructs, latent traits or attributes. In psychometrics, unobservable and subjective phenomena are inferred from variables (items) that can be observed and measured, in the case of psychiatry through the use of questionnaires and structured interviews. Such questionnaires are sometimes called instruments. Adjectival, Likert and visual analogue scales (VAS) are often used in such situations. Figure 4.1 shows an example of each of these.

An example of a published adjectival scale is the Beck Depression Inventory (BDI). This consists of a 21-question multiple-choice self-report inventory and asks questions about the feelings of the subject during the past couple of days. Each question (item) offers four possible answers, arranged in increasing severity. An example of statements for one item is:

0 – I do not feel like a failure.
1 – I feel I have failed more than the average person.
2 – As I look back on my life, all I can see is a lot of failure.
3 – I feel I am a complete failure as a person.

In Likert scales, a declarative sentence is given along with a number of response options. Respondents specify their level of agreement to this. While the descriptor of the adjectival scale is unipolar (from low to high), a Likert item is bipolar, with a neutral/undecided/no opinion term in the middle.

**Constructing a measuring instrument**

The aim is to develop a scale that is reliable (i.e. measuring consistently) and valid (i.e. measuring what it is supposed to measure). The first step in the development of a questionnaire is to generate a pool of items, which is assumed to measure the latent construct(s). From a statistical point of view, the choice of the scale (e.g. adjectival or Likert scale), the level (continuous, ordinal or categorical), the definition of the scaling responses (e.g. choice of adjective or the number of answer steps) and the wording of the question will influence the quality of the final scale. Particularly troublesome are floor and ceiling effects in short scales, where respondents tend to use a compressed interval at the top or bottom of the scale; this limits variability and hence the discriminatory power of the questionnaire.

To investigate how items might relate to latent constructs, it is common to perform a factor analysis, either exploratory (if little is known about how the items relate to factors) or confirmatory (if theory can predict this). Once the items that measure the construct(s) have been decided on, it is then common practice to add them up to make a scale total and/or subscale totals. In calculating totals, it is important that the response values (e.g. from 0 to 5) are in the same conceptual order to obtain a meaningful total score, so some items may need to be reverse-coded (e.g. 5 to 1, 4 to 2, 3 to 3, 2 to 4, 1 to 5). A summary of issues relating to health measurement scales in general is given in Streiner and Norman.

**Types of reliability**

A reliable measure is measuring something consistently, in a reproducible fashion. In psychiatry, many questionnaires are self-administered and the reliability of the respondent needs to be evaluated by administering the scale on two or more occasions. This is called test–retest reliability. The choice of the time interval between two administrations is crucial. It must be sufficiently long that respondents do not remember their previous answers, but short enough that the...
underlying process (such as degree of depression) has not changed. Typical test–retest time intervals for health-related studies range between 2 days and 14 days. Often tests are administered through structured interviews. In this case, one needs to assess the degree to which different raters give consistent estimates of the same phenomenon when rating the same patients (inter-rater reliability). Finally, the individual items need to reliably estimate the latent construct. **Internal consistency reliability** assesses the consistency of items within a scale or subscale.

**Indices of reliability**

Classical test score theory assumes that each person has a true score that would be obtained if there were no errors in measurement. However, measuring instruments are imperfect and an observed score will be the sum of the true score and error. **Reliability** reflects the relative contributions of those two sources of variation. Reliability for continuous variables is usually based on the *intraclass correlation coefficient* (ICC). It is the proportion of variance that reflects between-subject (‘true’) variability and ranges between 0 (no reliability) to 1 (perfect reliability). The most commonly used measure is the ICC for absolute agreement, which measures the absolute agreement between raters or between two observations at different time points and is the between-subject variance divided by the total variance. If we are interested only in relative agreement (i.e. ignoring constant bias between the raters or time points), then the between-rater or between-time-point variance would be removed from the model. The ICC for relative agreement would be estimated by the between-subject variance divided by the sum of between-subject variance and within-subject variance, and is consequently larger than the ICC for absolute agreement. Another statistic that can be used for pairs of observations (different occasions or two raters) is the so-called *concordance index* (see Bland and Altman); this is numerically similar to the ICC for absolute agreement.

Although many software packages calculate ICCs, they can also be estimated through random effects models (see Multivariate and other more complex techniques, below), which can easily extend the ICC to account for more than two factors. It is, for example, possible to include therapist as another random factor in the model to estimate sources of errors due to therapist effects. This extension of reliability is known as generalizability theory and is a powerful tool to identify sources of error in a measurement process.

The test–retest or inter-rater reliability of categorical variables is evaluated using Cohen’s *kappa*, a measure of chance-adjusted agreement that takes a value of 1 when there is perfect agreement and of 0 when observed agreement is equal to chance. Ordinal categorical variables, such as symptom scores with possible scores of low, medium, high, can be assessed using weighted *kappa*, which penalizes according to the extent of disagreement. The kappa coefficient is dependent on the prevalence of the different response types. For example, if the prevalence of depression is low, we can obtain a good reliability for the diagnosis of depression between two raters, even if the raters disagree strongly about the classification of the few positive cases of depression. It is therefore advisable not to rely solely on the kappa but also to assess the percentage agreement within each class.

For internal consistency, a common approach is to calculate Cronbach’s alpha for continuous data, which is the average of all possible split-half reliabilities (where the items are divided in half, e.g. odd versus even questions, and the reliabilities computed for the two halves). If the data are binary, the formula is the same but the index is known as the Kuder–Richardson Formula 20 (KR20). Because reliability increases with the number of items, the index can be adjusted by the Spearman–Brown formula, so that the reliability of scales with different lengths can be compared directly.

Table 4.2 summarizes the various types of reliability discussed.

Intraclass correlations can be classified as 0.6 (fair), 0.7 (good), 0.8 (very good) and 0.9 (excellent), although note that these are all subjective terms; kappas and Cronbach’s alphas are sometimes classified in a similar way.

**Types of validity**

Reliability does not say anything about what is being measured. A measure also requires validity – that is, finding

results that accurately reflect the concept being measured. Reliability is irrelevant without validity and validity implies reliability. Thus, reliability places the upper limit on validity. Some of the types of validity are summarized in Table 4.3.

The evaluation of validity is more of a scientific issue than a statistical one, since it depends on choosing appropriate scales for comparison. It is typically assessed through correlation or regression analysis, comparing the results of the scale of interest with results from other scales or designing experiments to reveal facets of the causal role of the construct. A common validity test involves comparing a screening test against a gold standard diagnosis that has established the true condition, for example as shown in the contingency table or cross-tabulation in Table 4.4.

### Diagnostic test measures

In a diagnostic test (and other situations where one predicts the value of a binary variable), there are a number of measures of predictive accuracy. Sensitivity (specificity) is the proportion of those with (without) the true diagnosis who screen positive (negative). The (positive) likelihood ratio (LR) is the value of the screening test in predicting a positive result and is the ratio of the probability of a positive test from someone with the disorder to the probability of a positive test from someone without the disorder (and similarly for the negative LR). These measures are independent of prevalence and so are generalizable across samples. Positive (negative) predictive power is more useful in clinical situations and is the proportion of those who screen positive (negative) who do (do not) have the diagnosis. Positive predictive value (PPV) and negative predictive value (NPV) are specific to the particular clinical situation since they depend on prevalence. Table 4.5 summarizes these various quantities.

The post-test probability is a useful measure for clinicians in assessing a positive test result for individual patients. It takes account of known prevalence and combines it with the test result, through the intermediate step of computing odds from probabilities, using the following relationships:

\[
\text{Odds} = \frac{\text{probability}}{1 - \text{probability}} \\
\text{Probability} = \frac{\text{odds}}{1 + \text{odds}}
\]

The relevant prevalence is that for the specific population of interest or may be obtained from similar samples. The post-test odds, and hence the post-test probability, can be calculated as follows:

\[
\text{Post-test odds} = \text{pre-test odds} \times \text{likelihood ratio}
\]

If a patient undergoes a series of tests, the LRs can be multiplied together to obtain the post-test probability based on all the tests simultaneously.

For example, suppose the prevalence in the population of interest is 20 per cent, so the pre-test probability of the condition is 0.2 and odds is 0.2/0.8 = 0.25. A patient tests positive using a test that has sensitivity 0.8 and specificity 0.9, and that therefore has \(\text{LR}_{\text{pos}} = 0.8/0.1 = 8\). The post-test odds

is $8 \times 0.25 = 2$. Using the relationship above, the post-test probability is therefore $2/(1 + 2) = 0.667$ (67%).

Finally, we illustrate a receiver operator curve (ROC) in Figure 4.2. This is a plot of sensitivity versus $1 –$ specificity for situations where the screening tool produces a continuous score. In that case, by using different cut-offs, one can balance sensitivity and specificity. The area under the curve is an overall measure of the predictive success of the tool. The example in Figure 4.2 is not particularly good at 0.609: perfection would be 1, and 0.5, the diagonal line, no better than chance. The further the curve is towards the left-hand top corner, the better (high sensitivity and low specificity).

**Figure 4.2 Example of a receiver operator curve (ROC)**

### STUDY DESIGNS

Although some psychiatric studies can be described as exploratory, most aim to answer specific questions such as: Does this new therapy work better than a standard therapy already in use? Can we identify factors that are risk or protective factors for developing certain diseases? Is it worth spending money on specific therapies or methods of delivering services? These three questions most often lead to intervention, observational, and health economics studies, respectively. This classification is somewhat simplistic, as there are often going to be overlaps, but it provides a convenient way of thinking about study design. See Pocock for an introduction to clinical trials.

**Intervention studies**

The main types of intervention (or ‘experimental’) study are now described.

In a randomized controlled trial (RCT), random allocation of patients to the treatments to be compared ensures fair comparisons. Any differences will be due to chance, and with large samples they will tend to be small. A crossover design involves giving the intervention and control to two randomized groups as usual but then, after a washout period, patients swap over, so that the controls have the intervention and vice versa. The advantage is that the difference between intervention and control is measured for each patient, so that patient differences are controlled for in the design. It is only possible for certain types of intervention (mainly drugs whose effect will become negligible during the washout period).

Randomization may be performed separately within strata (e.g. by centre in a multicentre trial, or by gender and/or age group). Methods of randomization include permuted blocks and minimization. The former produces sequences of codes (e.g. ABBA) that are generated at random and used to allocate patients to treatment arms A and B in small blocks, in this case four. Minimization is not a truly random method, but nevertheless it is generally acceptable and allows easy balance across several strata simultaneously. Double blinding means that neither the patient nor the therapist knows the group to which the patient has been assigned; a further protection is triple blinding, where the person analysing the data is also blind. The double-blind randomized, controlled trial is the gold standard of experimental designs since it minimizes most types of bias.

The interventions to be compared may include a placebo – that is, a dummy treatment that appears similar to patients but that has no medical effect. In open-label studies, both the patient and the therapist know the group to which the patient has been assigned; a further protection is being blind to the treatment arm and in this case a placebo is not feasible.

An ethical principal for RCTs is that there should be equipoise – a genuine uncertainty in the minds of the doctors concerned (whether specialists or the wider scientific community) about which arm would most benefit a subject. Another key issue is intention-to-treat (ITT): this refers to the recommended practice of analysing subjects as randomized, whether or not they are receiving the allocated treatment. This means that the benefits of randomization are retained, but it also means that it is the offer of treatment, rather than the receipt of treatment, that is being tested.

Trials are classified into phases depending on the stage of development of the intervention. The classification shown in Table 4.6 is most often used for drug trials. See also the Medical Research Council (MRC) Clinical Trial Unit definitions at www.ctu.mrc.ac.uk, from which some of these definitions were taken.

The reporting of trials is covered by the CONSORT guidelines, which include a diagram showing the numbers recruited, randomized and followed up (Figure 4.3).

Loss to follow-up has traditionally been dealt with using last observation carried forward (LOCR), but this is now discredited and so-called principled methods of dealing with missing values are recommended, such as multiple imputation, model-based methods such as maximum likelihood with predictors of being missing, and probability weighting.

![Consort diagram](https://example.com/consort_diagram.png)
In a cluster randomized trial, a group of patients (e.g. those in a particular hospital ward) are randomized together; outcomes may be measured at the patient level (e.g. symptoms) or the group level (e.g. ward atmosphere), or both. This type of design is relatively common in psychiatry, since therapies are often administered to whole groups at a time. The phrase ‘clustered data’ should not be confused with ‘cluster analysis’ (see Multivariate and other more complex techniques, below). Although randomization can balance the characteristics of the groups across the arms of the trial, it may not be sufficient to balance those of patients. This is a disadvantage compared with individually randomized trials, although practical considerations or a need to avoid dilution may override this. Dilution refers to the possibility of patients randomized to the different arms interacting with one another and sharing some of the effect of therapy. A slightly different version of the CONSORT diagram would be used for clustered trials, and sample sizes need to be increased to take account of the lack of independence within clusters.

In non-randomized controlled studies, two groups are compared but individuals are not allocated at random; rather, the intervention is given to a group of patients and compared but individuals are not allocated at random; controls’ . Major disadvantages of this approach are that one cannot distinguish the effect of the intervention from the possibility of patients randomized to the different arms, it may not be sufficient to balance those of patients. This is a disadvantage compared with individually randomized trials, although practical considerations or a need to avoid dilution may override this. Dilution refers to the possibility of patients randomized to the different arms interacting with one another and sharing some of the effect of therapy. A slightly different version of the CONSORT diagram would be used for clustered trials, and sample sizes need to be increased to take account of the lack of independence within clusters.

In patient preference trials, two groups are compared but individuals are not allocated at random; rather, the intervention is given to a group of patients and another group is chosen to be as similar in all respects to the intervention group as possible. Data may already exist (historical controls) or may be gathered at the same time (concurrent controls). Sometimes this design is the only feasible option, but it may be associated with bias (see Deeks et al. for a discussion).

Patient preference trials allow patients or doctors to choose the arm of the trial according to their preference; clearly this design loses the bias-reduction advantages of randomization, and it tends to be used only where randomization is unethical or would lead to impossibly low recruitment rates. Sometimes preference trials are combined with RCTs to give four groups: those who are content to be randomized (two groups) and those who choose for themselves (two groups).

Before-after (pre–post) studies measure an outcome on the same group of patients before and after an intervention. Patients are sometimes described as being ‘their own controls’. Major disadvantages of this approach are that one cannot distinguish the effect of the intervention from (i) natural improvement over time and (ii) regression to the mean. The latter phenomenon occurs where improvement of some patients is inevitable because their initial symptoms were high by chance. See Morton and Torgerson for a discussion of this phenomenon.

Observational studies

Observational or epidemiological designs are used to describe populations, to investigate risk or protective factors, or to study interventions when it is not feasible or ethical to perform an RCT. In case–control studies, a group of cases is identified and then a comparison group of controls is assembled; if each case is matched individually with one or more controls, this is known as an individually matched case–control study. The important point is that a control would be a case if they had the outcome of interest. By comparing two groups with respect to hypothesized risk factors, one can infer something about the aetiology of the disease. If the control group is similar in general respects to the cases (e.g. they may be chosen to have a similar age range and to live in similar areas) without being individually matched, this is sometimes known as group matching. The analytical methods for an individually matched case–control study would be to estimate odds ratios (ORs) for the risk factor in relation to case–control status using, for example, conditional logistic regression (see Correlation and regression, below). Positive ORs indicate increased risk for those with the factor, but note that ORs can be numerically identified with risk ratios (RRs) only when the risk is small, say less than 5 per cent.

A typical scenario might be to identify cases of schizophrenia and find an individually matched control for each of them of the same age, within ± 2 years, of the same ethnic group and born in the same postcode area. One might then look at birth records to determine whether birth trauma had occurred. Higher odds of birth trauma among those with schizophrenia compared with controls might imply that this was a risk factor.

Retrospective cohort studies compare outcomes in a group of people who have been exposed to a risk factor and another group who have not. An example would be a study of students in which previous neurotic symptoms in adolescence are self-reported. Current diagnosis of schizophrenia is made by a psychiatrist, and the association between the earlier self-reported symptoms and schizophrenia is estimated. Prospective cohort studies look forwards rather than backwards in time and collect data on patients as they become exposed to the risk factor, comparing the outcomes after the passage of time. An example might be a study of people from retirement comparing time to death for those with diagnosis of Alzheimer’s disease with those without. Prospective studies are preferable scientifically because there is less danger of recall bias (see below), but they may be impractical because of the need to wait until data on sufficient people have been collected. Figure 4.4 contrasts the designs of case–control and cohort studies.

Cross-sectional studies take a snapshot in time in order to investigate associations between risk factors and outcomes or to estimate the prevalence of a condition. For example, a survey might seek to detect all people in contact with mental health services in a specific area over a 6-month period; given the total population figures for the area, this could yield an estimate of the period prevalence of severe mental illness. If health service providers were asked how many new cases of severe mental illness occurred in the period, this would yield an incidence rate per year. If patients’ sociodemographic details were recorded, the
association between ethnic group and particular types of mental illness could be estimated (an association study).

Where the unit of observation is an area or group of people, such as a general practitioner’s (GP) practice, rather than an individual, the study is termed ecological. Such studies are most useful for health service provision, where conclusions are sought at institutional level so that changes might be implemented at that level. The ecological fallacy refers to the incorrect attribution to individuals of findings at the group level. For example, the link between the levels of presentation with depression among adolescents might be studied at health authority level, with local information campaigns as a possible predictor. If a link were found, one could increase campaigns as a public health measure. The fallacy would be to assume that information campaigns affected individual adolescents when in fact their influence was more diffuse. Confounding is a particular problem for ecological studies, although they are convenient to perform because routinely collected administrative data can be used.

Health economic studies

Health economic studies are usually focused on comparing the costs and consequences of competing courses of action, such as the use of a new drug, or ways of providing health services, such as the use of assertive outreach teams. See Phelps19 for a general introduction.

The consequences in a cost-effectiveness analysis might be, for example symptom reduction or social functioning. Cost-effectiveness analysis thus tends to be performed where there is a specific disease-related outcome. For example, if a new drug to lessen symptoms in schizophrenia were tested, the effectiveness might be the reduction in a symptom score. Typically, cost-effectiveness is measured as the average extra cost per unit increase in effectiveness – the incremental cost-effectiveness ratio (ICER). If this is less than a maximum willingness to pay, the therapy is considered cost-effective at that level. Cost-utility analysis is similar to cost-effectiveness analysis, except that, in order to place treatments for different diseases on a common basis, outcomes are measured in generalized units of utility. A commonly used utility is the quality-adjusted life year (QALY). One QALY is equivalent to 1 year of perfect health or 2 years in a health state valued at 0.5.

Typically, the results are displayed in a cost-effectiveness plane, as in Figure 4.5. Here, many samples consistent with the data have been bootstrapped to indicate the degree of uncertainty in the overall cost-effectiveness figure (the bold dot). Bootstrapping is a technique whereby many subsamples are taken from the observed data in which some cases are dropped and some replicated; each subsample supplies point estimates, the variation in which indicates the uncertainty in the data; it is used where distributional assumptions of standard statistics cannot be met – as is often the case for cost data. Two lines showing different values for willingness to pay are also shown. Points below these lines would be cost-effective using these criteria.

In cost-benefit analysis, clinical consequences are measured in monetary terms and can therefore be set directly against cost. It is used where different health technologies are to be compared with each other and/or with other types of expenditure. Cost-minimization analysis may also be a part of economic evaluation, where the health technologies to be compared have equal benefit, so that one requires only to compare costs. An increasingly widespread technique is the use of the cost-effectiveness acceptability curve (CEAC), a plot of the probability of cost-effectiveness against various choices of minimum willingness to pay.

IMPRECISION, BIAS AND CONFOUNDING

Psychiatrists want to know whether the observed advantages of a new therapy in comparison with one already existing can be generalized to all patients and need to be confident that the new therapy will work (on average) for all patients with the same diagnosis. A population in statistics represents all units of interests, such as all patients with a similar diagnosis or all nurses in the UK who care for patients with dual diagnosis. Usually we cannot study the entire population, and we have to draw a random sample
from a defined population, for example a sample of 30 nurses. Outcomes for the sample are assessed in relation to risk factors or interventions, and conclusions are assumed to be valid for the underlying population.

How far the conclusions can be justified depends on imprecision, bias and confounding. It is part of the job of the investigator to identify the sources of these errors and to control for them, as far as possible, either through an appropriate design or through the use of a particular type of analysis. On top of all of these factors is chance or random variation, which can affect results despite perfectly measured data, and the possibility of a conceptual error. An example of the latter might be reverse causality, when A is assumed to cause B because of an association between them, when in fact B causes A. Figure 4.6 shows a summary of these various factors.

**Imprecision**

Suppose we measure the mean knowledge before training for a random sample of nurses. This can be used to estimate the mean for the underlying population – that is, all nurses who care for similar patients. However, due to sampling variation (random fluctuations), parameter estimates differ from the true values in the population, and different studies will reveal different estimates. Precision can be increased by using larger sample sizes, since imprecision reflects the type of error that will be averaged out in summary statistics. Two

*Factors that can affect inferences from data*
measures are commonly reported to quantify the precision of parameter estimates: standard errors and 95 per cent confidence intervals (see Statistical inference, below).

Bias

Bias – a systematic error in results or inference – is potentially more serious than imprecision, since it will not average out. Often little can be done other than to recognize that bias may have occurred and to make due allowance in interpretation. Many sources of bias have been classified and given names. Some important ones are described below: see Sackett et al.19 for a more complete list and Lee et al.21 for information about bias in case–control studies in psychiatry.

- **Attrition bias:** the loss to follow-up of subjects from a study (once the population to whom the study applies has been defined). Reasons for attrition include illness that prevents contact, death (unless this is the primary outcome), a move to another area, the patient becoming well and being less interested in participation, and some other personal reason for unwillingness to continue. Attrition is a common problem in long cohort studies, but it can also occur in randomized controlled trials.

- **Ascertainment bias:** occurs when the disease or risk factor is not perfectly identified. This would be a problem in the Alzheimer’s cohort study mentioned above if it were designed as a prospective study, because of the difficulty of diagnosing Alzheimer’s except postmortem.

- **Berkson’s bias (or admission rate bias):** a spurious association may be inferred because the case data arise from a special source. This type of selection bias occurs especially in case–control studies based in hospitals; for example, if in-patients with schizophrenia are matched with controls, also in hospital, in order to investigate cannabis use as a risk factor. However, cannabis use in itself may tend to lead to admissions and therefore is seen more frequently among those in hospital.

- **Information bias:** a systematic difference in the information obtained for different groups of subjects. For example, risk factor data may be either easier or more difficult to obtain for controls than cases. Recall bias is a type of information bias particularly associated with case–control studies based on retrospective data. For example, parents of people with schizophrenia may be more likely to attribute the illness to childhood experiences because they have been searching for an explanation; on the other hand, they may be less likely to recall unfavourable circumstances such as poor nutrition if they felt themselves to be responsible. Observer or interviewer bias is another specific example of information bias, where the information gathered is affected by the views or experience of the observer.

- **Selection bias:** when those who are selected for a study are not representative of those to whom the conclusions are to apply. If each person in the population to whom results are to apply has an equal chance of being selected, then the sample is said to be representative. This is difficult to ensure, and representativeness is often tested after data collection by comparing characteristics of the sample obtained with the wider population. An example might be a study where advertisements are placed in the press for subjects. Only the section of society who read newspapers will be recruited. **Membership bias** is a subtype of this type of bias: people who choose to be a member of a group may tend to have particular characteristics, which differ from those people with the illness in general. For example, members of user groups may derive psychological advantage from campaigning on behalf of their fellow sufferers.

Causal inference and confounding

Causality can rarely be inferred directly from association with complete confidence. Some criteria for causal inferences have been suggested by a number of authors, including the famous epidemiologist Bradford Hill.22 Table 4.7 lists Hill’s criteria (the comments are from the useful discussion by Höfler).21

The applicability of the above needs to be judged in relation to each study, and those in Table 4.7 are perhaps common sense. However, confounding is a key issue that is ever present, although not always obvious. **Confounders** are variables associated with the outcome of interest and also with the risk factor or intervention. For example, keep-fit classes for patients with depression might be more attractive to young people than to middle-aged or older people. If young people were more likely to recover spontaneously from depression, then one might wrongly attribute a good outcome to the keep-fit classes rather than to youthfulness. Usually a confounding factor will produce a spurious positive finding, but in some cases confounding factors can mask a real association. Randomization (in intervention studies) and matching (in epidemiological studies) can average out unknown (or known but unmeasured) confounders to some degree. Analytical techniques such as regression can also deal with remaining confounding to some extent, by controlling for them. However, residual confounding can still occur when a particular factor has not been controlled for (perhaps because it was never measured or recognized or because it was measured inaccurately).

Sometimes intermediate variables are associated with both outcome and the explanatory factor of interest (e.g. intervention group or risk factor) but they lie on the causal pathway. Such variables are not considered as confounders and would not be controlled for in the analysis or design if the aim were to assess the increased risk associated directly with the factor of interest. For example, in a study of association between antipsychotics and bone fractures in elderly people, in order to predict who might need additional interventions, one would not control for bone density in assessing the risk of antipsychotics. This would control away the effect of interest. Finally, one would usually
assume that, in a well-thought-out study, the exposure has the potential to cause the outcome. However, sometimes it is necessary to consider reversing the outcome and the exposure (reverse causality). An example might be a hypothesized causal relationship between cannabis and schizophrenia: does cannabis cause schizophrenia through a direct action on the brain, or are people with mental illness more likely to take cannabis because it helps with the side effects of medication?

DISTRIBUTIONS AND SUMMARY STATISTICS

In a clinical trial, the first table presented in a report might contain estimates of the means, standard deviations, frequencies and proportions for key variables for the randomised groups at baseline. (Contrary to some practice, there should be no significance tests here, because it can be assumed that any differences, even if large, are due to random fluctuation.) The second table might contain the estimates of the mean difference between the groups at follow-up (after the intervention), its 95 per cent confidence interval and an associated P value. The first table provides essentially descriptive information. The second provides information from which inferences can be made – because in that case we hope to come to some conclusion about the effectiveness of the intervention in the population at large. This is discussed later in the section Statistical inference; here, we give some information on summary statistics and distributions that describe data.

Distributions describing data

In many datasets encountered in psychiatry, the underlying population distribution from which such data arise is the bell-shaped normal or Gaussian distribution. An example is shown in Figure 4.7. It is fundamental to statistics because it underlies many standard summaries and test statistics. In the normal distribution, most of the cases are close to the centre and relatively few examples are at the extremes. It is characterized by the mean μ (the central value or average) and the standard deviation σ, a measure of variation in the same units as the data, and is denoted N(μ,σ). The variance is the square of the standard deviation. Conventionally, parameter values for the population (true but usually unknown) are denoted by Greek letters and estimates from samples by lower-case roman letters.

In a normally distributed population:

- 68 per cent of the cases in the population lie within ±σ from μ;
- 95 per cent of the cases in the population lie within ±1.96σ from μ.

One reason why the normal distribution is so important is the central limit theorem, which states that under certain conditions the sum of a large number of independent and identically distributed random variables will be distributed approximately normally. Thus, the distribution of a mean tends to be normal, even when the distribution from which the means are derived is not, and it has the same mean as that of the original population. The theorem also explains why scores that reflect a diverse set of underlying additive biological or psychological influences emerge as approximately normal.

Two other distributions that are important in describing data are the Poisson and binomial distributions. The Poisson distribution describes counts that arise over time, in space or as rare events in a population. Examples might be the number of hospital admissions over a person’s lifetime, the number of lesions in a particular volume of the brain, and the number of incident cases of schizophrenia in the population of a health authority. Although the counts observed over a fixed time period are the data to which the Poisson distribution applies, the interest is in estimating the rate that has produced them. The distribution underlies typical epidemiological methods used in incidence and prevalence studies such as Poisson regression. The distribution is characterized by the mean rate (with variance equal to the

</table>
mean), and it is approximated by the normal distribution as the rate increases (Figure 4.8).

A Bernoulli trial is a term describing a single event, for example admission of a patient to hospital within a given week. Given a fixed probability \( p \) that this event does or does not happen, the distribution of the number \( k \) of such events out of a fixed total \( n \) is described by the binomial distribution. The binomial distribution underlies the analysis of proportions (including logistic regression). The mean and variance of the binomial are \( np \) and \( np(p-1) \). The observed proportion of events \( k/n \) estimates \( p \). When \( p \) is small (say, \(< 0.05\)), \( 1-p \) is close to 1 and \( p(1-p) \) is close to \( p \). In this case, the binomial is close to a Poisson distribution with rate \( p \). For example, if 1 person out of 10 000 dies over the course of a year, one could think of this either as a rate of 1 per 10 000 person-years or as a proportion of 1/10 000 (for a 1-year follow-up). The binomial distribution is approximated by a normal distribution in large samples unless \( p \) is very small. In both the Poisson and binomial distributions, the counts or events are assumed to be independent. In practice, this means that the probability of an event does not depend on what has happened before or, in the case of Poisson counts in a region, in the surrounding region.

### Summary statistics calculated from data

For categorical data, the usual summary statistics are simply frequencies \( n \) and proportions \( p \) (expressed as a percentage) for each category. The odds \( O = p/(1-p) \), where \( p \) is a proportion, is a quantity used as an intermediate quantity in analysis, for example as illustrated above for diagnostic tests or via the odds ratio in epidemiology, but it is seldom presented as a simple summary statistic. Note that the mode may be used as a (not very useful) measure of the typical value in a categorical variable. For example, if ethnic group is recorded as white (70%), black Caribbean (15%), black African (5%) and other (10%), then the modal category is white.

For rates, it is usually important to give the number of events on which the rate is based and the exposure. The term ‘exposure’ is slightly confusing, because it can also mean exposure to a specific risk factor; in this context, it means the total population at risk or the total follow-up time accumulated over all those studied (e.g. in a cohort study). For example, the incidence rate of schizophrenia might be expressed as 25 cases over a follow-up period of 3567 person-years (e.g. 1000 people followed for an average of 3.567 years each), giving a rate of 0.007, or 7 per 1000 person-years. Standardized mortality ratios (SMRs) provide a way of comparing rates across different populations with different characteristics (e.g. age, gender). For example, one might be interested in the rate of schizophrenia among recent immigrants where a confounding factor might be their typically younger age distribution compared with other subgroups or the population at large. A standard population is chosen (e.g. that of the UK) and is divided up into bands (e.g. by age and gender). Rates of disease (e.g.
schizophrenia) in the population are found, for example from national records held by the Office for National Statistics, and are applied to the age and gender bands in the study sample. From this, the expected number of cases can be calculated for each band and accumulated to give the total expected, \( E \). The ratio \( O/E \times 100 \) is the SMR, where \( O \) is the number actually observed.

For continuous data, there are a number of basic summary statistics, of which the mean, standard deviation and range, as shown in the Stata output for the change in knowledge scores for nurses in the scenario, are common:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>

</thead>
<tbody>
<tr>
<td>change</td>
<td>30</td>
<td>2.8</td>
<td>2.483046</td>
<td>-2</td>
<td>8</td>
</tr>
</tbody>
</table>

Medians and percentiles are used to summarize skewed data (the median is equal to the mean in symmetrically distributed data but lower if the data are skewed with a tail to the right). The mode is the value corresponding to the peak of the distribution. Table 4.8 gives the formulae.

In papers, percentages should generally be quoted without decimal places, except in very large samples, and they are usually given in relation to the valid (non-missing) cases. The total sample size should be given with and without missing values. Means and standard deviations are usually given to a small number of decimal points (two or three). Note that confidence intervals or standard errors for means as descriptive data are usually not necessary. Rather, the important figure is the standard deviation, since this describes the variability of the data. (Confidence intervals are more useful for derived statistics from which inferences are to be made). Altman and Bland give some general guidelines on these issues.1

Graphical presentations

Plotting data should be the first step in any analysis. Categorical data can be displayed in bar charts and pie charts. Examples of box plots, histograms and QQ plots for two types of continuous data are illustrated in Figure 4.9. The box in a box-and-whisker plot (or box plot, for short) shows cases between the upper and lower quartiles. The median is indicated on the box plot as a bold line. It is often

---

Figure 4.8 Examples of Poisson distributions (means 1, 3 and 10)
Distributions and summary statistics

Part 1: The foundations of modern psychiatric practice

taken as a ‘typical’ value, especially if the data are not
distributed symmetrically. The whiskers on the plot (the thin
lines) indicate the overall range of the data, after excluding
very atypical values, which are known as outliers. The his-
tograms show frequency distributions, where the range of
the data are divided up into equal-sized ‘bins’ (usually 15–
20) and the number on each bin counted and plotted. The
y-axis scale here is frequency, but proportions can also be
shown (in which case, it is important to give the total
sample size). A theoretical normal probability distribution
with the same mean and standard deviation is superim-
posed; here, the x-axis is continuous and the y-axis is a
probability.

The QQ probability plots are shown on the right. They
provide a way of visually estimating how close a distribu-
tion is to being normally distributed, as an alternative to
formal tests such as the Kolmogorov-Smirnov test. If the
data are normal, the points should lie on a straight line, as
is the case for the first row of data. The second row of
Figure 4.9 shows an example of a non-normal skewed dis-
tribution. (Duration of illness is often log-normally distrib-
uted.) Skewness refers to lack of symmetry and may be
important to consider. (Kurtosis is another feature of non-
normality, where the slope away from the peak is not so
marked as for a normal distribution.) This latter feature
of data is, however, rarely of any concern to data analysis.
Here, the data have a tail to the right, with a few very high
values, and the median is lower than the mean. Taking logs
of such data sometimes produces a normal distribution
(when the original distribution can be described as log-
normal). Analysis can be carried out on the log-transformed
values, and summaries such as the mean are then back-
transformed.

Reference ranges and outliers

In medicine, the mean ± 1.96 standard deviations is some-
times known as the reference range, since it indicates where
the vast majority of cases are expected to lie. It is not the
same as the 95 per cent confidence interval (see Statistical
inference, below). Values outside that range are not neces-
sarily inconsistent with the distribution – they may be just
at one end of a continuum. Outliers, on the other hand, are
cases that are considered to be so extreme as to be unlikely
to be part of the distribution, either because they derive
from another underlying population that has been mixed in
with the main population or because of a data measurement
or transcription error.24 The question of outliers is complex,
but general advice would be to remove data only if there is
definite evidence for a data error.

Dummy variables

In order to include the effects of categorical explanatory
variables, many statistical models employ dummy variables

Table 4.8 Basic formulae for summary statistics based on continuous data
- binary indicator variables where the value 1 indicates that a subject falls into a specific category and the value 0 that it does not. Categorical variables with k categories can be represented by k dummy variables. Since the information provided by a factor with k categories is contained in k – 1 dummy variables (once you know the value of all but one, the value of the last one can be inferred), only k – 1 dummy variables are used in models. The category that has been left out then becomes the reference category.

Here is an example of dummy coding for a factor with three categories (the single variable Factor is replaced by three new variables Dum1, Dum2 and Dum3, only two of which would be included in an analysis).

**Effect sizes**

The term ‘effect size’ often refers to the size of a mean difference or whatever quantity is the focus of interest. A measure of relative effect size can be presented to allow the scientific or clinical importance of the observed effects to be assessed on a common scale. The need for this arises because (i) a statistically significant difference in a large sample might be small and of no scientific importance; and (ii) different variables to be compared might be measured in different units. A widely used relative effect size is Cohen’s $d$, which, for the comparison of two groups, is the mean difference between two groups divided by the pooled standard deviation. The standardized response mean (SRM) may be more appropriate as a measure of responsiveness to change. It is the mean of the change scores divided by the standard deviation of the change scores. Values for Cohen’s $d$ or SRMs between 0.2 and 0.5 would be regarded as small, between 0.5 and 0.8 as medium, and above 0.8 as large. It is important to explain how any such standardization has been performed and to be aware that using the standard
deviation computed from a particular sample may limit the generalizability of the results. Because relative effect sizes can be compared across studies, they allow the accumulation of knowledge: a special statistical technique, meta-analysis, allows the combination of the results of several studies (see Multivariate and other more complex techniques, below).

### STATISTICAL INFERENCE

#### Point estimates, standard errors and confidence intervals

Statistical inference is concerned with drawing conclusions from data and generalizing them to populations. It typically involves calculating point estimates and estimates of uncertainty such as confidence intervals, and performing hypothesis tests (e.g. comparing two or more groups, perhaps two arms in an RCT or those at risk and those not in a cohort study).

A point estimate is a single estimate such as a mean. In the Stata output for the nurse example below, the mean of the change from baseline to follow-up is 2.8 (point estimate). The standard error (SE) is an estimate of uncertainty in the point estimate and is the standard deviation of the distribution of the means (here, it is 0.453 = 2.483/√30, 2.483 being the standard deviation (SD) of the raw data as shown earlier).

Confidence intervals (here, 1.87 to 3.73) are derived from standard errors (and they both give equivalent information), but the confidence interval is the preferred measure of the precision for a parameter estimate. In recent years, journals have increasingly recommended authors always to report confidence intervals, not least when results are inconclusive, because they indicate the largest and smallest estimates consistent with the data; these estimates are helpful in planning further research.12,13

What do confidence intervals show? If we repeat an experiment, trial or any other study involving a random sample many times and calculate each time a mean and its 95 per cent confidence interval, those intervals would contain the true population mean in 95 per cent of the repeats. An intuitive way of thinking about this is that it is the range within which we expect the true parameter to be with 95 per cent confidence.

The simulation illustrated in Figure 4.10 exemplifies this. We assumed that a distribution of a change score for the nurses was distributed normally with a true mean of 2 and a standard deviation of 2, and we drew 50 random numbers from this distribution, repeated 100 times. Each time, the sample mean and its 95 per cent confidence interval were calculated. Figure 4.10 shows the results. The average sample mean from the 100 simulations was 2.04, which is very close to the true mean. At no time was it estimated at the true population value of exactly 2, but 95 of the 100 95 per cent confidence intervals do include the true mean of 2. In only five simulations (filled circles) would we have made a wrong inference about the true population mean from the confidence interval.

#### Formulae for standard errors and confidence intervals

Tables 4.9–4.11 give formulae for standard errors and confidence intervals for a number of point estimates. It is not necessary to remember all of them but to remember rather the following key points, which relate to approximate standard errors and confidence intervals based on large samples (n > 50), unless otherwise stated:

- The 95 per cent confidence interval for a point estimate is given by estimate ± 1.96 × SE.
- Standard error for a mean of a normally distributed variable = SD/√n.
- In small samples, the 1.96 in the formula for the confidence interval of a mean is replaced by the corresponding value of a t distribution with n − 1 degrees of freedom.
- Standard error for a proportion \( p = \sqrt{p(1-p)/n} \).
- Standard error for a count \( a = \sqrt{a} \).
- Confidence limits for ratios of proportions, rates and odds are calculated on the log-transformed scale and then back-transformed.
- For samples smaller than 50, ‘exact’ methods using special tables or software are based on the underlying Poisson or binomial distributions.
- The larger the sample size n of a study, the smaller the standard error and 95 per cent confidence interval, and thus the more precise the estimate.

Table 4.9 gives formulae for summary statistics for a single proportion p based on k successes out of n trials or for a comparison of two proportions \( p_1 = a/(a + c) \) and \( p_2 = b/(b + d) \) (see Table 4.3 above for the layout of data assumed for these formulae). Ratios of proportions and odds, which are commonly used in case–control studies, are natural log-transformed before standard errors and confidence limits are calculated and are then back-transformed by exponentiation. For samples smaller than 50, ‘exact’ methods using special tables or software are based on the underlying binomial distribution.

Table 4.10 gives the formulae for a rate based on a events with a population or follow-up time (time at risk) in terms of person-years of \( N \), or a comparison of two rates \( a/N_1 \) and \( b/N_2 \). For samples smaller than 50, ‘exact’ methods using
special tables or software are based on the underlying Poisson distribution for counts.

The standard errors and confidence intervals for continuous data that can be assumed to be approximately normally distributed are shown in Table 4.11. For large samples (> 50), the 95 per cent confidence interval is given by estimate ±1.96 × standard error; for small samples, the appropriate point of the T distribution should be used instead of 1.96.

Note that in the above formula for the variance, the denominator is \( n - 1 \) and is called the degrees of freedom. It can be shown that the estimate of the underlying population variance is unbiased if \( n - 1 \) is used as a denominator rather than \( n \).

**Hypothesis tests**

In many studies there is a prediction of a difference between groups. This prediction is variously known as the experimental, research or alternative hypothesis (H1). The converse hypothesis is the null hypothesis (H0). We test H0 to see whether we can reject it beyond reasonable doubt in favour of H1. The procedure of classical hypothesis testing is to define a research and a null hypothesis, to collect sufficient data and to calculate a test statistic \( z^* \); this is compared against a probability distribution, which is known if the null hypothesis is true. We reject H0 if the observed test statistic is very unlikely to occur if H0 is true, according to the probability that \( Z > z^* \), where \( Z \) is a theoretical random variable with the known distribution. A null hypothesis is rejected if this probability – the P value – is below a critical value, \( \alpha \); thus, \( P \) is not the probability that H0 is true but the probability of an extreme value if it is true.

Typical values for \( \alpha \) are 0.1, 0.05 and 0.01. They may be adjusted if multiple tests are to be performed using, for example, the Bonferroni correction: this would divide \( \alpha \) by as many tests as are to be applied simultaneously (e.g. see Shaffer\textsuperscript{27} for a discussion of multiple testing). In the vast majority of cases, one assumes that the null hypothesis

---

**Figure 4.10** Results of 100 simulations from a distribution with mean 2 and standard deviation 2. Sample means and 95 per cent confidence intervals computed from 50 cases each time.
would be rejected with an extreme finding in either direction (i.e. large or very small), so a double-sided test is applied. Occasionally one knows in advance that deviations are impossible in one direction, so a single-sided test is applied.

In a single-sided test, $\alpha$ corresponds to the critical value $z^*$, such that:

- The probability that $Z > z^* = \alpha$
- The probability that $Z > z^* = \alpha/2$

</tbody>
</table>

CI, confidence interval, $a$ and $b$, counts $N_1$ and $N_2$, follow up times.

For example, if the desired significance level is 0.05, testing a mean value assuming a normal distribution for $Z$, the corresponding value for $Z$ must be greater than or equal to 1.645 (or less than or equal to $-1.645$) for a single-sided test. For a double-sided test (where the extreme values can be at either end of the distribution), we are interested in:
so that probability is divided up between the two extremes of the distributions and the critical value $z^*$ corresponds to the $\alpha/2$ significance level. To achieve a significance level of 0.05 for a double-sided test, the absolute value of the test statistic ($|z|$) must be greater than or equal to the critical value 1.96 (which corresponds to the level 0.025 for a single-sided test).

A 95 per cent confidence interval can also be used as a criterion to reject a null hypothesis: if it does not encompass the null hypothesis value, then the effect is statistically significant at $P = 0.05$. The null hypothesis value would be 0 (for a comparison of means in two groups) or 1 (for a comparison of proportions in two groups using ORs or RRs). A test based on $P$ values and a test based on confidence intervals are closely related, and they will almost always result to the same conclusion about rejection of a null hypothesis.

### Power and sample size calculations

When performing significance tests using $\alpha = 0.05$, over the long run the rejection of $H_0$ will be mistaken in 5 per cent of occasions; this is a type I error. The probability of accepting the null hypothesis even though the alternative hypothesis is in reality true is denoted by $\beta$ and $1 - \beta$ is known as the power of a test. The error is known as a type II error. The latter is more difficult to assess, but it is possible to control for it by doing a power analysis during the planning stage of a study. Here is a summary:

- **$\alpha$-error**: probability of making a type I error (rejecting $H_0$ although $H_0$ is true).
- **$\beta$-error**: probability of making a type II error (accepting $H_0$ although $H_1$ is true).

A sample size calculation requires the following information:

- The smallest difference (or ‘effect’) that is considered to be of clinical importance
- The significance level $\alpha$, or probability of a type I error, to be used – typically 0.05
- The expected level of loss to follow-up.

For continuous data, one needs an estimate of the standard deviation within groups; if this is unknown, then Cohen’s standard effect size (see above), which by definition has a standard deviation of 1, can be used as a generic solution. Sample sizes can be calculated using specialized computer software or using formulas and tables from standard textbooks (e.g. Cohen\(^2\)). A rule of thumb for the sample size for a power of 80 per cent and a two-sided $\alpha = 0.05$ for independent $t$-tests or $\chi^2$ tests is:

$$\text{Sample size per group} = 16/d,$$

where $d$ = Cohen’s $d$ (the standardized difference)

### Assumptions made by tests

Many statistical tests for continuous data depend on assumptions, for example that the data are distributed normally or that the variances of different groups are the same (variance homogeneity). Tests that depend on specific distributions are described as parametric. Before commencing with the main analysis, one may wish to investigate the following:

- Tests for normality, Levene test for variance homogeneity, are usually performed first, with large sample sizes may reject the null hypothesis even if the violations are minor and have little impact on the conclusions. Equality of variances can be evaluated by a rule of thumb: the larger standard deviation should be less than twice the smaller standard deviation.\(^2\)

Normality is best assessed visually by plotting box plots, histograms or QQ plots of the observed data for each group.

A further assumption that may be made is of independence of observations. This is often invalid for psychiatric
data and then special methods are required, either robust methods or methods specially designed for non-independent or clustered data (see Multivariate and other more complex techniques, below). Robust methods include those that use standard models, such as regression, but with adapted variances for the parameter estimates (so-called sandwich estimates), with the aim of more realistic \( P \) values even when the distribution of the data is not as specified in the model. Bootstrapping is another robust method that works similarly to simulation (see section on health economics, where bootstrapping is commonly used).

### Transformation

If the assumptions of a normal distribution and/or equal variances are not satisfied, then it may be advisable to transform the data. In psychiatric studies, data are often positively skewed, especially with essentially positive values such as service-use or cost data. Log-transformation is helpful both for producing normal distributions and also for unequal variances if the larger variance is associated with higher values. Note, however, that the back-transformed mean of a lognormal distribution is the geometric mean and is closer to the median of the original values rather than to the arithmetic mean. The arithmetic mean of the original untransformed data is estimated by \( \exp(m + s^2/2) \), where \( m \) and \( s \) are the mean and standard deviation of the (natural) log-transformed values, respectively. Other transformations are the square transformation \( (x^2) \), which is used if the data are negatively skewed and the square root \( (\sqrt{x}) \), which is recommended for count data (although note that it is usually preferable to use methods based on the Poisson distribution rather than to transform and assume normality).

### Non-parametric tests

An alternative to transformation is to use non-parametric tests, which do not assume particular distributions and are usually based on ranks. They do make other assumptions, however, depending on the test. A disadvantage of non-parametric tests is the difficulty of deciding on the appropriate summary statistic to illustrate group differences (instead of the mean and standard deviation). Another disadvantage is that it is difficult to extend analyses to take account of confounders (relatively easy with normally distributed data using regression). Siegel and Castellan\(^{29}\) is a good basic text on non-parametric tests.

### What do significant and non-significant results mean?

It is important to remember that statistical significance does not tell us anything about the importance of the effect. It reflects the amount of evidence that the effect exists. Small and clinically unimportant effects can become statistically significant if the sample size is large enough. Two quantities mentioned above are helpful in balancing statistical and clinical significance: the 95 per cent confidence interval for the point estimate, which quantifies the possible range of the effect, in original units, that is consistent with the data, and the standardized effect size, which places the point estimate on a scale measured in units of standard deviations.

As Altman and Bland discuss, ‘absence of evidence is not “evidence of absence”’.\(^{10}\) If the \( P \) value is above 0.05, this tells us that the observed effect is not large enough to exclude chance as an explanation. Thus, if there is no evidence to reject the null hypothesis, this does not mean that we have proved it to be true. Classical or frequentist hypothesis testing is thus fundamentally asymmetrical in that more weight is given to the null hypothesis, since it is accepted unless there is overwhelming evidence to reject it.

### The Bayesian approach

The frequentist approach may seem not to address the aim of the study, which is to assess the probability that a hypothesis is true. Furthermore, this approach uses only information from the current study and does not integrate other available information, such as results of previous studies or opinions of psychiatrists. The Bayesian approach adopts a different viewpoint, more concerned with weighing the evidence both for and against a research hypothesis. It is based on the beliefs about parameters and the hypothesis as well as the data (see Bolstad\(^{31}\) for an accessible introduction). In Bayesian statistics, population parameters are considered to be random variables and thus have probability distributions. In this context it is possible to express the belief or the probability that a research hypothesis is true. The belief in the hypothesis before the study starts is called the prior probability, which is converted to a posterior probability by the analysis of the data. This update is based on conditional probability through Bayes’ theorem. A major criticism of Bayesian statistics is the subjectivity of describing prior belief and, in the past, the difficulty of the mathematics and computation involved. However, Bayesian methods have become increasingly popular, especially in decision-making analysis.\(^{12}\)

### Illustrations of hypothesis tests

#### Summary of tests

Table 4.12 summarizes the most important parametric and non-parametric tests and when they are used. The most commonly used tests will be illustrated later in this section. The statistical distributions used in the tests in Table 4.12 are the Student’s \( t \), \( \chi^2 \) and \( F \) distributions. Their distributions depend on the degrees of freedom, which is generally
the sample size minus the number of parameters that have been estimated (e.g. for the $t$ distribution there are two parameters, the mean and standard deviation). Table 4.13 shows how these distributions are usually represented (the $d$s here are degrees of freedom, and some relationships that are worth remembering). The specific tests will be discussed later.

### The independent samples $t$-test

Let us illustrate hypothesis testing with an example of the knowledge of nurses before and after a training programme. We are interested in whether nurses with training improved their knowledge more than nurses on the waiting list, on the basis of the change in knowledge test scores. What is the likely range of the true mean difference in change scores, and is there evidence that this difference is significantly different from the null hypothesis value of 0? The test statistic is the mean difference between the two groups divided by its standard error – the $t$ statistic. The larger the difference between the two groups and the smaller the standard error, the larger the (absolute) value of $t$. The size of $t$ is judged in relation to the theoretical $t$ distribution; if it is above a critical value corresponding to $\alpha = 0.05$, it is deemed to be significant.

The output below presents the $P$ value, which is 0.0018. The chance of obtaining a $t$-value greater than $|3.45|$ if the null hypothesis is true is thus less than 0.05 and we can therefore reject the null hypothesis. Alternatively, we can say that the observed mean difference of improvement is significant.

between waiting list and training group nurses of -2.67 is too large to be explained by chance. The 95 per cent confidence interval of the difference in change score is -4.25 to -1.08 and does not include 0. It also informs us that the test can be rejected at 0.05. Additionally, it tells us that the possible mean difference ranges between -4.25 and -1.08 (see Stata output, above).

The $t$-test assumes that in the population the variable is distributed normally in each group, the variances are the same (variance homogeneity) and the observations are independent of each other. The $t$-test is fairly robust against some violations of the assumptions of normal distribution and variance homogeneity but not against violations of the independence of observations. As $n$ increases, the $t$ statistic approaches the $z$ statistic, which has a $N(0,1)$ distribution. For large samples, therefore, any estimate of a mean difference from an approximately normal distribution whose absolute value is more than twice its standard error is significantly different from 0 at $P = 0.05$. This rule of thumb comes from the (rounded) double-sided 0.05 point of the normal distribution i.e. 1.96.

The Mann–Whitney U (Wilcoxon rank sum) test
A non-parametric test that can be used for comparing two independent groups when the data are not normally distributed is the Mann–Whitney U test (MWU; also known as the Wilcoxon rank sum test). The MWU test is based on the ranks of the data and does not have any distributional assumption. However, note that it tests equality of medians only if the distributions have the same shape. Figure 4.11 shows two types of non-normal data, illustrating how

![Figure 4.11](image-url)
important it is to plot the data to decide whether the median interpretation is reasonable.

Using the MWU test for our example, we get the following output (see Stata output, above).
The test statistic is \( z = -3.182 \), \( n_1 = 15 \), \( n_2 = 15 \), \( P = 0.0015 \) (based on an approximation), so at the 0.05 level we can reject the null hypothesis that the two groups have the same distribution in the population. If the sample size is small (< 10), exact P values should be requested from the statistical software or the test statistics should be referred to statistical tables.29

Comparing more than two groups: analysis of variance

Analysis of variance (ANOVA) is used to test differences among two or more means. It is closely related to linear regression and can be analysed using regression techniques; the t-test is a special case. The F-test in an ANOVA compares the variability between means to that within means. Once an overall difference is established, post-hoc comparisons between groups can be applied using either specific predefined contrasts or all pair-wise comparisons with a suitable adjustment for multiple testing (e.g. Bonferroni adjustment or the Tukey test, which is less conservative). In the example below, the F-test indicates strong evidence for differences among the groups (\( P = 0.0009 \)). The regression-style output below the F-test shows differences between dummy-coded variables (see Statistical inference, above) with the reference category, the highest-coded group in this case 3, denoted ‘dropped’. Here, group 1 is not significantly different from group 3 but group 2 is (see Stata output, below).

Here is a contrast, that between groups 1 and 2, which
In a *factorial design*, several factors are varied in the same experiment. For example, drugs A and B may be given at two levels, to give four combinations. This design allows two questions to be answered at the same time, and in particular it can test whether the combination of A and B is more effective than the additive effects of either (a phenomenon known as synergy). This design is easily analysed using the ANOVA framework. A synergistic effect would result in a significant interaction F-test between drug type and level. Figure 4.12 shows another example of an interaction between two factors, gender and time (pre- and post-drug treatment): the blood level of a certain hormone was measured in males and females before and after a drug treatment. The effect of the drug on hormone level depends on gender: only in females was an increase of the mean blood levels of a hormone after the drug treatment observed.

Where a continuous variable is controlled for (e.g. severity of illness), ANOVA is known as analysis of covariance (ANCOVA); and is usually analysed by regression. The Kruskal–Wallis test is a non-parametric version of ANOVA that compares medians in two or more groups.

**Comparing two related samples: paired t-test and Wilcoxon signed rank test**

Often we want to compare changes within a group, such as the pre- and post-training knowledge for those nurses who were trained. In this case, our two measurements are not independent. A nurse who scored above average in the knowledge test before the training started is more likely to score above average after the training programme than a nurse who scored poorly at the beginning. We need to consider the dependency of these repeated measurements, otherwise we will lose the advantage of the within-individual comparisons. This is done by the dependent samples *t*-test or its non-parametric equivalent, the Wilcoxon signed rank test. The null hypothesis here is that the mean change in the group with training is zero (see Stata output, below).

The mean difference between post- and pre-training knowledge is 4.13, with a 95 per cent confidence interval of 2.779 to 5.488. Because 0 is not included in the 95 per cent confidence interval, we can conclude that there is a significant increase in knowledge after the training. This conclusion is confirmed by the test statistic \( t = 6.5458 \).

A similar result is obtained if a non-parametric test is used. A Wilcoxon signed rank test shows that the pre- and post-training knowledge levels are significantly different.
Research methods and statistics

post-training scores are significantly different ($z = 3.358$, $N = 15$, $P < 0.001$). Here, $N$ is the sample size minus the number of tied observations within a subject. Exact $P$ values should be calculated from tables or software if the sample size is smaller than 10.

The above paired tests are also used if the individuals of two groups are different but linked in some other way. In twin studies, twins with a psychiatric disorder are often compared with their respective unaffected sibling. Parent-child studies and comparison between the two halves of the brain are other examples.

Note that these paired tests look only at changes within a group; if a comparison between groups is the issue, one would use an independent $t$-test on the change scores as above: two separate within-group $P$ values are not appropriate for comparing groups (e.g. a contrast between a significant $P$ value in one group but not in the other). This is because, as already noted, the non-significant $P$ value indicates not absence of an effect but lack of evidence for an effect.

**A single group: one-sample $t$-test**

The one-sample $t$-test assesses whether the mean value differs from a theoretical value, for example does the mean knowledge score of the nurses differ from 10? The comparison value is often called a norm (a value obtained from very large sample, perhaps over many years, and that becomes a standard; intelligent quotient (IQ) of 100 is one such norm). Again, the confidence interval of the estimated mean of 13.5 ranges between 12.58 and 14.49 and does not include 10. Therefore, we can conclude that the nurses score significantly better than 10. A formal one-sample $t$-test below shows that we can reject the null hypothesis that the knowledge score of the nurses before the treatment started is 10 at the 0.05 level and again conclude that nurses score significantly better than 10 (see Stata output, below).

If the data are seriously skewed, we can use the one-sample Wilcoxon test as a non-parametric alternative.

**Chi-squared and Fisher’s exact test, and McNemar’s test for paired proportions**

The chi-squared ($\chi^2$) test can be used as a goodness-of-fit test to compare a theoretical and an observed distribution. More widely used is the $\chi^2$ test for proportions in a two-way contingency table. It is based on a comparison of observed and expected frequencies in the cells of the table. The degrees of freedom are $(k_1 - 1) \times (k_2 - 1)$, where $k_1$ and $k_2$ are the number of categories in the rows and columns, respectively. An amendment to the basic $\chi^2$ statistic, aimed at improving the fit to distributional assumption, is the continuity correction or Yates’ correction. If any of the expected frequencies is less than 5, then the distributional approximation to the $\chi^2$ test statistic is inaccurate and Fisher’s exact test would be used. This test does not work with a test statistic as such but enumerates all possible tables with the same marginal totals to find the proportion as extreme as that observed and so produces only a $P$ value. The example below illustrates a test of whether diagnostic groups differ according in the proportions above and below a functioning threshold as measured by the GAF.

```

```
The participants are followed from a starting point or recovery or relapse (e.g. time until a relapse of a psychosis). The participants in a study experience a specific event such as death or recovery or relapse (e.g. time until a relapse of a psychosis). The participants are followed from a starting point (which can be different for each participant) until the time when the event of interest occurs. If the participant withdraws or the study ends before the event occurs, the data are described as censored: we do know that the time to event (survival time) is longer than the measured follow-up, but we do not know the actual time. Simple statistics such as the standard $\chi^2$ test or the mean time to the event are oversimplistic for censored data, which are preferably analysed with survival analysis methods.¹⁴

A popular non-parametric survival method is Kaplan–Meier analysis, which allows the estimation of a survival function (proportions of people at successive time intervals who survive without the event occurring). It is drawn as a plot with time on the $x$-axis and survival probability on the $y$-axis drawn as a step function, since only times when events actually happen are plotted. The time at which 50 per cent of people survive is the median survival time, and this is often used as a summary statistic, along with its 95 per cent confidence interval. Figure 4.13 shows the survival curve for patients with severe Alzheimer’s disease in two different treatment groups. The difference in survival probability increases until about 50 months. Then the curves start to merge and after 12 months both curves approach 0.

Formal tests such as the log-rank test are used to compare the survival distributions for two or more groups. This is a $\chi^2$ test that compares the observed numbers of events at each time point with the number expected if the survival curves were the same for the two groups. It does this by ordering the survival times of all participants and hence dividing up the follow-up time into intervals in which events occur. In each time interval, the number of events is recorded and the number of participants who remain at risk is reduced accordingly. The numbers observed and expected under the null hypothesis of no difference between the groups are accumulated over the whole time period. See Collet³⁵ for further details.

The distribution of the times to death for the two groups is significantly different according to the log-rank test. The median time to death of patients in the new treatment group is 40 months, while it is only 27 months in the old treatment group (see Stata output overleaf).

Other survival analysis methods such as Cox regression can allow for the effects of covariates (including covariates that change over time) on the survival time.

### CORRELATION AND REGRESSION

So far, we have analysed measurements from different groups. Often, however, we want to assess the relationship between two variables in a single group. For example, using the nurse dataset, one might wish to assess the relationship between the knowledge score before and after the training program. Does a high score after training depend on a high score before training? Such an analysis should start with a scatter plot, in which one variable is plotted against a
The horizontal axis (x-axis) and another one against a vertical axis (y-axis). If one variable is considered to be dependent on the other (e.g. if one follows the other in time), then that variable should appear on the y-axis.

Figure 4.14 shows a scatter plot between pretreatment scores and post-treatment scores of the 30 nurses. Note that six cases have the same values and do not appear as separate points. The line is from a fitted straight-line regression of post-treatment on pretreatment score. This would differ from the regression the other way around, of pretreatment on post-treatment score, because it finds the line that minimizes the squared errors or residuals. These are measured by the vertical distances between the points and the line using a method of estimation known as least squares.

Regression assumes that one variable (the dependent variable on the y-axis) is a random variable whereas the other (the independent or explanatory variable) is a fixed error-free measurement. This is of course rarely the case and is not true of the nurse data. Errors of measurement in the independent variables attenuate the slope of the line (make it less steep), and it is worth bearing this in mind, although in practice this feature is usually ignored.

The difference between regression and correlation

Although mathematically (and in terms of the situations where they are used) correlation and regression are closely allied, there are conceptual differences between them. When one of the variables is thought to depend on or be predicted by the other, the natural approach is that of regression (see below). When the question is simply a matter of the degree of an association, then correlation analysis is more appropriate. Correlation is essentially symmetrical, and distributional assumptions about both variables are necessary for hypothesis tests, whereas in regression no distributional assumptions are made about the independent variables. In the above example, one could treat the data either way: correlation between the scores could be estimated, or a regression of knowledge after training could be fitted to that before training (the reverse relationship would probably not make much sense, indicating the importance of actively choosing what is to be the dependent variable and bearing in mind the criteria for causation, e.g. as in the Bradford–Hill criteria listed earlier).

Pearson’s product moment correlation

The most commonly used measure of association is the Pearson product moment correlation coefficient, $r$, used to measure the strength of a linear relationship between two normally distributed variables with equal variances. It ranges between $-1$ (perfect negative relationship) and $+1$ (perfect positive relationship). The square of $r$ is the percentage of variance in one variable explained by the other. In the nurse example, $r$ for the relationship between pre- and post-training knowledge is 0.52. Pretraining scores explain therefore 0.52² or 27 per cent of the variance of the post-training scores. Hypothesis tests for the population correlation $r$ can be based on the Fisher transformation:

$$ z = \frac{1}{2} \ln \left( \frac{1 + r}{1 - r} \right) $$

which produces a test statistic $z$ that is approximately $N(0,1)$. A hypothesis test (single-sample $z$-test) of the null hypothesis that the population correlation is 0 shows that the observed $r$ of 0.52 is significantly different from 0 ($P = 0.003$, 95 per cent confidence interval 0.20 to 0.74).

A correlation coefficient of 0 means that there is no linear relationship, but this does not mean that there is no relationship of any kind – it might be non-linear (hence the need to plot the data). It is important that there is no funnel shape in the data where the spread widens or narrows at different levels of the variables (indicating heteroscedasticity, i.e. a change in variance) and no outliers, to which Pearson’s correlation is very vulnerable. Partial correlations are correlations between a pair of variables after adjusting...
for a third (and can be derived from the three pair-wise correlations).

**Spearman and Kendall’s tau correlation**

Non-parametric alternatives are available, such as Spearman’s rank correlation \( \rho \). This is equivalent to the Pearson’s correlation calculated on the ranked data and detects any monotonic (i.e. increasing or decreasing) relationship, such as an exponential relationship. Spearman’s \( \rho \) ranges from \(-1\) to 1 and is interpreted in a similar way to Pearson’s \( r \). However, \( \rho^2 \) cannot be interpreted as a percentage of variance explained in the same way as \( r^2 \). If there are tied observations in the data, a corrected version should be used. Furthermore, if the sample size is small (<15) or if there are tied observations among the data, either exact \( P \) values should be computed or a statistical table for critical values of \( r \) should be consulted.\(^{29}\) Spearman’s \( r \) assumes that the difference between all subsequent ranks is the same (e.g. the difference between ranks 1 and 2 is the same as between ranks 10 and 11). This a commonly made assumption for Likert scales in psychiatric measurement scales. If the assumption of equidistance cannot be assumed, then Kendall’s tau correlation coefficient is an alternative for ordinal-level variables.

**Linear regression**

Multiple linear regression is used for prediction of a variable from a set of other variables, or to control for confounders when the interest is in one particular variable (e.g. treatment arm). For example, one might use a \( t \)-test to compare the mean values of a continuous variable, such as symptom score, between two groups in a randomized controlled trial. Then one might wish to control for the baseline value and perhaps also sociodemographic variables using regression. This procedure is often known as ANCOVA. Regression and ANOVA, and ANCOVA (a mixture of the two), are examples of *general linear models* – not to be confused with the even more general *generalized linear models* (see below).

The example below shows typical output for a regression of functioning (GAF score) on days in hospital, randomization group of the patient’s nurse and admission cohort (three categories, included as two dummy variables). (Because the patients are ‘clustered’ within the nurse, a preferable analysis would take this into account; see Multivariate and other more complex techniques, below) (see Stata output, below).

The linear regression prediction equation is (rounded):

\[
\text{GAF score} = 59.39 + 7.470 (\text{if randomization group} = 1) + 2.844 (\text{if admission group} = 2) + 21.952 (\text{if admission group} = 3) + 0.00323 (\text{days in hospital})
\]

The coefficients are the estimates of the increase in the dependent variable for a one-unit increase in the independent variable, adjusted for all other variables. Thus, since \( \text{group} \) is coded 0 and 1, the coefficient for \( \text{group} \) in the
regression equation is the adjusted difference between groups. With no other variables in the equation, it would be the same as a \( t \)-test. The \( R^2 \) is the percentage of variance explained and is equal to the correlation between the predictions made by the above equation and the dependent variable. \( R^2 \) depends on the number of parameters; a value that is more comparable across different numbers of parameters is the adjusted \( R^2 \), which takes these into account. The F statistic in the top right corner reflects the significance of the group of explanatory variables taken together. The F statistic at the end reflects the significance of admission cohort as a categorical variable. Specific comparisons between the dummy-coded diagnostic groups 2 and 3 and the reference category appear in the main body of the result: \( P = 0.288 \) and \( P < 0.001 \), respectively.

### Logistic regression

If one wished to compare the groups in terms of a binary variable, for example symptoms improved, then the approach would be a \( \chi^2 \) test to compare proportions followed by logistic regression to control for other variables. Logistic regression analysis maximizes the likelihood (the probability \( p \) of the observed data given a particular statistical model) to estimate the parameters of a linear equation for the log of the odds – \( \ln(p/(1-p)) \) – also called the logit.

It does this through an iterative process to maximize the likelihood (maximum likelihood estimation). The output can be expressed in terms of the coefficients that apply to the logit through the linear predictor. An alternative formulation is in terms of exponentiated coefficients, which are the estimated adjusted ORs, and these are usually more useful for interpretation.

The example below shows the output in OR format for a logistic regression of binary (0/1) functioning category against randomization group (coded 0/1) and three-category diagnostic group for 30 of the patients (see Stata output ➀, below).

Here, diagnosis 2 seems to be significant at about \( P = 0.05 \) compared with diagnosis 1. However, we need to test the whole variable, so we still need to perform a likelihood ratio test. We rerun the analysis without diagnosis to see whether the likelihood drops significantly, as illustrated below. Such tests can be validly applied when model A is nested in model B (i.e. A’s parameters form a subset of B’s) (see Stata output ➁, below).

| Prob > chi2 | 0.1128 |

---
The likelihood ratio test compares the likelihoods with and without diagnosis and shows that there is no significant reduction. Diagnosis as a whole is not significant and can be omitted from the model.

The output below illustrates the use of the linear predictor format as an alternative to the OR format to obtain logit (or log odds).

This linear predictor can be used to form predictions of the odds and hence the probabilities for individuals, as shown in the example for someone aged 20 years in group 1:

\[
\text{Logit or In(odds)} = 3.466 + 2.132 - 20 \times 0.2783 = 0.0323 \\
\text{Odds} = \exp(0.0323) = 1.0328 \\
\text{Probability} = \frac{1.0328}{1 + 1.0328} = 0.5081
\]

The adjusted ORs for a positive outcome (\text{gaf\_cat} = 1) in relation to a unit increase in the independent variables are found by exponentiating the coefficients, for example \(\exp(2.131) = 4\).

Logistic regression is commonly used in case–control studies: the case–control status is the binary dependent variable and the ORs measure the degree of association between the risk or protective factors and that status. In this situation the ORs are often interpreted as RRs, although this is numerically accurate only when the risk is very small (e.g. < 0.05). It is true, however, that, whatever the risk, a significant OR will indicate a significant RR, even if numerically they are not equivalent. Note that the calculation of probabilities as above cannot be performed: this is because the mean is subtracted and the value divided by the sample standard deviation (cf. standard effect sizes). The result is that the coefficients are sometimes called ‘beta coefficients’. If both dependent and independent variables are standardized, then the betas have a similar interpretation to partial correlation coefficients, although they are numerically slightly different. This is a useful way of comparing (within a given regression model) the relative sizes of coefficients for variables that are measured in different units. For logistic regression, one would only standardize the independent variables, because the dependent variable, being binary, does not need to be standardized.

### Conditional logistic regression

One further type of regression that is especially important for individually matched case–control studies and other situations where the observations are not independent is conditional logistic regression. Here, the observations that are individually matched (e.g. in a case–control study) or connected in some other way (e.g. the two patients of each nurse in the example) are indicated by a ‘link’ variable or ‘match group’ (e.g. the nurse identification in the example). The likelihood that is maximized in estimating the parameters of a logistic model for case status is conditional on membership of the linked group and so effectively controls for characteristics that the members of the linked group have in common. This is the point of matching – to control for unmeasured confounders – and so it is important to make use of conditional logistic regression rather than standard logistic regression where appropriate, otherwise the benefits of matching may be wasted.

### Other types of regression

Some other types of regression worth knowing about are multinomial logistic regression, where the dependent variable is categorical non-ordered, such as diagnosis; ordered logistic regression, where the dependent variable is ordered categorical, such as grade of illness; and Poisson regression, for count data, such as the number of admissions to hospital, or binary data, such as admitted or not where the time at risk is either measured or implied and one is interested in rates rather than proportions. Poisson regression is commonly used in cohort studies to estimate rate ratios over a follow-up period after controlling for confounders and produces rate ratios. Cox regression is appropriate where the outcome is time to an event, as in survival analysis. It produces hazard ratios, which are ratios of the risks of an event at any given point in time (rather than averaged over the follow-up time, as in Poisson regression). A more general model, which encompasses all of the above as well as linear and logistic regression and a number of others, is the generalized linear model.

### Model-building in regression

The best way to include variables in a regression model of any type is on the basis of theoretical background in the subject matter of interest. However, sometimes investigators are faced with a large number of potential independent variables without much guidance as to which to use. A rule

| gaf\_cat | Coef. | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|----------|-------|-----------|---|--------|-------------------|
| group    | 2.13168 | .9555024  | 2.23 | 0.026 | .2589298 | 4.004431 |
| age      | - .2782977 | .157653 | -1.77 | 0.078 | -.5872919 | .0306965 |
| _cons    | 3.466657 | 2.40287  | 1.44 | 0.149 | -1.242881 | 8.176196 |
of thumb is to have at least ten cases per parameter to be estimated, so there is often a need to cut down the number of variables included. Some possible automatic methods are as follows:

- **Backward selection:** first include all variables, then omit variables one by one, starting with the least significant and refitting the model each time.
- **Forward selection:** start with the single most significant variable (having tested each separately), then progressively add in a variable at a time (again refitting the model each time).
- **Stepwise:** a mixture of the above procedures.

None of these is necessarily optimal, and they may give rise to different sets of variables. See Derksen and Keselman\(^\text{36}\) for a discussion. An increasingly popular alternative to model selection based on significance testing is the use of information criteria, such as the Akaike information criterion (AIC).\(^\text{37}\) This allows the comparison of the likelihood of a set of different candidate models, which need not be nested, as is the case with likelihood ratio tests.

**MULTIVARIATE AND OTHER MORE COMPLEX TECHNIQUES**

**Principal components and factor analysis**

Principal components analysis (PCA) transforms the data variables into components (linear combinations of original variables) that explain decreasing proportions of the variance in the data and that are uncorrelated.\(^\text{38}\) It is essentially a data-reduction technique – often the first few components are plotted to illustrate the main features of multivariate data. The last few are useful for indicating any outliers. It is also used as the mathematical first step in a factor analysis. However, although factor and principal components analysis are often confused, they are conceptually distinct.

**Exploratory factor analysis** seeks underlying factors that explain the correlation or covariance between variables. The unmeasured variables are assumed to be linear functions of underlying unmeasured or latent variables, plus measurement errors (called residuals or specific factors). The analysis is often initiated by running a PCA to determine the number of factors. Factors are extracted using e.g. maximum likelihood methods, which can be rotated, either orthogonally (e.g. using the varimax method – axes are kept orthogonal/parallel) or obliquely (e.g. using the oblimin method – axes are allowed to form oblique patterns). The rotation often allows the coefficients that define the factors (factor loadings) to be interpreted more easily. It is common practice to set loadings to zero if they are below a cut-off (e.g. 0.40), with the aim of finding factors that are each associated with a mutually exclusive set of variables. (The others are not zero, but this presentation simplifies the results.) Costello and Osborne\(^\text{39}\) provide some guidance on this method.

Table 4.14 shows typical factor solutions for hypothetical data from a quality-of-life scale. Interpretations of the factors are given along the top (these are the prerogative of the investigator). The percentage of the variance explained by each factor is given along the bottom. In this case the three-factor solution seems to be more interpretable because the variables load into different factors. Note that the negative coefficients do not matter for interpretation (so long as they are consistent within a factor). If scales were to be derived from the factors, then common practice would be to add up the values of the items within factors (i.e. set the factor loadings to 1). It is important that item response scores are in the same conceptual order.

In a confirmatory factor analysis, the researcher sets up

in advance a hypothesis for the latent constructs and measures a number of variables that reflect different aspects of these constructs. The set of relationships between the observed variables and the constructs is called the measurement model, which is then tested for fit against real data. In more complicated models, the factors themselves will have a relationship with one another; this combination of factor analysis and regression analysis is called a structural equation and is analysed with specialist software. Figure 4.15 shows how such a theoretical model might be set up. Such diagrams are known as path diagrams.

**Other multivariate methods**

Principal components and factor analysis are widely used methods. Here, we mention some other methods that are much less popular but worth noting. Discriminant analysis is a method for classifying individuals into predefined groups by producing linear discriminant functions of the variables (if equal variances can be assumed) or quadratic functions (if not). It also provides a plot in a lower dimension than the original number of variables (analogous to principal components, except that the plot maximizes the variance between group means rather than between individual data points). It has a similar function to binary logistic regression (or multinomial logistic regression when there are more than two groups), but unlike those methods it assumes multivariate normality of the variables used and is hence somewhat more restrictive in application. The main advantage is the plot it produces. Another classification method is classification and regression tree analysis (CART); this focuses on finding interactive effects (i.e. combinations of variables) rather than linear functions, as in discriminant analysis or logistic regression analysis, and produces a tree-like diagram (e.g. see Thomas et al.40). Correspondence analysis is a method for graphically displaying cross-tabulated data; although it is little used in psychiatry, it is potentially very useful for exploratory

![Image of a structural equation model](https://via.placeholder.com/150.png)

**Figure 4.15** Example of a structural equation model. This relates the two latent traits ‘Pain’ and ‘Body function’ to the latent trait ‘Depression’. Each latent trait is measured by five items (measurement model)
analysis of large cross-tabulations. Canonical correlation analysis again is little used, probably because the results are difficult to interpret; it is a method for investigating linear functions that maximize the correlation between the variables in one set with the variables in another set. Cluster analysis is a vast set of methods that seek subgroups within a dataset. It is a data-driven exploratory method, overlapping with data-mining, neural networks and pattern recognition. Everitt et al. give an overview of the more standard methods. They differ from the classification methods mentioned above in that the groups are unknown a priori – the aim is to use the data to find the groups.

For an introduction to applied multivariate data analysis, see Everitt and Dunn or Tabachnick and Fidell.

Methods for non-independent data

Many standard statistical methods assume that each data point has been sampled independently of the others. However, in some situations this is not the case. Clustered trials and matched case-control studies have already been mentioned. Other examples are sampling of families where all members are interviewed, and of students within classes within schools. Repeated measurements for the same subject – sets of measurements of the same variable at different time points or sets of different variables that measure the same underlying within-subject factor – are also dependent.

In a multivariate analysis of variance (MANOVA), the purpose is to compare groups (e.g. gender or experimental condition) in terms of sets of dependent measures simultaneously. It is sometimes known as profile analysis when different variables are involved. It has been superseded to some extent by a number of specialized techniques appropriate for such data, such as multilevel models and general estimation equation (GEE) models. Other terms that will be encountered are random effects and mixed models. This collection of techniques is very flexible and can cope with within-subject repeated measures and multilevel sampling of different subjects. It can allow the inclusion of several levels of cluster (e.g. individuals clustered within families, families clustered within a therapist, and even cross-clustering, where individuals are clustered within families but family members do not have the same therapist). These modelling techniques allow the inclusion of both individual-level and cluster-level covariates.

To illustrate these, below is a simple regression of GAF score of the 60 patients on randomization group of the nurse in the training example. Because of the clustering of the pairs of patients within the nurses, this would not be correct and would underestimate the standard error for group and hence overestimate the significance.

Overleaf are the same data analysed as a random effects regression. Here, the effect of nurse that is common to his or her pair of patients has been explicitly modelled. The standard error increases and the estimate of the group effect is changed slightly, from 8.86 to 7.93 (see Stata output 1, overleaf).

Another approach is to use standard techniques such as linear regression but with specially adapted estimation methods that are robust to non-independence (such as the sandwich estimator mentioned earlier). Overleaf are the results for the above example: the point estimate for group is the same as the simple regression, but the standard error has been adjusted to take account of the clustering and is now called ‘robust standard error’ (see Stata output 2, overleaf).

A simple alternative approach for clustered data is to construct a summary statistic for each cluster and then analyse these summary values, for example with a weighted t-test using the numbers of subjects as a weight. However, this latter approach is not efficient and does not allow a more complex analysis including individual covariates.

Meta-analysis

Sample sizes in psychiatric studies are sometimes too small to detect clinically important effects. However, it is possible to combine the results of several similar studies by means of meta-analysis. A typical meta-analysis starts with a

systematic review: studies of the same or similar treatments
of generally randomized controlled trials are collected in a
formalized process. Meta-analysis is a statistical tech-
nique that allows the combination of the effect sizes
extracted from different studies into one overall estimate
with an associated confidence interval and a hypothesis test
of treatment effectiveness.

The statistical models used in meta-analysis weight the
individual study results using either fixed or random-effects
models, the choice between them depending on the degree
of between-study variability, which can be tested in relation
to pooled variation within studies with a $\chi^2$ test for hom-
ogeneity (sometimes called the Q test). If they are homoge-
neous, then a fixed effects model should be used. In this
case, the weights are proportional to the inverse of the
within-study variation (e.g. as reported in the standard
errors of the effects). If the studies are heterogeneous, then
a random-effects model is more appropriate; here, the
weight combines the studies’ individual precisions with the
between-study variation.

Figure 4.16 shows a so-called forest plot, a graphical
summary of a meta-analysis. This shows the effect sizes
obtained from the individual trials with their confidence
intervals (the lengths of the lines); the size of the boxes is
proportional to the sample sizes, and a vertical line indi-
cates the overall effect.48

A common problem is publication bias. Scientists tend to submit only studies with significant results, and editors of journals are more likely to publish such studies. Smaller studies without statistically significant effects or even contradictory effects are less likely to be published, so that the overall effect tends to be overestimated. The possibility of bias can be assessed informally by a funnel plot (Figure 4.17). This is a simple scatter plot of the sample sizes (or precision) of the studies against their estimated effect sizes.

The funnel plot in Figure 4.17 shows such a gap (bottom right), which suggests a publication bias although a formal test for bias (Begg’s adjusted rank test) was not significant.

**KEY POINTS**

- Validity types include face; content; criterion; concurrent; discriminant; predictive; construct. Test–retest and inter-rater reliability are assessed by kappa coefficient (categorical data), intraclass correlation (continuous data), and item consistency by Cronbach’s alpha.
- In diagnostic testing, post-test odds = pre-test odds × likelihood ratio where odds = probability/(1 − probability); receiver operator curves, sensitivity, specificity (both independent of base rate), PPV and NPV are also key concepts.
- The randomized controlled trial is the gold standard study design, and involves the following concepts: phases of development,
Meta-analysis allows one to combine the results of several similar studies into one overall estimate with an associated confidence interval, and uses forest plots (to show the estimates) and funnel plots (to detect possible publication bias).

**REFERENCES**

INTRODUCTION

Epidemiology is the study of health in relation to populations. Succinctly, it has been described as the basic quantitative science of public health. It differs from clinical medicine in that the results of epidemiological research have relevance to public health with consequences for health at the level of the population rather than the individual. It has been described as the study of the distribution and determinants of health-related states or events in specified populations and the application of this to the control of health problems.

Epidemiological methods have a number of useful functions: to describe the burden of illness in a population; to elucidate the aetiology of disease and biological dysfunction; to test the effectiveness of health interventions; and to assess need for services.

Historically, psychiatric epidemiology began to develop from purely descriptive to analytical epidemiology, aimed at understanding the aetiology of disorders in the mid-1970s. This began with empirical work on improving the reliability of psychiatric diagnoses, shown in the 1960s to be very unreliable. In the US/UK comparative diagnostic study, rates of schizophrenia in New York and London, which were thought to be very different, were found to be similar when standard methods of diagnosis were used in both settings. Operational criteria for a range of disorders were then developed and standardized psychiatric interviews were used to identify specific psychiatric disorders. Diagnoses such as schizophrenia were also strengthened by genetic adopted-away studies, which confirmed genetic rather than solely cultural transmission of disease between generations.

An important study of the time was the World Health Organization (WHO) International Pilot Study of Schizophrenia (IPSS), which found that a core syndrome of schizophrenia could be diagnosed reliably in different settings across the world by using a standardized psychiatric interview. More recent studies have questioned whether schizophrenic syndromes are equally frequent across cultures, but at the time this study greatly increased confidence in pursuing cross-cultural epidemiological research. This led to developing new diagnostic instruments that could be administered by interviewers without clinical training in large epidemiological field studies, such as the Epidemiologic Catchment Area Study (ECA) in the 1980s. This was followed in the 1990s by the National Co-morbidity Survey (NCS) and its replication study (NCS-R). Genetic epidemiology has progressed from family, twin and adoption designs to linkage including whole-genome studies. Analytical epidemiology has made substantial progress, for instance identifying, for schizophrenia, genetic inheritance, obstetric complications and, intriguingly, urban and winter birth as risk factors.

The advantages of studying an illness in a population rather than a clinical sample are several. Clinical samples, especially those seen in psychiatric out-patient and in-patient settings, are often the more severe or complex cases. Epidemiological samples give a better idea of distribution of the full range of illness severity, including milder cases, that may be helpful for understanding disease aetiology, and results found in epidemiological samples can be applied to the population from which they were taken. The type of bias observed through the choice of a sample of patients recruited from a health services source, to do with the selection processes involved in referral to health services, is called Berkson’s bias.

Epidemiological studies are often used in determining causation of disease, where the potential aetiological or causal variables are referred to as the ‘exposure’, to be related to the dependent variable, the illness ‘outcome’.

RATES OF DISEASE

The distribution of illness in a population is expressed in terms of rates of disease, which allow the frequency of diseases to be compared within and across populations (Box 5.1). There are two important rates: the prevalence rate and the incidence rate. Prevalence rate assesses the proportion of a specified illness or condition in a defined population. Point prevalence refers to the prevalence of illness at a specific point in time (e.g. on a census day), whereas period prevalence refers to the number of cases counted during a longer period (e.g. 6 months).

Prevalence is distinguished from incidence because incidence rates include the time dimension (see Box 5.1).
Hence, incidence rates deal with the number of new cases or episodes of illness developing in a population over a unit time, usually a year. Strictly, for entirely new cases of an illness, the term ‘inception rate’ rather than ‘incidence rate’ is correct because incidence may include recurrent episodes.

Rates are always expressed in relation to the population at risk as the denominator. In other words, the denominator is specified as the population that is potentially at risk of developing the illness. For example, prevalence rates of Alzheimer’s disease will be expressed as a proportion of the elderly population— it would make no sense to include children in the at-risk population.

Types of study in epidemiology
Epidemiological data can be collected either through new studies or by using routine statistical data. Useful routine data include statistics on mortality and cause of death drawn from death certificates, which can be accessed in the UK from the National Health Service (NHS Central) Registry and have nearly complete data on deaths. Other routine sources of data include the national cancer registry and birth certificates. In some areas, detailed systematic information is collected on health service attendees, including diagnoses, as a case register. When these data are complete and relate to a specific geographical area, they can be very useful for assessing burden of disease and trends in incidence of diagnosed disease. However, routine data sources should be treated cautiously, as there are often missing data. Usually, in order to understand the aetiology of a psychiatric disorder, it is necessary to carry out an epidemiological study. Broadly, studies may be either cross-sectional or longitudinal. Cross-sectional studies include straightforward prevalence studies and analytical case–control studies. Longitudinal studies include incidence and cohort studies.

Cross-sectional studies
A cross-sectional study is a study in which any association between two factors relates to a single point in time. Their uses include estimating needs for health services, providing statistics for health education, and screening for undiagnosed disease. Cross-sectional studies are quicker and cheaper than longitudinal studies, but can be applied to the relevant population, and investigate hypotheses that are relevant at that point in time. Their disadvantages are that it is difficult to interpret associations in terms of causation, they are not suitable for rare or short-duration diseases, and they provide no estimate of incidence. They can, however, provide prevalence estimates, although these may be biased by movers in or out of the study area.

Case–control studies
In case–control studies, a type of cross-sectional study, a representative group of cases is compared with a group without disease that is representative of the population from which the cases derive. Unlike in observational cross-sectional studies, subjects are sampled on disease rather than exposure. All possible eligible cases should have an equal likelihood of selection; for example, patients with depression who undergo cognitive-behavioural therapy (CBT) could be matched to a control group of patients with depression who do not undergo CBT. Controls are then matched to cases either on an individual or a group basis. Matching is typically carried out for age, sex and sometimes social class, depending on the study. If subjects are inadvertently matched on a factor that is part of the study question, this is referred to as ‘overmatching’.

As the selection of subjects is based on cases, this study design is useful for rare diseases, can involve screening for a wide range of possible risk factors and expensive or time-consuming tests, can test current hypotheses, and is not biased by dropout over time. This type of study is often seen as ‘quick and dirty’, as there is scope for bias in the selection of cases and controls, measurement bias and recall bias (see below for discussion of bias).

Longitudinal studies
In longitudinal studies, also referred to as prospective studies, a group of people are studied over a period of time. Certain characteristics are determined at the beginning of the study, and the incidence of disease in the group is then observed. This is a classical incidence study. Alternatively, in a cohort study, a group of subjects is studied at baseline and then followed up with recurrent waves of data collection, which collects data on new exposures and outcomes. Examples are the British Birth Cohort Studies that follow up a sample born in a week in 1946, 1958, 1970 and 2000. A specialized form of cohort studies are occupational cohorts, where a group employed in the same organization is followed up over time (e.g. Whitehall II Study of civil servants) or populations with special exposures are followed (e.g. victims of a disaster followed up for post-traumatic stress disorder). The advantage of longitudinal studies over cross-sectional studies is that incidence rate can be measured, the longitudinal association of exposures and outcomes is more likely to indicate causation, and the longitudinal observation of cases gives a truer picture of
severity, fatality, impact of therapy, and social class distribution of disease. Importantly, risk factor assessment at baseline is unbiased by presence of disease that develops by follow-up. Additionally, information about changing risk factor states may be obtained, and information given by subjects is not open to bias. However, these studies are expensive, gathering of results is slow, and refusals and dropouts may introduce bias. It is also difficult to maintain constant measurement techniques over time with changes in study researchers. In incidence studies, there is a need to test fixed hypotheses, and this design is not suitable for rare diseases.

Clinical trials

The intervention study or clinical trial can provide higher-quality data than observational studies because the investigator randomly allocates the exposure status (treatment) of the participants, thus ensuring greater validity to the results. Participants are randomly allocated to ‘treatment’ or ‘control’ groups. It is slightly more complex than that because intervention studies may be therapeutic (determining the ability of a treatment to diminish symptoms, prevent recurrence or decrease mortality) or preventive (testing whether a procedure can reduce the risk of developing a disease). Subjects are selected from an experimental population in which the trial is to be carried out; this will be a subset of the reference population to whom the results of the trial would be expected to apply. It is essential to select a large enough sample to give sufficient power to test the hypotheses and a sample that has enough outcomes (e.g., recovery from depression) to allow meaningful comparisons between the study groups within the study follow-up period.

Study subjects are invited to take part, having been informed of the nature of the study and the fact that they may be allocated to a control group without the active treatment. Potential participants are then screened to ensure they fit the inclusion criteria or may be ruled out on the basis of predefined exclusion criteria; such criteria control the population sampled in the study. Randomization of subjects to intervention or control group should be carried out in a double-blind fashion, so that neither the subject nor the investigator is aware of which group they are in. This reduces bias related to the subject’s report and bias in the investigator’s assessment of outcomes that could be influenced by knowledge of whether the subject was in the treatment or control groups (observation bias). This might also influence allocation to treatment or control group (e.g., investigators might tend to allocate more severe cases to the treatment rather than the control group). Another advantage of randomization is that groups will be similar in background and both known and unknown confounding variables.

A type of non-randomized intervention study uses a historical control group in which a group of patients allocated a new treatment is compared with a group that received an earlier, less advanced treatment. If the new treatment is much more effective than the old treatment, then a difference may be observed. However, if the difference between the groups is small, then it may be difficult to be certain whether the new treatment is more effective because of confounding by changes over time in patient populations, diagnoses or other treatments.

Compliance is an important issue, as non-compliance with, for example, a drug treatment will weaken the difference between treatment and control groups. Similarly, it is important to minimize dropout from the trial; frequent contact between investigators and participants can help to avoid this. To reduce bias in analysis, all subjects must be included (not excluding dropouts) in what is called ‘intention to treat’ analysis – ‘once randomized, always analysed’ – otherwise there may be a temptation to exclude subjects with less favourable outcomes.

The progress of epidemiological knowledge is not straightforwardly linear. Often results of studies on the same topic are contradictory or show varying strengths of association between risk factors and outcomes. Observational studies may be subject to unmeasured confounding factors and may be contradicted by the results of randomized controlled trials (RCTs). How should the results of such a bewildering array of scientific knowledge be synthesized? Systematic reviews of the literature attempt to bring together all relevant studies on a topic by scanning the range of relevant databases (e.g., PubMed, PsycINFO, Web of Science), including those papers that fulfill predetermined quality criteria and then summarizing the results narratively or statistically. Where studies have comparable estimates of the magnitude of effects, these can be combined to give a summary measure of size of effect through a technique called meta-analysis. Pooled estimates of magnitude of effects are extremely useful as summary measures and are usually accompanied by measures of heterogeneity showing how consistent these effects are across studies and subgroups, such as by gender or age.

Selecting a sample

In epidemiological studies, it is important to select a sample that is representative of the population you are studying. The simplest method is to use random sampling to randomly select a sample from a defined population, so that all individuals within the population of interest should have an equal chance of being surveyed. This, however, is often difficult to achieve; the approach usually taken instead is to define a population that is thought to be representative of the population of interest and to sample from within this population. Bias can occur in the selection of the population fairly easily; for example, people who have an interest in the topic you are researching are more likely to participate in the study; alternatively, the use of a Web-based survey to collect data rules out the participation of people who do not have access to a computer. If you need greater
numbers of one population group in your sample, then you may want to oversample in certain groups (e.g. women or elderly people) and you may use stratified sampling with a higher proportion or ‘sampling fraction’ from the specific groups. Samples are usually selected from a convenient source of names that covers the relevant population – a sampling frame – such as the electoral roll, general practice age-sex registers and postcode address files.

Bias

There are several important types of bias or potential error in epidemiological studies that you need to be aware of because they may lead to misleading results. In selection bias, errors arise from the initial identification of the study population – for instance, where the rate of response to the study is related to exposure status; this may be particularly an issue when control subjects are recruited from groups of students or staff or from newspaper advertisements.\(^8\) Observation (information) bias results from a systematic difference in the way information on exposure or outcome is obtained from subjects. Recall bias refers to ill individuals recalling previous exposures differently from controls. A classic example of recall bias relates to studies of life events and depression, where individuals with depression tend to remember more negative life events, which non-depressed individuals forget or do not report. Interview bias involves bias in the interviewer’s technique contingent on the interviewer knowing the disease status of subject; for example, if interviewers are aware of the case status of subjects, they may consciously or unconsciously put more or less effort into getting information on exposure variables. Control of bias may involve precautions taken in the study design, the choice of study population and the methods of data collection and can be addressed in the analysis of results.

Measurement in psychiatry

The easiest measuring instruments to use in psychiatry are self-report questionnaires, either as screening questionnaires for psychological distress, for example the General Health Questionnaire (GHQ) and the Malaise Scale, or for specific conditions, for example the Beck Depression Inventory (BDI), the Hospital Anxiety and Depression Scale (HADS) and the Center for Epidemiologic Studies Depression Scale (CES-D). The advantage of these scales is that they can be used as a continuous score for analysis, although they may not be normally distributed. The disadvantage is that they do not yield diagnoses.

Diagnostic agreement measured by kappa, intraclass correlations and Cronbach’s alpha

It is important to ensure that such instruments are reliable. Reliability is of basically two types. One type of reliability refers to the internal consistency of the scale – whether the items on the scale are all measuring the same underlying dimension – assessed by high item-total score correlations, or Cronbach’s alpha. The other type of reliability is retest reliability: does the test give the same score if it is repeated in the same individuals after a time interval? This is more relevant for dimensions that remain stable over time (e.g. neuroticism) rather than those that change (e.g. depressed mood).

Cronbach’s alpha produces a value between 0 and 1. Typically, a value of 0.6 or higher is regarded as indicating adequate reliability, although ideally a value of 0.8 or higher should be sought. It is important to appreciate that the value of alpha will increase with the number of items in a scale.

Psychiatrists frequently measure various characteristics of individuals by the use of inventories, scales and measurements, making it necessary to measure the degree to which there is agreement between the raters undertaking the assessment. This is known as inter-rater reliability. The two most commonly used tests are described below.

The kappa statistic is used to assess agreement between two observers and an outcome. For example, if two psychiatrists both assess the same 30 patients for a diagnosis of schizophrenia, what is the extent of the agreement between them? Kappa assesses the reliability between the observers. Kappa can range from −1 to +1: −1 indicates no agreement at all between the two psychiatrists’ diagnoses, 0 that there is agreement between the two psychiatrists but that this is not greater than the agreement we would expect by chance, and +1 that there is perfect agreement between the diagnoses for the psychiatrists. The significance of kappa is determined by a rule of thumb that states that agreement between observers should be at least 0.6 or higher if possible.

If there are more than two observers and with interval data, intraclass correlation (ICC) is used to assess agreement between observers. ICC compares the variability of different ratings of the same individual with the total variation in ratings across all the observers and individuals – that is, the variability of ratings for patient A are compared with the total variation across all the patients and all the observers. Like kappa, ICC produces an estimate that ranges from −1 to +1: it approaches +1 when there is little variability – that is, when the ratings for the individual patients are similar across observers. It is unusual to observe negative values in ICC.

In epidemiological research, case identification is important in counting the number of people with psychiatric disorders for assessing service need and changes in rates of illness. In most areas of psychiatry, there are no objective tests of psychiatric diagnosis such as raised blood sugar is for diabetes mellitus. Psychiatric diagnosis relies on clinical interview. In the past, different psychiatrists would have a range of diagnoses for the same patient. In other words, diagnoses had low reliability, where several assessors disagree in rating the same subjects; this is referred to as low inter-rater reliability. This has led to the development of
Internationally agreed systems of diagnosis based on symptoms such as the International Classification of Diseases, version 10 (ICD-10), championed by WHO, and the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV), championed by the USA. Standardized interviews have been devised to gather data on symptoms in a systematic way in order to make diagnoses, such as the Present State Examination (PSE) and its successor Schedules for Clinical Assessment in Neuropsychiatry (SCAN), the Diagnostic Interview Schedule (DIS) and the Composite International Diagnostic Interview (CIDI). These interviews are often semi-structured, with screening questions that, if acknowledged, are followed up by additional probe questions. Such interviews require extensive training and are predicated on the interviewer being clinically trained. Increasingly, these interviews have been developed as fully structured, eliminating the need for interviewer discretion to enable their use by less expensive lay interviewers.

As well as reliability, an instrument needs to have validity – that is, does it measure accurately what it is supposed to measure? Face validity and content validity refer to whether the instrument appears to measure what you want to capture. Construct validity and discriminant validity relate to the instrument measuring the underlying construct but not other similar constructs. For instance, a valid measure of depression should not be measuring neuroticism or lack of social support. An important form of validity in psychiatry is criterion validity. In this, the sensitivity and specificity of a newly developed instrument are usually compared against a criterion, a so-called ‘gold standard.’ These gold-standard criteria are hard to find in psychiatry but often refer to a standardized psychiatric interview against which a simpler questionnaire is being assessed. Sensitivity of an instrument indicates the extent to which it identifies true positive cases of the illness. Those true cases of illness not identified by the test are false negatives and, together with true positives, comprise 100 per cent of cases. Specificity refers to the extent to which the instrument identifies true negatives, or non-cases of disease. Those who score positively on the screening instrument but who do not have the illness are false positives; this is often a fault of screening instruments for common mental disorders that tend to exaggerate the true prevalence of disorder. Together, true negatives and false positives comprise 100 per cent of non-cases. There are two other useful indices of the precision of an instrument. The positive predictive value (PPV) is the probability that a person actually has the illness given a positive test on the instrument. In contrast, the negative predictive value (NPV) is the probability that a person is free of the illness given an illness-free score on the instrument.

Increasingly, it is being recognized that psychiatric symptoms tend to fluctuate over time and may be transient indicators of more stable underlying latent traits or constructs. These underlying latent constructs may not be directly measurable and require sophisticated life-course analyses to identify them. These underlying constructs may constitute endophenotypes that are linked more strongly to underlying genes than are symptoms or conventional psychiatric syndromes.

It is important to assess whether an association may be subject to bias. This may be due to confounding. A confounding factor is one that is associated with the exposure and also associated independently with the outcome and introduces a source of error that either diminishes or magnifies the true association. The association of the confounding factor with the outcome may not be causal, for example age and sex as confounding factors. It is important to adjust for confounding factors in analysis in order to see how much they may explain the association.

### Descriptive and inferential statistics

**Significance tests** are used to evaluate numerical data, including categorical, ordinal and interval data, to test specific hypotheses between variables/measures. For example, imagine we are testing the hypothesis that, within a sample, females report higher rates of depression than males. Wherever there is a hypothesis, there is also a null hypothesis – which in this case would be that there are no differences between males and females in reports of depression. Significance tests evaluate whether the results of a study are likely to have happened by chance. When epidemiological studies report the statistical significance of associations between variables, this is based on the $P$ value. Levels of significance that are typically employed in epidemiological studies are 5 per cent ($P \leq 0.05$), 1 per cent ($P \leq 0.01$) and 0.1 per cent ($P \leq 0.001$), indicating, respectively, that the observed relationship between variables has a 5 in 100, 1 in 100 and 1 in 1000 probability of being due to chance. The lower the $P$ value, the more certainty that the result is not due to chance. So, for example, if we found that females reported higher rates of depression than males and we found $P \leq 0.001$, we could be fairly certain that a gender difference did exist and we would accept our hypothesis that females report higher rates of depression than males. If the $P$ value was greater than 0.05, this would indicate that there was no significant difference between males and females, and we would accept the null hypothesis. Note that the latter finding would be described as ‘non-significant’ in the text, not ‘insignificant’ – a frequently made lexical error.

In accepting and rejecting hypotheses, two types of error can be made. The first, known as a type I error, occurs when the null hypothesis is rejected even though it is true. In our example, this would mean that we would conclude that there was a gender difference in reports of depression, when actually there was not. The second, known as a type II error, occurs when we incorrectly reject the hypothesis and accept the null hypothesis. In our example, this would mean we would conclude that there was no gender difference, when there actually was. A type I error is most likely to occur...
when the \( P \) value that we are willing to accept is set high; type I errors can be avoided by setting a lower \( P \) value and thereby reducing the probability of chance findings. Conversely, type II errors are more likely when we set a very low \( P \) value. The standard approach to balance the chance of making type I and type II errors is to set \( P \leq 0.05 \).

When a population has been sampled randomly, results can be generalized reasonably accurately to the entire population from which the sample was drawn by the use of confidence intervals (CIs). Confidence intervals define the range of values within which the true estimate for the parameter must lie. Confidence intervals are expressed as percentages, so the commonly used metric of 95 per cent confidence intervals indicates that we can be 95 per cent sure that the estimate lies within the intervals. Epidemiological research often reports the 95 per cent confidence intervals for odds ratios, derived from logistic regressions. For example, a reported logistic regression analysis of the 1958 British Birth Cohort found that females were more likely to have a depressive episode at 45 years of age than males, with the odds ratio reported as 1.85 and the 95 per cent confidence intervals as 1.33 to 2.57. Although the overall odds for the statistical analysis is 1.85, the confidence intervals indicate that we have 95 per cent certainty that the true odds lies between 1.33 and 2.57 – that is, there is a 5 per cent margin of error. The significance of logistic regression analyses is evaluated by assessing whether the confidence intervals include 1. In the example above, being female has a significant effect on depressive episode at 45 years of age, as the confidence intervals range from 1.33 to 2.57. If the odds ratios crossed 1, for example from 0.97 to 2.57, then there would be no significant effect of being female on reports of depressive episode. If the confidence intervals covered a range below 1, for example from 0.26 to 0.94, then this would indicate support for the hypothesis that males were more likely than females to report a depressive episode.

The width of a confidence interval is affected by the size of the sample under investigation. If confidence intervals become very wide, this suggests that the estimates are unreliable, which is usually associated with a small sample that lacks power. Ideally, confidence intervals should be fairly narrow in their range, indicating that the sample is large enough for reliable estimates to be produced. Confidence intervals can be derived for many different types of estimate, including odds ratios, relative risk, proportions, means and percentages.

The main advantage of confidence intervals over \( P \) values, which makes them particularly attractive to epidemiologists, is that they permit the range of true estimates to be derived, enabling the effect size of the relationship between variables to be identified: confidence intervals enable the highest and lowest true estimate to be identified. In the example above, from the \( P \) value analyses, we would know only that we were more likely to see more females than males with depression; from the confidence intervals, we would know that we were likely to see between 1.33 and 2.57 times more females than males, which may alter how resources are allocated.

### Specific statistical tests

Different statistical tests are used to determine relationships between variables of different types of data, such as categorical/discrete, continuous and ordinal. Descriptive statistics are used to describe the data collected in a study or experiment, as opposed to inferential statistics, which use the data to draw inferences about the population. Epidemiological studies typically employ a within-subject approach to analyses, focusing on describing and assessing differences across the subjects within the study population. For example, a birth cohort study may make comparisons between males and females, or between people in employment and people not in employment. All the subjects are from the same population. Another commonly used approach is the between-subject approach, which is a more experimental method in which two or more populations are compared with each other. For example, an RCT compares subjects who receive the intervention with subjects who do not receive the intervention.

Tests exist for both of these types of study, ranging from tests that simply provide estimates that describe the data (e.g. means, measures of central tendency) to tests that compare differences in outcomes between groups, such as males versus females. Many tests describe the associations between variables (e.g. that depression is associated with life events) but are limited in terms of being able to draw conclusions about the strength of association or causality between variables. This section describes some commonly used and encountered statistical tests within epidemiology.

### Descriptive statistics for categorical data

The chi-squared (\( \chi^2 \)) measure of association/goodness of fit is based on evaluating the distribution of observed data. The test is most often used to analyse data from independent samples, as in the contingency table in Table 5.1; the term ‘independent’ means that each individual in the sample can appear in only one of the four cells. The test assesses goodness of fit, which is the test of the null hypothesis that there is no significant difference between the observed frequencies in the cells. In this example, the null hypothesis would be that there is no difference between current rates of depression by previous depression.

#### Table 5.1 Example contingency table showing the frequency of reports of current depression by previous depression

<table>
<thead>
<tr>
<th>No previous depression</th>
<th>Current depression</th>

<td>50</td>
<td>40</td>
</tr>
<tr>
<td>Previous depression</td>
<td>30</td>
<td>60</td>
</tr>
</tbody>
</table>
Depression for people who have and people who have not experienced depression before.

The most commonly used test is Pearson’s $\chi^2$ test, which is applied to normally distributed data. If the $P$ value for the test is above the level of significance, which is conventionally set as $P \leq 0.05$, then the null hypothesis is accepted. If $P \leq 0.05$, then the null hypothesis would be rejected and we would conclude that there was a significant association between previous and current depression. One disadvantage of the $\chi^2$ test for epidemiologists is that it does not tell us where the difference lies between the different cells in the contingency table: the test simply identifies that there is a significant association.

**Descriptive statistics for continuous data**

Most inferential statistical tests (see Inferential statistics, below) require that data be normally distributed. This means that the mean, mode and median have the exact same value and are located in the centre of a symmetrical distribution.

**Variance** measures the degree to which the value for each individual in the sample differs from the mean for the whole sample, thus assessing variability within the data. Variance is always a positive number, as any negative numbers, which can result from an individual scoring lower than the mean, are squared. Calculating variance is the first step in calculating the standard deviation, which is the square root of the variance. Standard deviations are usually reported wherever mean scores are reported, as they indicate the spread of the scores from the mean value.

Confidence intervals have two further popular uses in epidemiology. The first is as a means of describing the range within which the true value of a mean, proportion or median lies for the sample. Confidence intervals can also be derived for assessing the difference between two estimates of means, proportions and medians. This test assumes that the two samples have the same variance and are independent and that the data are normally distributed. The test involves deriving the estimate for each group, for example males and females, calculating the standard error of the difference between the two groups, and then deriving the confidence intervals by computing the estimate for the group of interest (e.g.) females $\pm 1.96 \times$ standard error. 1.96 is the value to use for 95 per cent confidence intervals and 2.58 the value to use for 99 per cent confidence intervals.

**Inferential statistics**

Inferential tests are applied to the data to enable researchers to draw inferences and make assumptions about the population under study.

**$t$-Tests** are applied to test the difference in mean scores between two samples. These can be independent samples, such as the difference in the mean score on a depression scale for males and females, or they can be dependent, such as the difference in a depression scale score for the same sample of people before and after an intervention such as CBT. The $t$-statistic relies upon knowing the mean, standard deviation and number in each of the samples and requires that the data be normally distributed. The $P$ value is used to evaluate whether the hypothesis that there is a significant difference between the mean scores is supported or refuted.

Where the data are not normally distributed and are from independent samples, the Mann–Whitney $U$ test may be used instead. This test assumes only that the distributions from the two independent samples be of a similar shape, not that they be normally distributed. The test produces a $U$-statistic and a $P$ value.

$t$-Tests can be used only where there are two samples to be compared. Where there are more than two samples, analyses of variance (ANOvas) can be used. Unlike $t$-tests, which assess mean scores, an ANOVA compares the variance of scores across the different samples. ANOVAs are appropriate where data are interval, ratio or ordinal; independent; and normally distributed. ANOVAs produce an $F$-statistic and a $P$ value.

Epidemiologists frequently employ regression techniques to develop complex models that examine the role of a predictor variable or several predictor variables on an outcome variable. For example, air pollution levels near schools may be used to predict asthma in children, and smoking behaviour may be examined in relation to mortality or heart disease. Such techniques are extremely useful for analysis of longitudinal datasets, where predictors from earlier in life can be examined as predictors of later outcomes.

Regression techniques exist for a range of types of outcome data, including continuous and categorical data, and that data measure the time taken for an event measured as a binary outcome to occur, for example mortality or disease onset. Continuous-outcome data, such as a score on a test, are analysed using linear regression; categorical data are analysed using logistic regression; and time-to-event binary data are analysed using Poisson or Cox regression, the latter also being known as survival analysis.

One of the main advantages of regression techniques is that confounding factors can be included in the model, along with the predictor variables. This means that the association between the predictor and the outcome can be examined after taking into account other important factors. For example, if a researcher examines the association between smoking behaviour and heart disease, they may want to adjust for other lifestyle factors such as diet and socioeconomic factors, as well as gender and age.

Another attraction for epidemiologists of regression techniques is that regression techniques result in estimates of the size of the effect of the predictor on the outcome. Knowing the size of the influence of the predictor on the outcome is important for public health.

Factor analysis is a data-reduction technique that examines the underlying structure of a set of variables, using the variance between the variables. Factor analysis identifies traits from the intervariable correlation matrix between variables. Factor analysis requires that data are continuous: categorical data cannot be factor analysed, and typically
this analysis is conducted on data that are collected using Likert scales.

Factor analysis is usually used to examine or identify unobserved latent traits or factors within datasets. For example, if the individual items on the Big 5 personality inventory were factor analysed, the result would be five different factors, or latent traits, of personality – neuroticism, conscientiousness, openness, extraversion and agreeableness. This is an example where the traits or factors are already known to the researcher. Factor analysis can also be used to identify factors where the researcher has not a priori identified the traits. For example, a number of continuous variables that measure attitudes towards antidepressant use could be factor analysed to identify the underlying structure of attitudes. It can be problematic to identify factors from the analysis; one approach, which has its critics and supporters, is to use *eigenvalues*, which identify the total variance that the factor accounts for in the analyses: factors with eigenvalues greater than 1 are typically thought to be worth examining. Factor scores can also be derived from the analysis, giving an estimate of each respondent’s score for the factor, which can be used in further analysis.

*Principal components analysis* (PCA) is a similar data-reduction technique to factor analysis that also requires continuous data. PCA makes different mathematical assumptions about the nature of the relationship between the variables. PCA is usually used where the researcher wishes to reduce the number of variables in an analysis but to explain the same amount of variance, whereas factor analysis is used where underlying unobserved factors or latent constructs are of interest.

### EPIDEMIOLOGY OF SPECIFIC PSYCHIATRIC DISORDERS

National surveys, such as the National Survey of Adults in Private Households carried out in the UK in 1993, 2000 and 2007, give useful estimates of the prevalence of psychiatric disorders (Table 5.2). In the USA, these include such surveys as the Epidemiologic Catchment Area (ECA) studies in the 1980s and the National Comorbidity Survey (NCS) conducted in 1990–92 and its replication survey carried out in 2001–03 (Table 5.3). Rates of disorder differ between these studies, depending on the measuring instruments used, the study procedure, the choice of sample, and secular changes in rates of disorder. For instance, prevalence rates of psychiatric disorder were considerably higher in NCS than in the UK surveys.

*Kessler et al.*

**Kessler et al.*

Part 1: The foundations of modern psychiatric practice
the earlier ECA studies – it is unlikely that these changes represented a real increase in prevalence. More recent prevalence surveys include the WHO World Mental Health Survey using the CIDI across 28 countries and finding a broad range of prevalence estimates for mood disorders; the WHO Collaborative Study of Psychological Problems in Primary Care;¹¹ and the European Study of the Epidemiology of Mental Disorders project (ESEMED).¹²

A brief summary of epidemiological data for specific diagnoses follows.

**Schizophrenia**
The lifetime prevalence is 4.3 per cent, lifetime risk is 0.72 per cent and adult point prevalence is 4.5 per cent. Incidence of schizophrenia is 15.2 in 100,000. The male/female ratio is 1.4 : 1. Compared with native-born individuals, migrants have an increased incidence and prevalence of schizophrenia. Exposures related to urbanicity, less advantaged economic status and certain latitudes (increased in winter births) are associated with increased risk. People with schizophrenia have a two- to threefold increased risk of dying prematurely compared with the general population (median standardized mortality ratio = 2.6 for all-cause mortality).¹⁶

**Manic–depressive psychosis (bipolar disorder)**
Lifetime prevalence of bipolar I disorder in the NCS replication study is 1.0 per cent; 6-month prevalence is 0.6 per cent. Lifetime prevalence of bipolar II disorder is 1.1 per cent and 12-month prevalence is 0.8 per cent.¹⁷ Onset is in late teens to late thirties. Regarding the co-morbidity of lifetime bipolar disorder, 63–87 per cent of patients have a lifetime anxiety disorder, and 35–60 per cent a lifetime substance use disorder. It is related inversely to age, educational level and previous marriage. It is unrelated to sex, ethnicity and income.

**Major depression**
Lifetime prevalence in the NCS replication study is 16.2 per cent (95% CI: 15.1% to 17.3%). The 6-month prevalence is 6.6 per cent (95% CI: 5.9% cent to 7.3%).¹⁸ The male/female ratio is 2 : 1. Major depressive disorder (MDD) is highly co-morbid, with a 59 per cent risk of a lifetime anxiety disorder and 24 per cent risk of a substance use disorder. The median age of onset is 32 years (interquartile range 19–44 years). Risk factors include negative (loss) life events, low socioeconomic status, physical illness (e.g. coronary heart disease, cancer) and childhood adversities.

**Suicide**
The prevalence is 16.7/100,000 annually. Suicide makes up 1.5 per cent of all deaths and is the fourteenth leading cause of death.¹⁹ The lifetime prevalence of suicide attempts is 0.4–5.1 per cent. The male/female ratio is between 3 : 1 and 7.5 : 1. There is an increase in non-fatal self-harm in people aged 12–20 years, peaking at age 16 years. Risk factors for completed suicide include male, adolescent, older adult, certain ethnic groups, unemployment, certain psychiatric disorders (depression, impulse-control disorders, alcohol/substance use disorders, psychotic disorders, personality disorder), hopelessness, stressful life events and certain occupations (e.g. military personnel, doctors, pharmacists).

**Generalized anxiety disorder**
The lifetime prevalence is 4.3, 5.9 per cent. The 12-month prevalence is 1.2–1.9 per cent. The male/female ratio is 1 : 2. Onset is usually before age 25 years. Some 66 per cent of patients have co-morbid major depression; a similar proportion have other anxiety disorders.²⁰

**Panic disorder**
The adult prevalence of panic disorder with agoraphobia is 2–3 per cent; the prevalence is 1 per cent without agoraphobia. The lifetime prevalence is 1–2 per cent. The male/female ratio is 1 : 2. Onset is in late adolescence or early adulthood. Fifty per cent of patients develop depression during their lifetime, and there is an increased risk of suicide. Risk factors include heritability (40%), anxious temperament, anxiety sensitivity, neuroticism, early life trauma and recent life events.

**Specific phobias**
The adult prevalence is 2–5 per cent. The lifetime prevalence is 7–11 per cent. The male/female ratio is 1 : 2. Onset is usually at 5–8 years.

**Agoraphobia**
The adult prevalence is 2–3 per cent. The lifetime prevalence is 1.6 per cent. The male/female ratio is 1 : 4. Onset is usually around 18–35 years. It is associated with co-morbid major depression.

**Social phobia**
The adult prevalence is 4–6 per cent. The lifetime prevalence is 13 per cent. The male/female ratio is 1 : 1.5. Onset is usually in the teens (from 11 years) to early twenties (80% by 20 years). Risk factors include heritable components related to behavioural inhibition and neuroticism.²¹

**Obsessive–compulsive disorder**
The lifetime prevalence is 2.5 per cent. The 12-month prevalence is 0.7–2 per cent. The male/female ratio is between 1 : 1.5 and 1 : 1. There is increasing incidence with
age from 15 years to 35 years; the mean age of onset is 19.5 years. The most common co-morbid conditions are anxiety disorders (75.8%), mood disorders (63.3%), impulse-control disorders (55.9%) and substance use disorders (38%). Sixty-five per cent of patients report severe role impairment.\textsuperscript{22}

**Post-traumatic stress disorder**

The lifetime prevalence is 8 per cent. The 12-month prevalence is 1 per cent. The male/female ratio is 1 : 2.

**Alcohol use disorders**

The lifetime prevalence is 13.8, 23.5 per cent. The adult 12-month prevalence is 6.8, 7-7 per cent. The male/female ratio is 2 : 1. Alcohol use onset is usually in adolescence and peaks in late adolescence or early adulthood. Risk factors include alcohol-relieving negative affect, stimulating brain reward centres, pharmacological vulnerability, deviance proneness, heritability, parental substance abuse and peer influences. There is co-morbidity with all anxiety and mood disorders, particularly mania, antisocial behaviour disorders and drug use.

**Drug dependence**

The adult 12-month prevalence is 6.1, 7.5 per cent. The lifetime prevalence is 15 per cent. Eighteen per cent of people with a lifetime major depressive disorder have a substance use disorder. There is a higher risk for bipolar disorder.

**Anorexia nervosa**

The incidence rate is between 4.7 and 8.3 per 100,000. The lifetime prevalence is 1.2–2.2 per cent. The 12-month prevalence is 0.37 per cent. The 12-month prevalence of bulimia nervosa is 1.5 per cent. The male/female ratio is 1 : 8.\textsuperscript{21}

**Alzheimer’s disease**

The incidence rate is 1 per 1000 person-years in people aged 60–64 years, and 25 per 100 person-years in people over 85 years of age. The age-standardized prevalence rate is 4.4 per cent in people over 65 years and 22.2 per cent in people over 90 years. It is more frequent in people of advanced age, females, carriers of the apolipoprotein E4 gene, current smokers, people with a low education, income, and lower occupational status, and family history.

INTRODUCTION

The practice of evidence-based medicine (EBM), which is the integration of the best available evidence of clinical experience and patient values in patient or clinical decision-making, can be broken down into five steps:1

1 Translation of uncertainty to an answerable question.
2 Systematic retrieval of the best available evidence.
3 Critical appraisal of the evidence.
4 Application of the results in practice.
5 Evaluation of performance.

Put another way, to practise EBM, you need to do the following:

1 Ask structured clinical questions.
2 Access the best available evidence.
3 Appraise the evidence.
4 Apply the evidence.
5 Assess performance and patient outcomes.

This chapter systematically considers each of these five steps. It builds upon the earlier chapters in this part on epidemiology and research methods and statistics.

STEP 1: ASK QUESTIONS

Many questions emerge in the course of clinical practice. One model for translating uncertainty into an answerable question is to break it down into four parts known by the acronym PICO:

- Patient
- Intervention (or E for exposure)
- Comparison
- Outcome.

For example, imagine you are faced with the following clinical situation:

Mrs B is a 31-year-old single mother with three primary school-aged children. She has suffered from recurrent episodes of depression since the age of 23 years. The latest depressive episode is severe, she is not eating and she is barely drinking. The treatment options include electroconvulsive therapy (ECT) and antidepressant medication.

We might ask: is ECT more effective and safer than antidepressants in the treatment of a woman with a severe depressive episode? Using the PICO model, we could break down this question into four parts:

- Patient: woman with a severe depressive episode
- Intervention: ECT
- Comparison: antidepressant treatment
- Outcome: remission of the depressive symptoms, side effects.

STEP 2: ACCESS THE EVIDENCE

Types of clinical question

Therapy questions, such as ECT versus antidepressants for the treatment of severe depression, are particularly common in clinical practice. However, clinical practice throws up other types of question: diagnosis, prognosis, aetiology and harm. Epidemiology, the study of the distribution and determinants of disease, provides a framework for addressing each type of question. Different types of study are best suited to answering specific types of question. It is essential to determine what type of question is being considered before searching the literature. The more common types of clinical question are described below.

Diagnostic questions (distribution of disease)

The medical paradigm is predicated on making a diagnosis. We seek to determine whether a patient is suffering from an illness and, if so, the exact nature of that illness. This decision-making process is informed by knowledge of the distribution of possible illnesses in the target population. Diagnostic instruments and tests are often used to assist in this process as the clinician seeks to confirm or refute
hypotheses (differential diagnoses). As clinicians, we need to stay abreast of the evidence relating to prevalence and the accuracy of diagnostic tests. Cross-sectional studies are used to address these questions.

**Prognosis questions**

When patients ask what will happen to them, they are asking about their prognosis. Prognosis describes the likely course in a person with specific characteristics.

**Aetiology, harm and therapy questions (determinants of disease)**

What caused this disease? Is this drug an effective treatment for this disease? These are examples of aetiology, harm or therapy questions. Aetiology questions seek to ascertain what factor or factors caused a diagnosed disease, while therapy and harm questions focus on interventions that may change the course of the disease.

**Hierarchy of evidence**

The optimal study design to address a particular question depends on the type of question being asked. The pitfalls outlined in Chapter 4 can threaten the validity and importance of any clinical study, but certain designs are potentially better than others. The hierarchy of study architecture for each of the three groups of clinical questions is shown in Table 6.1.

It is also worth reflecting on two specific types of study, which are particularly important to the practice of EBM – systematic reviews and N-of-1 studies.

**Systematic reviews**

In 1979, Archie Cochrane, a British epidemiologist, lamented the failure of the medical profession to ‘organise a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomised controlled trials’. Thirteen years later, the Cochrane Collaboration was founded to ‘Prepare, maintain and promote the accessibility of systematic reviews of the effects of health care interventions’. Although systematic review methodology is most advanced for the synthesis of randomized controlled trials (RCTs), the same principles can be applied to any study design. Consistent results from valid and important studies synthesized in a systematic review can provide the best available evidence for all clinical questions.

**N-of-1 studies**

Evidence-based medicine focuses on the care of the individual patient, while evidence-based healthcare relates to the effects of exposures in groups. It may not be appropriate or possible to apply population-based observations to the care of a particular patient. In certain circumstances, it may be possible to undertake research in partnership with an individual consenting patient. For conditions that are chronic

RCT, randomized controlled trial.
and the effects of an intervention are transient, we could conduct an \textit{N} of-1 study.

By definition, the observations will be applicable to the patient under consideration. In an \textit{N} of-1 study, the patient is sequentially randomized to intervention and placebo and the outcomes assessed. Such a prospective design reduces the risk of performance and measurement bias and allows an assessment of the relative efficacy of an intervention. It is argued that the \textit{N} of-1 study design is primary for questions of therapeutic effect (therapy).\textsuperscript{3}

### Searching for the evidence

Having formulated a structured clinical question and determined the optimal study design, it should now be possible to search efficiently for the best available evidence. Developments in information technology, notably the development of electronic databases, have made the practice of EBM possible.

Table 6.2 lists some of the more common databases that may be of use when practising EBM. There are an increasing number of meta-resources, including clinical practice guidelines and evidence-based clinical decision support tools. These provide pre-appraised material addressing common clinical questions. To answer questions not covered by these resources, we must appraise systematic reviews or the original literature.

Electronic databases such as PubMed and Embase are useful resources for searching the scientific literature. PubMed is provided free by the US National Library of Medicine and is North American in focus, while Embase catalogues more European journals. The Cochrane Library includes the Cochrane Reviews, which are regarded as the gold standard for systematic reviews, and the Cochrane Controlled Trials Register (CCTR). The CCTR contains randomized and controlled trials drawn from sensitive searches of a number of databases, including Embase and PubMed.

Most electronic databases use Boolean logic to combine search terms. Table 6.3 provides some useful tips for searching. Returning to the clinical question about ECT, if we wish to find as many of the therapy studies as possible, then we could combine terms using the Boolean operator OR. As ECT is also known as electroshock therapy and electroconvulsive therapy, it would be sensible to search for these terms as well. A comprehensive search for papers on ECT could include the following search terms:

- `electroconvuls*` or `electro-convuls*` or `electroshock*` or `electro-shock*` or `convuls*` or `ECT`

As we are interested only in ECT for the treatment of a patient with depression, we could combine the ECT terms with search terms for depression. ‘Depressive episode’ is a synonym for ‘depression’, but both terms could be identified by truncating depression to ‘depress*’. Similarly we could search for synonyms of ‘antidepressants’. As we wish to restrict the search to these three criteria, we could use the Boolean operator AND.

Read a paper in less than 15 minutes

As busy clinicians, we often have to make rapid judgements. We do not have time to wade through piles and piles of research papers. With practice, it becomes easier to identify quickly which research papers are likely to address our clinical questions.

The title of the paper often gives clues as to whether it is likely to address the question of interest. More detail is given in the abstract. The title and the abstract help us to assess whether the paper is applicable to our patient – that is, whether it addresses our focused clinical question and uses an appropriate study design. Having spent no more than a minute looking at the paper, we should be able to make a judgement as to whether the paper is worth more than a minute looking at the paper, we should be able to make a judgement as to whether the paper is worth more detailed consideration.

The introduction rarely provides any useful information for critical appraisal, although the hypothesis under consideration or the aim of the study is usually described in the final paragraph. The methods and results sections should provide us with the data needed to critically appraise the paper. Having critically appraised the paper, there should be no need to read the discussion section, as we can draw our own conclusions. This whole process should take no more than 15 min.

The GATE frame: critical appraisal with pictures

Rod Jackson and colleagues have proposed a simplified approach to critical appraisal. Inspired by the symbols on the Sony PlayStation, they have created a frame (Graphic Appraisal Tool for Epidemiological studies, or GATE) comprising a triangle, circle, square and cross, upon which the key components of epidemiological studies can be hung (Figure 6.1).

The triangle represents the three levels of selecting participants for a study. For the ECT study, the source population would comprise patients with severe depression, the eligible population, those who satisfy the inclusion and exclusion criteria, and the sample those who agreed to take part. The circle is divided into two segments: those receiving the intervention (or exposure) and those receiving the comparison. The square can be broken down into a two-by-two table and is useful when we are interested in dichotomous outcomes (remission or no remission).

The triangle, circle and square serve as a template to guide the extraction of key data about where the participants came from and what happens to them during the course of the study. In parallel, we need to consider the potential pitfalls in the design and execution of the study. The GATE frame proposes that these can be summarized by the acronym RAAMbo.

- **Represent**: this asks the question ‘Is my patient sufficiently similar to the participants in this study?’ This is also known as generalizability, external validity or applicability.
- **Allocation**: for therapy studies, this considers how the participants were allocated to the intervention and comparison groups. Randomization with allocation concealment seeks to reduce the risk of selection bias, by achieving balance between the two groups with respect to known and unknown risk factors. Imbalance between the intervention and comparison group results in confounding. In prognostic studies, the cohorts are defined by whether or not they have a particular characteristic or exposure. Strategies may be employed to control for known prognostic factors when comparing the two groups in both the assembly (e.g. matching) of the groups and the analysis.
- **Accounted**: ideally, by the end of the study all participants should be accounted for, but this is rarely the case and typically some participants will drop out, switch treatment or be lost to follow-up. To maintain the integrity of the original allocation, attempts should be made to analyse all participants in the group to which they were allocated. This may require us to make judgments about how to handle dropouts (e.g. last observation carried forwards, best case/worst case scenario). Analysing all participants in the group to which they were originally allocated is known as ‘intention-to-treat’ analysis. Studies that experience a significant difference in dropouts across the two or more arms are prone to bias.
- **Measurement**: measuring outcomes typically requires some subjective judgement, and there is a risk that the outcome assessors may apply different thresholds, depending on whether the participant was allocated to a particular intervention. Blinding is a strategy to reduce the risk of measurement bias, and it is important that the study authors describe who was blinded and how blinding was achieved. There is less scope to make judgments if the outcome measures are objective (e.g. death).

The GATE frame provides a model for extracting data and making judgements about the applicability and validity of the study. If we are satisfied that any failings in the design or execution of the study are not catastrophic and that the study provides the best available evidence, we can...
turn our attention to the numbers or importance of the study. When dichotomous outcome measures are considered (event or no event), it is possible to calculate measures of effect such as absolute risk reduction (ARR), risk ratio (RR), relative risk reduction (RRR) and number needed to treat (NNT). These terms are described in Table 6.4. The terms ARR and RRR are used when the intervention reduces the risk of adverse events. Absolute benefit increase (ABI) and relative benefit increase (RBI) are more appropriate when considering positive outcomes.

Is it a poor-quality study or a poorly reported study?
There is a danger with critical appraisal that we become cynical about research. Most enterprises involving large numbers of people rarely go exactly to plan. Even the most perfectly designed study will encounter problems in its execution. It is common for participants to withdraw and no longer be available for follow-up.

Mindful that word limits and copy space present researchers and editors with challenges, even the most fundamental information about the conduct of the studies is often omitted. Therefore it is difficult to judge whether the study is of poor quality or just poorly reported.

In an attempt to ensure that readers of the scientific literature are equipped with all of the necessary information, editors and researchers have agreed standards for reporting research. The Consolidated Standards of Reporting Trials (CONSORT) statement recommends that authors and journal editors follow a 22-item checklist when reporting RCTs and use a flow diagram to describe the progress of study participants. Although only 20 per cent of high-impact medical journals refer to the statement in their advice to authors, the quality of reporting of RCTs is improved in journals that have adopted it.

Like the CONSORT statement, the Quality of Reporting of Meta-Analyses (QUORUM) statement describes the critical steps in a systematic review and meta-analysis of RCTs. Guidance to authors and editors is not confined to RCTs and meta-analyses: there are also Standards for Reporting of Diagnostic Accuracy (STARD).

**STEP 4: APPLY THE EVIDENCE**

The best available evidence is only one factor that should be taken into account for patient or clinical decision-making. There are clearly clinical considerations such as the severity of the illness and co-morbid risk factors. Patients, like clinicians, draw upon experience and have opinions and values. We make decisions in the context of healthcare policy, such as what is available in our particular health economy. There may be specific legal considerations that also need to be taken into account, such as the use of ECT when a patient refuses treatment or lacks capacity to give consent.

Clinical expertise is the ability to integrate research evidence and patients’ circumstances and preferences in order to help patients arrive at optimal decisions. This is otherwise known as the X-factor (Figure 6.2).

</table>
**STEP 5: ASSESS PERFORMANCE AND PATIENT OUTCOMES**

The most neglected step in the practice of EBM is the assessment of performance. As we strive to improve patient safety and care, we must assess whether patients have been helped and then consider what lessons can be learned from the care of individual patients. It may be the case that our review of the evidence focusing on the care of an individual patient highlights opportunities to improve the care of other patients.

**REFERENCES**

INTRODUCTION

The assessment of mental functions such as memory, concentration, language, intelligence, reasoning and judgement is a cornerstone of psychiatric practice. Impairment is germane to important disorders such as learning disability and the dementias, while there is some relevance to just about every other major diagnosis in psychiatry. It has been demonstrated repeatedly that poor cognitive ability is associated with both increased risk for mental disorder, and poorer personal and social function. A thorough understanding of cognitive function can, therefore, illuminate patient formulation to a surprising degree and may inform management in terms of how the patient can be expected to function in the future. This is particularly consequential for rehabilitation.

This chapter comprises an exposition of cognitive assessment beyond the usual few questions traditionally taught as part of mental state examination and the Mini-Mental State Examination (MMSE). Comprehensive cognitive assessment starts with the taking of a history and examination of the rest of the mental state before formal screening for impairment. This in turn directs attention to more specific areas, or further psychometric tests may be indicated. The recognition of patterns of impairment informs diagnostic possibilities: common associations between specific profiles and the diagnoses which they imply will be given.

TAKING A HISTORY

Intelligence is a reasonable synonym for overall cognitive ability. Even without standard formal measures of intelligent quotient (IQ), a rough estimate can be made from the patient’s history and general presentation. It should be possible to distinguish patients likely to be learning disabled (IQ 70, or IQ 75 where there is functional disability) with reasonable confidence.

IQ can be compromised by any significant insult to the brain, from gestation onwards. A history of adverse events in utero, birth complications, head injury, infections and systemic disorder in the preschool years or beyond may all be relevant here. The timescale of achievement of developmental milestones is useful information if available.

The patient’s family background is also significant. Children brought up within very socially disadvantaged families or subjected to neglectful or abusive parenting are unlikely to learn as they should, through lack of appropriate stimulation and encouragement. There was previously a diagnosis, now obsolete, of ‘subcultural subnormality’, in which children assumed to be of ordinary intelligence were unable to manifest the intelligence because their parents were either very unintelligent or neglectful, or both. These children could not learn from their parents, and they grew up with poor interest in and expectations of their achievement from family, schools and themselves. Presently, growing up with social and cultural deprivation potentially leads to a failure to access and benefit from learning opportunities, and a lack of interest in achieving potential in adulthood. Relevant enquiries about family poverty and disadvantage include the patient remembering being cold, hungry or in the dark, disconnection of utilities, the absence of a parent, separation from the parents, parenting from non-parents, family criminality, periods in foster care or on the Child Protection Register, and any kind of physical or emotional neglect and abuse.

These matters may impact equally, or more, on personality development in addition to compromising intellectual ability and potential. Although rather beyond the remit of this chapter, it is worth pointing out that deviance in cognition (as opposed to impairment) is one of the areas in which DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, 4th edn) personality disorder manifests itself, cognition here defined qualitatively as ways of perceiving and thinking about oneself, other people and events.

School performance can be an important indicator of intelligence. Was the patient educated in remedial classes or in an educational facility for children with learning problems? Did the patient have a Statement of Special Educational Needs from the local education authority? If so,
why, and what provision was made (e.g. one-to-one sup-
port)? Did the patient truant, or leave school early or with-
out qualifications? What was the patient’s attitude to
leaning? Did the patient have a favourite subject? Again,
this information has implications for a number of other
issues apart from cognition, such as personality, cognitive
style, attitudes and values.

It is unusual for patients with learning disability to be
able to read, comprehend and write competently, and to be
numerate. Establish everyday numeracy: the patient may be
asked whether they can ensure that they pay the right
amount for purchases and receive the correct change after-
wards. Do they need help with filling in forms? Do they
read regularly? If so, what can they read and understand
(e.g. the tabloid press)?

Higher or further education, successfully completed,
comprises additional evidence of cognitive ability. Even the
patient who failed to complete secondary education may
demonstrate the ability to learn new skills, such as driving
a vehicle. Cognitive assessment naturally encompasses abil-
ity as well as deficit: what patients like to do and what they
are good at. Such attributes are useful in addressing reha-
bilitative aspects of mental disorder. Interests, sports and
hobbies may constitute evidence of intellectual aptitude or
motor abilities, or both.

Apart from current intellectual capacity, psychiatric for-
mulation is concerned with alterations in cognition, which
may be related to or constitute illness: deterioration after
traumatic or other insults to the brain, degenerative disor-
ders such as dementia, and schizophrenia, in which there is
evidence of cognitive decline in many patients. The
patient’s most senior position in employment can be a good
indicator of what the patient was capable of, alongside an
indication of what the patient actually had to do. The ubiq-
uous nature of euphemisms in job description may dis-
guise an appointment that in reality required little skill,
responsibility or motivation. An informant history may be
extremely useful in mapping out what has changed since
then: people living with or closely acquainted with the
patient are in a good position to notice this. They may be
asked about, or spontaneously describe, absent-mindedness,
forgetfulness, lack of concentration, vacant spells, lack of
understanding of what is said, loss of interest in intellectual
pursuits such as reading and keeping up with current
affairs, and carelessness in completion of tasks. The natural
history of the change should not be omitted: when did it
start, were there any clear precipitants, and was it acute,
insidious, stepwise or fluctuating?

Enquiries should always be made regarding drug and
alcohol abuse and dependence. Although alcohol-induced
cognitive impairment is recognized in several guises (delir-
ium, persistent dementia, amnesic syndrome), the literature
on the cognitive impairment produced by illicit drug use is
in its infancy. Alternatively, the possibility of exposure to
environmental or industrial toxins should not be
disregarded.

COGNITIVE ASSESSMENT IN
MENTAL STATE EXAMINATION:
NOT JUST AT THE END

In the author’s experience, junior doctors prefer to keep
tings simple. The problem with this approach is that it can
obscure the integration of relevant observations into a
coherent whole, which is actually the purpose of the psy-
chiatric history, examination and formulation. Otherwise, a
series of disconnected comments is produced, tick-box
fashion, which fails to inform diagnosis or management.

The patient’s appearance may be relevant to cognition. A
classic example is dressing apraxia, in which the patient
puts their clothes on the wrong part of their body. An
unkempt, dirty and malodorous appearance is non-specific
but may be associated with learning disability, dementia or
schizophrenia, where self-care skills are poorly developed
or lost. Similarly, in the assessment of behaviour, there are
classic phenomena related to organic disorder, such as per-
severative utilization behaviour seen in patients with
frontal lobe disorders, in which objects are used repeatedly,
for instance wearing three pairs of glasses on top of each
other. A more common example is the catastrophic reac-
tion, also known as emotional incontinence, in which the
dementing patient suddenly becomes very angry or upset
for relatively minor reasons.

Facial expression can give some clues as to intellectual
status: again, patients with dementia may have a fixed or
vacant expression, while patients with learning disabilities
may appear placid, child-like or restricted in their facial and
general emotional expressions. Emotionally inert patients
may present so for a variety of reasons, including cognitive
compromise. There is a recognized association, for instance,
between the negative syndrome in schizophrenia, with its
poverty of emotional responsiveness, and intellectual
decline.

Much may be inferred from the patient’s manner of
speaking. Indeed, formal cognitive assessment may be
terribly unnecessary in the patient who gives an articulate,
fluent, detailed and accurate account, who clearly under-
stands all that is asked of them, and who demonstrates
normal memory and concentration in their conversation. It
makes little sense to ask such a patient if they know where
they are, who they are and what time it is at the end of the
interview. By contrast, patients with any kind of general
intellectual impairment may speak little, and in simple con-
crete terms, betraying poor general knowledge and aware-
ness of themselves and their environment. Even if the
patient says a lot, they may impart very little information.
They may struggle to understand and to answer more com-
plex enquiries, look puzzled or perplexed, fail to come up
with expected information, and demonstrate a surprisingly
poor memory for fundamental facts about themselves and
their families during their account. This may extend to the
names and ages of their partner and children, for instance.
A classic example is age disorientation in schizophrenia,
when the patient says they are many years younger than their chronological age. This is considered cognitive rather than delusional.

Patients’ language structure itself may be abnormal, as in expressive and receptive dysphasias, leaving aside formal thought disorder. Alternatively, poor educational standards are evinced by an overt ignorance of grammar (particularly the proper use of pronouns and verb conjugation in the author’s experience) and correct pronunciation, although the vagaries of marked regional accents need to be taken into account to a certain degree.

Patients with delirium produce speech that is rambling, incoherent, disjointed and irrelevant. Acute intoxication with alcohol or other substances may present similarly. Such speech may be reminiscent of that of schizophrenic patients with marked thought disorder, but the latter should be fully conscious, alert and reasonably oriented, without the characteristic disturbance of sleep–wake cycle, fluctuation and worse presentation at night of the confused patient. Dysphasic patients produce characteristic speech anomalies: while the patient with receptive dysphasia may sound thought-disordered, with fluent but less than intelligible speech, expressive dysphasia manifests as very restricted speech and word-finding difficulties despite adequate comprehension.

Psychotic phenomena, by contrast, are linked less obviously to cognition. It is generally considered that the ability to experience and to express abnormal ideas and perceptions is related inversely to cognitive function: hence, the diagnosis of schizophrenia is difficult if not impossible to confirm in patients with moderate or severe learning disability. There are a handful of specific psychotic phenomena that may support diagnoses with cognitive impairment, such as visual hallucinations in Charles Bonnet syndrome and Lilliputian hallucinations in delirium tremens. Despite a great deal of research into the neuro-psychological underpinnings of psychotic phenomena in schizophrenia throughout the 1990s, positive symptoms do not map easily onto the well recognized cognitive deficits manifest in more obviously organic brain disease, particularly deficits associated with circumscribed lesions.

Similarly, the relationship of insight to cognitive function is far from simple. Loss of insight is, like emotional inertia, a mental state anomaly that is possibly but not inevitably associated with cognitive impairment. In many patients, partial or absent insight may be understandably attributable to psychological defence mechanisms and personality factors. Do not forget to ask the patient whether they have noticed any problems with their memory or their ability to concentrate and pay attention. Can they take in a kitchen equipment, or becoming unaware of what people have said to them?

By the end of the mental state examination, it should be reasonably clear whether and what simple cognitive tests are appropriate. Essentially, these tests screen for clinically significant cognitive impairment in a variety of important intellectual functions. Language barriers should be taken into account in patients whose mother tongue is not English. The skill in appropriate cognitive assessment consists of deciding how much or how little to carry out, administering very simple bedside screening procedures for a reasonable spectrum of cognitive function where indicated, and adding further tasks if impairment is suggested by screening. Beyond this, the services of a clinical psychologist may be required.

As mentioned above, examination of orientation to place, person and time may be superfluous. Disorientation to time of day has the reputation of particular sensitivity, however. Ideally the patient should not have sight of a clock or a watch.

Use common sense in the interpretation of mistakes: patients living in a deprived environment may have little reason to know the exact date or even the day of the week – this is not the same as being presented with the date or day and then forgetting it. The patient should, however, know the month (except at the end or beginning of the month) and the year. If in doubt, ask additional questions such as what season it is, whether the patient has had breakfast today, and what sort of a job the patient does, in order to evaluate the patient’s grasp and general awareness of their surroundings. Asking the patient to tell you what has been going on in the news can also be informative, particularly if momentous or highly publicized events have just taken place.

Memory should be divided into short-term or working memory (see below) and longer-term memory. Working memory can be tested by digit span – that is, repeating a series of digits after the doctor says them. The normal range is 5–9. Reversed digit span may also be tested and should normally extend to four or more digits. These and similar tests, such as saying the days of the week or the months of the year backwards, test attention and concentration as well as pure working memory. There is a good deal of overlap between the two. Mental arithmetic is another way of testing attention and concentration, plus the specific ability to calculate. Most patients find ‘serial sevens’ – subtracting seven repeatedly from 100 – rather challenging. Subtracting three from 20, or counting backwards from 20, is easier: again, take into account educational achievement.

Longer-term memory can be assessed by asking the patient to remember a name and an address comprising five or six elements. Use common sense: do not present something that is highly irregular or that you might not remember either. Make sure the patient has encoded the name and
address by asking them to repeat it after you, correctly, at least once. Then ask the patient to perform other brief tasks for 2–5 minutes before asking them to repeat the name and address. The patient should be able to remember all of it, especially if it was only five items long.

Semantic memory may be assessed by asking the patient some general-knowledge questions, such as the name of the current monarch and prime minister, and the years during which the Second World War took place. Some questions may be so easy as to exclude the effects of incomplete education and disinterest in current affairs.

Frontal lobe function was classically assessed in terms of abstract conceptual ability – that is, asking patients to think beyond the concrete, by explaining the meaning of proverbs, or explaining the differences or similarities between objects. Proverb interpretation is in the author’s experience performed very poorly, particularly by medical students asked the meaning of, ‘It’s an ill wind that blows nobody any good’. Again, take into account educational and cultural factors and keep it simple: ‘Too many cooks spoil the broth’ is probably OK to start with. Differences such as that between a fence and a wall, a child and a dwarf, and a table and a chair may be followed by an enquiry as to how the items are similar. More difficult abstract pairs include a poem and a statue, and praise and punishment. Reasoning and judgement can be examined by asking the patient to ‘guessestimate’ how fast racehorses gallop, the height of the average woman in the UK, the age of the oldest person in the UK, and the best paid occupation in the UK.

Frontal function is a somewhat overinclusive entity, unfortunately. What this means is that abstraction is not sufficient on its own. The best recognized frontal functions that lend themselves to bedside testing, apart from abstraction, are initiation (i.e. mental response to an external stimulus), maintenance of set (i.e. inhibition of inappropriate responses) and set-shifting (i.e. changing response as appropriate). To test initiation, ask the patient to generate as many animals as they can think of in one minute: ten or fewer indicates impairment, as does perseveration (repeating an answer). Similarly, ask the patient to say words beginning with the letter ‘s’ (or ‘f’ or ‘a’) in one minute; again, fewer than ten per minute and perseveration indicate definite impairment.

Frontal lobe tasks tend to be performed poorly by people with learning disability, dementia or schizophrenia.

In the patient in whom dementia or other organic psychosyndrome is considered, it may be well worth carrying out tests of more localized dysfunction (see below). The tests from the MMSE comprise a useful screen: naming a watch and a pen (to which may be added naming the hands, winder, nib, clip, etc.), writing a sentence, repeating a phrase, following the written instruction ‘Close your eyes’, following a three-stage spoken instruction, and copying intersecting pentagrams. To this may be added basic praxis, for example, asking the patient to demonstrate how they would comb their hair, strike a match and wave goodbye.

**WHY NOT JUST DO A MINI-MENTAL STATE EXAMINATION?**

There is no doubt that the MMSE is a very well established screen for clinically significant cognitive impairment. However, it is based almost entirely on memory, with virtually no frontal testing. If the patient scores less than 24 on the MMSE, then this merely raises the question of definite deficit, which will not have been addressed in more specific cognitive or diagnostic terms. The MMSE does not constitute an end in itself.

More importantly for junior doctors, in the Royal College of Psychiatrists’ clinical examinations that evaluate the candidate’s ability to assess cognition, the MMSE test sheet is not available. It is of course possible to administer the MMSE from memory, and lots of candidates do, but it is highly likely that a more specific evaluation will be required. Candidates facing standardized clinical stations with role-players may be given instructions to examine any area of neuropsychological function and not just the presence of clinically significant cognitive impairment as per MMSE score. Outside formal examinations, however, the MMSE is clinically useful when there is a question-mark over whether the patient is cognitively impaired. Nonetheless, this circumstance should not be the rule, given the many other avenues of exploration possible. The other use of the MMSE is as repeated measure, to track emerging cognitive decline or response to treatment, particularly in dementing illness where memory deficit is to the fore.

**CLINICAL PSYCHOLOGISTS AND PSYCHOMETRIC TESTING**

Historically, clinical psychologists ‘followed diagnosis with numbers’ – that is, carried out IQ tests, memory tests, language tests, etc. at the behest of the psychiatrist, whose provisional diagnosis implied an impairment. Clinical psychology has now become a diffuse discipline in which psychometric testing is very much a minority interest. A vague non-specific referral is likely to lead to a ‘full assessment’ and ‘formulation’, which may prove completely free of any neurocognitive content whatsoever. It therefore behoves the referrer to know what they are talking about, to have carried out a range of bedside tests, to know the basics of more formal evaluation, and to demonstrate justification for what is asked for. The request should state what neuropsychological deficit is suspected and why, and should indicate what specific psychometric tests may be useful.

Psychologists sometimes return reports devoid of numbers, for instance describing current IQ as ‘normal’ or ‘average’. This tendency should be discouraged and precision
aimed for. After all, the investigation may need to be repeated in the future. The author would, furthermore, suggest that all psychiatrists should be capable of carrying out a premorbid IQ estimate, the National Adult Reading Test (NART) and a current IQ estimate, the Quick Test. The standard psychometric IQ evaluation, the Wechsler Adult Intelligence Scale (WAIS), is a very lengthy test, onerous for both the patient and the clinical psychologist. Indeed, it is often ‘pro-rated’—that is, a selection of sub-tests, rather than all of them, is administered and an IQ score derived from partial completion.

Finally, it is always well worth ordering all the patient’s previous case notes. A summary of notes, although time-consuming, may generate much useful information about family history, development and previous personal function, which may not be available at initial interview. Occasionally there may have been a psychological assessment, even including an IQ score or other psychometric tests.

FROM THE CLINICAL TO THE THEORETICAL: STRUCTURAL–FUNCTIONAL RELATIONSHIPS

As a whole, cognitive function or the lack of it is as heterogeneous and variable as the spectrum of psychiatric disorder. Taking a hierarchical approach, the most gross cognitive impairments and anomalies are likely to be encountered in the dementias, learning disability and other organic psychosyndromes, produced by the usual range of neurodevelopmental, traumatic, neoplastic, metabolic, endocrine, vascular, infective, autoimmune, toxic and degenerative insults. An isolated area of cognitive dysfunction that can be attributed to a localized lesion, in the setting of preserved performance otherwise, is particularly likely to afford specific diagnostic implications. Moreover, ‘functional’ psychotic disorder, particularly schizophrenia, is increasingly recognized as including cognitive impairment in frontal function and long-term memory. These are disproportionate deficits considering overall intellectual ability. Even so, a fall in IQ from premorbid levels is extremely common in patients with schizophrenia. Similar chronic impairments are beginning to be described in bipolar affective disorder.

On the other hand, ‘neurotic’ disorder, personality disorder and substance (apart from alcohol) abuse were never of great interest in cognitive terms, although this is an emerging experimental field. Even so, it has long been recognized that depressed patients tend to complaints of absentmindedness or inability to concentrate. On testing there can be a patchy impairment of memory and concentration owing to anxiety and difficulty in paying attention.

Occasionally, patients present with cognitive impairment that is more apparent than real, such as in dissociative amnesia and depressive pseudo-dementia. It pays to be aware of discrepancies between the pattern of impairment expected and that produced by the patient. Furthermore, there are particular issues with learning disability in the author’s experience. Much subnormal IQ, whether original or recently acquired, goes undetected in psychiatric practice. Conversely, it is not rare to encounter patients thought to be learning disabled by other professions and who return a Quick Test estimate within one standard deviation of the mean.

Some important cognitive functions, principally attention, concentration, memory and executive function, are not localized to specific hemispheres or areas of the brain. These have a distributed neural basis and tend to be compromised by generalized cerebral dysfunction, by definition more than minor although not always permanent. Other functions such as verbal skills and visuospatial function are lateralized to the left and right hemispheres, respectively, depending on cerebral dominance. Discrete unilateral lesions, therefore, may have very different consequences compared with distributed compromise. Furthermore, the causes tend to differ: metabolic, electrolytic, infective, pharmaceutical and endocrine pathology is unlikely to target some parts of the brain more than others, as opposed to cerebrovascular, neoplastic and in some instances degenerative pathology.

The frontal lobes are something of an exception to the basic diffuse versus localized distinction, since they have a crucial integrative role across a number of important functions. Therefore, limited lesions of the frontal lobes can impact upon distributed functions. This is probably why ‘frontal lobe function’ is such an inherently overinclusive and unsatisfactory term.

DISTRIBUTED FUNCTIONS

Attention and concentration

The reticular activating system connects the brainstem to the thalamus and neocortex via ascending cholinergic, monoaminergic and serotonergic pathways. There is neocortical feedback, particularly from the prefrontal cortex and the posterior parietal and inferior temporal cortex, all of which receive afferent perceptual input. The result is conscious attention. Disruption of attention leads to confusion, termed delirium at the moment, at least when it comprises an acute presentation attributable to a new insult to the brain rather than a chronic degenerative picture.

Like any other disorder, there is a spectrum of severity applicable to attentional impairment. Clinically, it presents as poor orientation, an inability to sustain attention, distractibility by irrelevant stimuli, and inability to inhibit inappropriate responses. Such patients may perseverate, fail to repeat and reverse strings of digits, fail to reverse the days of the week, fail simple mental arithmetic, and fail to learn a name and address. There is obviously an overlap
with compromise of working memory. Although usually the result of a diffuse insult, right-sided prefrontal lobe lesions are supposedly more likely to produce attentional impairment than the left-sided variety. Many delirious patients are quiet and lethargic, but some are actively agitated, deluded and hallucinated: this phenomenon is recognized in severely physically ill patients as ‘ICU psychosis’. Some forms of delirium, the classic example being delirium tremens, are usually accompanied by hallucinosis.

Memory

The overall concept of memory is neuropsychologically quite complex and occasionally rather bewildering. The major subclassification into implicit and explicit memory has much more theoretical than clinical utility. Essentially, explicit (also known as declarative) memory subsumes what can be recalled by conscious (i.e. voluntary) recollection. Implicit memory is something of a ‘rag-bag’ and includes everything else. First, implicit memory includes what the patient has learned (i.e. not forgotten) but cannot voluntarily remember on demand. Such implicit memory material can be brought to consciousness by priming or cueing: if the patient is given a list of ten words to learn but can recollect only five of them, they may recall some of the others if given the initial letter or other clue. Second, implicit memory includes the learning and retention of motor skills, such as driving a car, typing, or playing a musical instrument. This is known as procedural memory. Third, implicit memory subsumes other non-verbal but entirely unconscious forms of learning such as conditioned reflexes.

Implicit memory tends to be relatively preserved, even in serious psychotic or degenerative disorder, and is not assessed routinely in psychiatry. However, loss of motor skills, if the patient had any, can be asked about in the history, particularly if an informant is available. It should not be forgotten that motor skills may deteriorate without regular practice, leaving aside the effects of mental disorder.

Explicit memory is divided into short-term memory (also known as working memory) and long-term memory. The working memory system serves to keep small amounts (five to nine items) of verbal, auditory or visual material present in conscious awareness for recall or manipulation, or both, for a brief period of up to 30 s. There is an obvious overlap with conscious attention. Working memory functions alongside long-term memory, but surprisingly the acquisition and retrieval of long-term memories can occur despite defective working memory.

Long-term memory is divided into episodic and semantic memory. Episodic memory is what most people would call memory – the recollection of personal experience – for instance, what one did yesterday. Semantic memory is what most people would call knowledge: the capital of France is Paris, and a dog is a four-legged domesticated animal that barks and wags its tail.

An added layer of complication in the understanding of memory is the processes through which the systems work. In other words, information of whatever kind must be encountered (consciously or otherwise), encoded, reinforced or consolidated, and then accessed for recall; otherwise, the information cannot become a memory. This may have practical clinical implications: for instance, the author was asked to complete a second opinion on a patient whom several ‘assessments’ had concluded was suffering from post-traumatic stress disorder. The flaw in the argument was that the traumatic incident comprised a blow to the head that produced unconsciousness accompanied by several minutes’ amnesia both before and after the event. Logically, the patient could not suffer re-experiencing and avoidance symptoms related directly to an event of which he had no memory at all. This elementary error had understandably compromised the patient’s management for the 3 years since presentation.

Another relevant process is forgetting: there are further theoretical distinctions between the functions of searching or accessing memories, and the existence of a store where representations are held. Recall is thought to be harder than recognition for these reasons: recall of material requires a search for and access to what is in the store, while recognition involves only a check for familiarity between the material presented and the content of the store.

Although memory is overall a distributed function, its subdivisions do have localized affiliations. Thus, the basal ganglia and cerebellum are thought to be of particular importance in conditioning and procedural memory. Regarding working memory, the substrates for verbal content (phonological loop) and non-verbal content (visuospatial sketch pad) devolve to the dominant and non-dominant hemisphere, respectively, while the frontal cortex includes a central executive function to operate them effectively. The circuit of Papez, a component of the limbic system comprising the medial temporal lobe, diencephalon, basal forebrain nuclei, fornix and cingulate gyrus, is essential for episodic memory. Semantic memory is lost with lesions of the dominant temporal neocortex.

Classic neuropsychological distinctions between these types of memory are of limited utility in psychiatry. Clinically, the ability to acquire, retain and recall new episodic material (i.e. anterograde memory) as opposed to the ability to recall old episodic material (retrograde amnesia) is much more relevant. Working memory and attention are usually compromised in anterograde amnesia, alongside this long-term episodic memory failure. The Rivermead Behavioural Memory Test (RBMT)⁹ is the standard measure of episodic memory function in anterograde terms. The RBMT includes both non-verbal and verbal elements (words, drawings, faces) and tests of both recall and recognition. Interestingly, patients with schizophrenia perform very poorly on this test and on tests of semantic memory. The bedside test of verbal episodic memory recall, asking a name and address learned a few minutes previously, is a useful screen. Retrograde memory evaluation turns upon
whether the autobiographical history given by the patient can be validated. In some patients it may be obviously confabulatory rather than missing. Formal tests exist, such as the Famous Faces Test, in which the patient is presented with photographs of famous people or events from different periods in the past.\(^9\)\(^10\)

Amnesic syndrome is an important entity in psychiatry: anterograde or retrograde amnesia, or both, occur in the absence of other cognitive dysfunctions, including, surprisingly, implicit memory. Amnesic syndrome can be acute or chronic.

Acute amnesia occurs in delirium and in transient global amnesia: it may present with alcohol and drug intoxication, closed head injury and focal epilepsy. Anterograde amnesia is the rule, alongside some working memory/attentional impairment. Patients cannot remember anything for more than a few minutes: attentional impairment inevitably results in a degree of disorientation in place and time. Nonetheless, in transient global amnesia, the patient may have normal working memory and attention (i.e. normal digit span and reversal tests) and be acutely aware of their difficulty, repeatedly asking where they are, how they arrived at that location and what has happened. Furthermore, in transient global amnesia, there is a dense retrograde amnesia that may go back for decades. The patient may be unaware of the death of a relative or the achievements of their children, for instance.

Chronic amnesic syndrome indicates long-term bilateral damage to the medial temporal lobe, particularly the hippocampus, as in, for example, early Alzheimer’s disease, herpes encephalitis and posterior cerebral artery stroke. It is also associated with closed head injury. Diencephalic damage is a classic complication of alcoholism in the form of Korsakoff psychosis. In chronic amnesic syndrome, there is a preserved intelligence quotient but severe anterograde amnesia accompanied by retrograde amnesia. This is much worse with diencephalic than hippocampal compromise. There is a temporal gradient that is counterintuitive, in that more distant memories are clearer than more recent memories. Working memory, attention and aspects of implicit memory are unaffected.

Semantic memory disorder occurs in Pick’s disease, herpes encephalitis and severe schizophrenia. It also surfaces in progressive dementing disorder, particularly Alzheimer’s disease. Bedside tests of semantic memory are not usually indicated, but there is some overlap with the ‘frontal’ category fluency test (i.e. naming as many items as possible, such as animals, or words beginning with a specific initial, in a brief period such as 1 minute). Asking about general knowledge (e.g. name of prime minister) is also useful. The patient may be asked to verify (or otherwise) statements such as ‘Admirals are in charge of ships’ and ‘Beer is sold at a butcher’s shop.’ By far the best formal test of semantic memory is the Hodges semantic memory battery,\(^11\) which has been used widely in formal neuropsychological assessment and research. The Graded Naming Test is much shorter: the patient is asked to look at a number of pictures of increasingly obscure items and say what they are.\(^12\) The Silly Sentences Test consists of correct and nonsensical statements as above, the patient being asked to determine which is which.\(^13\)

**Frontal lobe function**

Frontal lobe function, also known as executive function, is problematic in terms of its heterogeneity and ubiquity. In summary, frontal lobe function involves generating responses to stimuli, choosing the most appropriate, inhibiting inappropriate responses, planning and problem-solving, keeping a sequence of behaviours on course to achieve an overall goal, and yet changing response parameters when required by environmental variation. Bedside tests for frontal function have arisen from the study of patients with circumscribed frontal lobe lesions.

Frontal lobe compromise can be suggested by the history. Disinhibition in mood and behaviour and a lack of empathy for others are of course not specific to patients with frontal lobe disorders, but they can be of sufficient magnitude and difference compared with the normal personality and behaviour to be significant. Lack of suppression of inappropriate internal stimuli is thought to be responsible. On the other hand, the apathy and marked slowing also observed in frontal patients reflects that they may respond very poorly to internal and external stimuli. Adequate response to external stimuli enables patients to attempt testing, although this must be done carefully if cooperation is not to be lost. Category fluency for animals (or vehicles or household items, for instance) and words beginning with specific letters can be considered a frontal test. Perseveration occurs when items are repeated (the patient gets stuck rather than forgets they have said the item or word already), and irrelevant items or words may be offered owing to distractibility; one schizophrenic patient of the author’s responded to a request to name sea creatures with the phrase ‘men in aqualungs’, for instance. Planning and strategy is compromised: most people when asked to name animals would use superordinate categorization to identify groups of animals, such as thinking of farm animals, domestic animals or jungle animals. Patients with frontal lobe disorders do not do this as effectively.

If frontal impairment is suspected, it may be useful to ask the patient to carry out non-verbal tasks as well as proverb, difference and similarity explanation, cognitive estimates and category fluency (see above). The patient may be asked to copy an alternating sequence of triangles and squares (Figure 7.1) or to tap on the desk twice when the examiner taps once (under the table), and vice versa (i.e. the patient should tap once when the examiner taps twice). This is repeated until the examiner is satisfied that the patient can or cannot do it. Further formal testing is within the remit of clinical psychologists. They may use a structured initiation task such as the formal FAS fluency test\(^14\) (the patient is
asked to say as many words as they can think of beginning with the letter F in 1 minute, then with the letter A, and then with the letter S) and ‘dual tasks’ of divided attention (since the working memory central executive is compromised), such as the Stroop Test and the Trail Making Test. Divided attention clearly overlaps with the ability to maintain and change set. The standard set maintenance and shifting task is, however, the Wisconsin Card Sorting Test, in which cards are sorted according to the different numbers of various shapes of separate colours that appear on each one. The Tower of London (or Hanoi) test is used to assess planning and sequencing. The Cognitive Estimates Test comprises ten ‘guesstimate’ questions (see above) and assesses reasoning and judgement. The Behavioural Assessment of the Dysexecutive Syndrome (BADS) is an ecologically valid test that covers functional aspects of frontal impairment.

Causes of frontal lobe syndrome include focal dementia such as Pick’s disease, anterior cerebral artery stroke, head injury (closed or local trauma) and tumours. Frontal signs are eventually seen in degenerative disorders that have the effect of isolating the frontal lobes, for example subcortical dementias such as Huntington’s and Parkinson’s diseases, progressive supranuclear palsy, leucodystrophies and acquired immunodeficiency syndrome (AIDS) encephalopathy.

LOCALIZED COGNITIVE FUNCTIONS

The dominant hemisphere

The left hemisphere is dominant in right-handed people and about half of left-handed people: its functions include language, calculation and higher motor control (praxis). Dysphasia (impairment of language function) should be distinguished from dysarthria (failure of articulation). Dysarthria has a variety of causes, the most common in psychiatric practice probably being antipsychotic drug treatment with extrapyramidal side effects. Cranial nerve palsies, cerebellar and basal ganglia pathology, and anterior left hemisphere lesions can also contribute to dysarthria.

Dysphasia presents in two forms, receptive and expressive. In receptive dysphasia there is a lesion affecting Wernicke’s area in the dominant posterior superior temporal lobe. Language is not understood and speech output is fluent but unintelligible to varying degrees, including neologisms, grammatical and syntactical errors, and overinclusiveness. In expressive dysphasia there is a lesion affecting Broca’s area in the dominant inferior frontal lobe, usually extending into the frontoparietal region served by the superior middle cerebral artery. Language is understood but the patient cannot find words and assemble phrases and sentences: speech output is simple, minimal and not entirely correct in structure, but it betrays better comprehension than the irrelevant speech output of patients with expressive dysphasia. Both types of dysphasia affect the ability to repeat and to name objects. The Graded Naming Test can be used to evaluate naming impairment and semantic memory. Repetition can be examined simply using the MMSE phrase ‘No ifs, ands or buts’. Language comprehension can be evaluated with the Token Test: a number of tokens of different shapes and colours are assembled before the patient, who is then given standard verbal instructions of variable complexity, such as ‘Put the small red circle on the big green square’. Furthermore, most dysphasic patients are dyslexic, having difficulty in reading aloud or comprehension of text: they can be asked to read a short passage from a book, newspaper or magazine, and then describe its content. The distinction should be drawn between patients with learning disability and illiterate patients, however, and those who have lost a pre-existing ability. Similarly, there may be dysgraphia (difficulty in writing): the patient may fail to write a sentence or copy text. Dominant parietal lobe damage may be associated with dyspraxic dysgraphia, in which the motor control of writing is impaired. Both dysgraphia and dyslexia may present as neglect phenomena owing to non-dominant lesions (see below): the left (first) parts or words are not written or not read at all, or they are read or written incorrectly.

To the rear of Wernicke’s area is the angular gyrus, which connects the temporal, parietal and occipital lobes. Lesions here produce Gerstmann syndrome: dysgraphia, dyscalculia, right–left disorientation and inability to name individual fingers according to convention (finger agnosia). The angular gyrus appears very important for numeracy in general. If a patient cannot carry out serial subtractions of three from 20, then simpler arithmetic function can be checked, for instance single-figure addition. If further examination is required, the patient may be asked to point to numbers on command, copy numbers, write numbers to dictation, and read aloud written numbers. Again, the context of overall intelligence quotient and educational and motivational factors should be considered.

Finally, apraxia, the loss of simple motor skills, can be a consequence of dominant hemisphere compromise. The patient may be asked to demonstrate buccofacial actions (how they would lick lips, cough, sip through a straw, blow out a match), limb actions (how they would wave goodbye, beckon ‘come here’, salute, hitch a lift) and object usage...
Given the impact of current IQ upon personal and social function, it is important to judge the patient’s general intellectual capacity to inform formulation and management. The population mean IQ score is 100: the range is between zero and 200. The standard deviation is 15. People with an IQ outwith two standard deviations of the mean are statistically abnormal: hence, learning disability is defined by an IQ below 70, while an IQ of over 130 denotes superiority. The measurement error is five points. For this reason, a person may be classed as having a learning disability with an IQ of 75 if there are sufficient impairments in (separately assessed) adaptive functioning. Conversely, if there is adequate adaptive functioning, then learning disability would not be diagnosed in the context of an IQ of 65. The low score would be attributed instead to measurement error. Because practice effects are observed in neuropsychological evaluation, and the WAIS does not include multiple versions, it can be misleading to repeat the evaluation particularly over a brief period of time.

WAIS assessment is, as mentioned above, rather lengthy and cumbersome, potentially presenting the individual with multiple experiences of failure, which can be demoralizing. Furthermore, IQ evaluation may be seen as undesirable for social reasons, undermining the value of people and constituting grounds for discrimination. IQ evaluation measures, it has been argued, no more than the ability to complete IQ tests successfully. Nonetheless, in cognitive terms, IQ tests load quite heavily on aspects of frontal and memory function, which are known to be crucial for independent living skills.

Availability of the WAIS equipment is limited by its publisher to properly qualified clinical psychologists. A good compromise is the Quick Test (Figure 7.2; Table 7.1).

Premorbid intelligence is of great interest where IQ decline is suspected, as in degenerative or other instances of permanent brain damage however caused. Estimation requires a test that accesses aspects of cognition at least relatively preserved subsequent to psychiatric or neurological disorder: scores on the test should correlate highly with current IQ in the normal population. The best established premorbid IQ evaluation is the NART (Table 7.2). This test asks the patient (whose first language should be English) to read 50 words whose spelling does not reflect their pronunciation. The implication is that because reading one’s mother tongue is such a well established skill, acquired in childhood, it is resistant to the effects of cerebral pathology.

IQ decline can be assessed by comparing the NART score with the Quick Test score. Substantial discrepancies are manifest in dementia, after serious insults with permanent effects, and in some patients with chronic schizophrenia. Both the presence of decline and the current IQ estimate can be useful information in terms of diagnosis and prognosis.

**Conclusion**

Every competent psychiatrist must have an adequate working knowledge of cognition: the generality and specifics of

normal function, how it can go wrong, the clinical discovery of deficits, and their diagnostic and prognostic implications. Cognitive evaluation is, however, predicated not upon an afterthought of mental state examination but on foregoing referral information, and the patient’s previous history, history at interview and mental state assessment. Only then can appropriate screening take place, followed up with further enquiry and referral to colleagues in clinical psychology when necessary.

Repeated and extensive practice with a broad spectrum of patients will illustrate how cognitive issues insinuate themselves into psychiatric formulation and so inform investigation, management and outcome. It is hoped that the material presented in this chapter constitutes a good starting point.

ACKNOWLEDGEMENT

The author is indebted to Professor John R Hodges, whose standard work, Cognitive Assessment for Clinicians,26 very much informed a substantial minority of what is presented here. Professor Hodges’ work is unreservedly recommended for further reading.

CONCEPTUAL FRAMEWORKS

Nature and nurture

Are individual differences in behavioural and physical traits determined by genetic variation or by differences in environmental circumstances? Historically, theorists have tended to advocate extreme positions in this debate, but it is now widely accepted that genetic and environmental influences do not operate independently but are interactive. In most cases, genetic factors provide a set of parameters in which an infant can develop, with the exact nature of this development being determined by the environment. Thus, it seems that the important question is not which influence is most important, but rather how genetic and environmental factors interact to determine human development.

The heritability statistic used to express the relative contribution of genotype and environment to the observed behaviour or trait (i.e. phenotype) is widely misunderstood. This is a population statistic that provides information on the proportion of variability in the observed phenotype that may be accounted for by variability in the genotype (and, therefore, information on variability accounted for by the environment). The number of fingers on one hand, for example, although determined genetically, is not highly heritable, as any variation in this number is generally the result of environmental factors. Height, however, is highly heritable, since most diets – even relatively poor ones – are sufficient to promote growth, so that environmental variation plays a smaller role, with any residual variation being the result of genetic factors. The latter example also indicates that a heritability statistic for a given phenotype is specific to the time and population on which it was calculated: in populations where the diet is more variable, more of the variation in height in that population may be associated with this environmental factor, so that the heritability coefficient will be different even if the underlying distribution of genes is the same.

Stage theories

Many abilities and behaviours develop in a uniform way. The prerequisites for these behaviours, such as basic motor skills, are inherited, but through dynamic interaction with the environment children learn to develop these skills. Stage theories propose that development passes sequentially through qualitatively different phases. In most cases, accomplishment of one stage is necessary before development of the next can proceed. The rate of development is influenced by environmental factors, but some stage theories identify critical periods by which accomplishment of certain skills should be achieved.

Stage theories have been used to describe many aspects of development, including linguistic, moral and motor development. Piaget’s theory of cognitive development is one of the best-known examples. The goal of stage theorists is to determine the distinct qualitative features of the developmental process and the important changes that characterize transition from one stage to the next.

Maturational tasks

Development of a skill or behaviour occurs when a child performs or practises tasks that strengthen, extend or consolidate current knowledge or abilities, so that higher levels of that skill or behaviour can be achieved. For example, a child will master the art of standing unaided before attempting his or her first steps, which will be unsteady at first, becoming more assured and steady over time. These tasks propel the child through the critical periods of development.

Maturation refers to a largely genetically determined ‘blueprint’ that sets out a child’s critical periods of development (i.e. the sequential aspects of development that are under biological control). The concept of maturation is linked closely to the nature–nurture distinction, as it is the interaction between maturation and experience that shapes an individual’s development.

Although it is relatively easy to understand maturation in the development of physical abilities, the applicability of this framework to psychological development is not accepted universally. It is also important to distinguish between simple maturation, which is the pure biological unfolding driven primarily by genetic factors, and development, which is the sequence of changes over the lifespan that results from the interaction of some behaviours and the environment.
Maturity

Maturity in a physical sense refers to the time in life when physical growth has ceased. From a psychological viewpoint, however, maturity is somewhat more difficult to define. Unlike growing in height, for example, there is no clear cessation in psychological growth. In fact, learning and development continue on an emotional, cognitive and intellectual level throughout an individual’s lifetime. Therefore, it may be more relevant to think of maturity as the conclusion to a biologically predetermined pattern of development, or the culmination in the maturation process described above.

James Tanner devised a series of longitudinal charts to illustrate growth references on physical parameters, including height, weight, skin folds and puberty, ranging from birth to maturity. Their purpose was to provide a standardized tool for clinicians to assess whether a child’s size and growth rate were within the normal limits for his or her age, sex, socioeconomic position and ethnic group, and to help diagnose growth disorders such as short stature and low growth velocity. Despite originally being designed for clinical use, the charts have also been used to predict adult physical characteristics such as height in adulthood. Questions have been raised regarding the validity of the charts, particularly due to trends of increasing size over time, which have been answered, to some extent, by revisions to the original work. There does, however, remain some confusion over the comparability of Tanner scales with other growth references. Tanner’s charts are still in clinical use in the UK, often in combination with other growth references (Figure 8.1).

Figure 8.1 Example of Tanner growth chart for height. A series of charts of longitudinal growth standards for physical development (including parameters for height, weight, skin folds) were developed for children according to age, sex and sexual maturity. From Tanner JM, Whitehouse RH (1976) Clinical longitudinal standards for height, weight, height velocity, weight velocity, and stages of puberty. Archives of Disease in Childhood 51: 170–79.
Gene–environment interactions

The broad implication of interactions between genetic and environmental influences has been described above. More recently, more specific findings have contributed to the debate concerning the nature and development of intelligence and personality, both of which have been claimed to be up to 80 per cent heritable, although most estimates range from 50 per cent to 60 per cent. Although twin studies and other methods have certainly suggested a genetic component to intellectual ability, the interpretation of these results is problematic, given the highly interactive nature of the factors in question and the complex nature of intelligence itself.

Early, simple additive genetic models of intelligence suggested that genotype and environment both contributed independently to the phenotypic expression of intelligence, so that the relative contribution could be determined by certain empirical means (e.g. the comparison of identical twins raised apart, or the comparison of monozygotic (MZ) versus dizygotic (DZ) twins). Notwithstanding the methodological limitations of many of these studies (and a few celebrated scientific frauds), the model of genetic influence guiding this research is potentially inappropriate. The model of genotype–phenotype interaction, proposed by Scarr and McCartney in 1983, highlights this (Figure 8.2).

Although genotype and environment will influence the phenotype of the individual, these relationships may not be unidirectional. Most importantly, the phenotype of the individual will influence the environment, so that physically short individuals will be less likely to find themselves playing basketball, for example. In this sense, it would be possible to find a genetic component for basketball-playing, but this would not be interpreted as a gene ‘for’ basketball (whereas comparable findings in intelligence are so interpreted). Rather, the combined influence of a number of genes related to physical development, when expressed in a given context (i.e. a population where basketball is played) would influence the likelihood of an individual playing basketball. The various influences in this interactive model include the child’s genotype on the child’s phenotype, the child’s environment on the child’s phenotype, the child’s phenotype on the child’s environment, the parents’ genotype on the child’s genotype, the parents’ genotype on the child’s environment, and various external influences on the child’s environment.

The influence of the parents’ genotype on the child’s environment may also, because of the obvious genetic relationship between parents and child, appear as a genetic influence rather than an environmental one. Finally, because of certain cultural norms, certain physical characteristics will result in the individual being treated in a certain way. Attractive children, for example, are likely to receive more stimulation in infancy, which may result in faster or improved cognitive development. This may appear as a genetic influence, even though the gene found is ‘for’ physical attractiveness, which, in a specific culture, results in certain treatment that may facilitate intellectual development, so that the genetic influence is mediated by a culturally determined environmental influence. In this case, it would be more proper to call the environmental mediating variable, rather than the genetic variable, causal.

![Figure 8.2 Scarr and McCartney’s model of genotype–environment interaction in behavioural development. The child’s observable behaviour (phenotype) will arise from an interaction between his or her genotype and rearing environment. The genotype of the parent will determine the genotype of the child and thus also indirectly influence the child’s phenotype. Parental genotypes will have an additional influence over the child’s rearing environment. The model also allows for a bidirectional influence between the child’s behaviour and rearing environment, highlighting that the child actively contributes to their own behavioural development. Ec, child’s rearing environment; Gc, child’s genotype; Gp, parent’s genotype; Pc, child’s phenotype. From Scarr S, McCartney K (1983) How people make their own environments: a theory of genotype–environment effects. Child Development 54: 424–35.](image)

Early versus late adversities

At various times in an individual’s lifetime, they will encounter negative events or life stressors. A key question in developmental research is how the outcomes and coping strategies associated with these events differ as a function of when they occur. A young child may be particularly resilient to adversity; underdeveloped cognitive systems, for example, may restrict encoding of the event, such that its impact on future development is negligible. However, children are particularly vulnerable when the negative or traumatic event disrupts the normal course of development.

Over the last hundred years there have been several reports of children being rescued from severe adverse experiences, often involving considerable social and emotional neglect. Generally, the normal development of the child is severely compromised and, although improvements do occur with significant medical and psychiatric intervention, the child remains intellectually and socially impaired. These cases support the suggestion that children must attain specific developmental achievements within a critical age period.
These cases are, however, both extreme and rare. Many children experience some form of less severe adversity in childhood that may lead to behavioural disruption, but to what extent does this disruption persist— if at all? This will certainly depend on the nature of the negative event; a single short-lived adversity, such as a one-off hospitalization, while traumatic, may be less detrimental than sustained problems such as extreme poverty or an alcohol-dependent parent. However, individuals differ greatly in the extent to which they are vulnerable or resilient to the effects of negative events. Thus, it may be particularly important to consider why some individuals fare better than others following negative experience. Generally, events in early life will influence the development of risk factors such as self-concept, social skills and so on, while later events will act as causal factors given the existence of such risk or protective factors. This accounts for the apparent resilience found in some individuals where appropriate early experiences and subsequent emotional and cognitive development may act as protective factors.

Historical models and theories

Psychoanalytical theories

Psychoanalytical theories have common origins in the work of Sigmund Freud. They emphasize a role of unconscious as well as conscious processes in governing human behaviour. Early focus was on social and emotional characteristics of the adult and how these were shaped during early development. According to traditional theories, personality traits can be traced back to fixations held during various aspects of early development. An ‘anal’ personality type, for example, describes someone who is overly pedantic and compulsive, and would have had strong fixations in the anal stage of development. Parents and their methods of care are considered particularly important, with the infant playing a largely passive role in the outcome of their own development.

Social learning

A major component of social learning theory is learning through the observation and imitation of others, often termed ‘observational learning’ or ‘modelling’. Although many imitated behaviours are reinforced in some way, studies by Albert Bandura in the 1960s and 1970s showed that children would mimic the behaviour of an observed model in the apparent absence of any positive or negative reinforcer. Imitation, however, does not occur spontaneously. Children appear to actively select the behaviours that they imitate. Contemporary social learning theorists are particularly interested in the factors that influence this selectivity, such as the personality or past experience of the child, or situational factors. More recently, social learning theory has been adapted to link closely with cognitive theories of development.

Jean Piaget’s epistemological account of cognitive development is considered in more detail in other sections of this chapter. Based predominantly on the observations of his own children, Piaget developed a stage theory of cognitive development that emphasized the interaction between biological predispositions and environmental influence. His work also encompassed other aspects of development (e.g., moral development); however, it is his cognitive model of development that has been particularly influential. One of the most important contributions that Piaget made was to establish the child as playing a dynamic role in his or her own development, through interaction with physical and social worlds, that is driven by simple, inherited predispositions.

Summary

Understanding human development requires consideration of the relative influences of inherited biological dispositions and of environmental factors on phenotypic expression. This is referred to as the nature–nurture debate, and it is now accepted widely that genetic and environmental factors are not simply additive but interact in complex ways. Generally, it is believed that an individual may vary on any given characteristic within limits determined by their genotype, while the variation within these limits is determined by the environment.

Stage theories have been employed to explain many important aspects of human development. They describe qualitative changes that occur at various periods during development. Individuals pass through developmental stages in a fixed order, with attainment of the characteristic skills of one stage being required before the individual can pass on to the next. Although sometimes criticized for their rigidity, stage theories have been extremely influential and describe behaviours that are often readily observable in the developing child. A related concept is that of maturational tasks, which consolidate and expand current skills necessary for development on to higher levels of functioning.

It is important to be aware of several key theoretical frameworks, in particular psychoanalytical theory, social learning theory, and Piaget’s stage theory of cognitive and intellectual development. These theories have been extremely influential in shaping understanding and research in human development.

METHODOLOGIES

Cross-sectional studies

Cross-sectional studies examine age-related differences in behaviour by comparing children of different age groups in the same situation and at the same point in time. This enables relatively quick and easy collection of large amounts of data. However, this method provides little information on how individual children develop or on the influ-
ence of past determinants on observed behaviour. It is possible to obtain self-reported retrospective accounts of past development, but this method is potentially flawed and has questionable reliability and validity. Furthermore, selection of different individuals means that comparison groups may differ on factors other than age. A 10-year-old child born in 1998, for example, may differ from a 5-year-old child born in 2003 due to different economic or social influences during their early development. Thus, there are limits on the conclusions that can be drawn from cross-sectional studies, and longitudinal or cohort methods are employed to tackle more complex questions such as individual stability over time.

Cohort studies
In cohort studies, individuals are chosen on the basis of one or more unifying characteristics. For example, studies examining the genetic and environmental risk factors for schizophrenia often enlist the children of schizophrenic patients, as the incidence of schizophrenia is elevated in these children compared with the normal population. However, this presents problems relating to the generalizability of the findings. Longitudinal studies also require substantial resources to sustain them over the, often lengthy, study period. They also may achieve a less representative sample than a cross-sectional study, due to some people being unwilling to commit to repetitive testing over time. Furthermore, dropout rates are often high and such attrition may not be random.

Individual studies
On occasion it is beneficial to study an individual child in a detailed manner, which is not practical with larger groups of children. This method is particularly useful when studying unusual cases, such as rare diseases, where individual examples are uncommon. The fundamental limitation of such an idiographic approach, however, is an inability to generalize findings to the wider population; it is plausible that the observations are unique to the child being studied. Nevertheless, this method can provide useful insights that guide future research using more systematic techniques in a large number of individuals.

Identification and evaluation of influences
There is substantial interest in the relative influence of genetic and environmental factors on development. Methodologies for investigating this rely on comparison being made along certain phenotypic dimensions between individuals of varying genetic similarity. For example, identical (MZ) twins are genetically identical, while non-identical (DZ) twins share only, on average, one-half of their variegated genotype. As such, if a psychological characteristic is correlated more strongly in MZ twins compared with DZ twins, then this suggests a genetic influence. Several varying degrees of genetic and environmental similarity are possible: MZ twins reared together, MZ twins reared apart, DZ twins reared together, DZ twins reared apart, siblings reared together, siblings reared apart, cousins, and adopted (i.e. unrelated) children reared together. Other combinations are possible, but this demonstrates the variety of comparisons that may be made.

On a variety of phenotypic characteristics (e.g. personality and other psychological dimensions), the degree of similarity between individuals increases with genetic similarity (and also with environmental similarity). The interpretation of such results, however, is highly problematic, and it is becoming increasingly clear that accurate characterization and reliable measurement of the phenotypic characteristic of interest are of primary importance. Moreover, this basic methodology relies on a simple additive model of genetic and environmental influence that is probably incomplete, as it fails to take into account gene x environment interactions.

Summary
Three main methodologies have been employed to study human development, all of which have their own strengths and weaknesses. Cross-sectional studies are conducted at one point in time in groups of children of different ages. They provide a quick and easy method of collecting a large amount of data, but they do not enable deeper understanding of how individuals develop over time. Cohort studies recruit individuals based on a unifying characteristic; however, there are problems when generalizing these data to wider populations. Longitudinal studies involve the repeated testing of the same sample at various periods during their development, which allows analysis of individual development across time, but these studies are time-consuming and costly. Less commonly, a single child may be studied in depth, which is not possible with larger samples, although there are problems associated with the generalizability of the findings.

By studying individuals of varying genetic and environmental similarity, it is possible to examine the relative influence of these factors on phenotypic characteristics. However, interpretation of results from these studies can be problematic.

**ATTACHMENT THEORY**
Attachment theory attempts to describe the behaviour of infants (generally in primate species) and relate this to behaviour in adulthood, in particular focusing on the progression of these behaviours as they become focused on (usually) one primary caregiver, known as the attachment figure, through infancy, and the relationship between the resulting attachment style and interpersonal behaviour in adulthood. The main premise of attachment theory is that the
need for physical proximity and emotional closeness is an innate behaviour and a necessary precursor to and stimulus of psychological, emotional and social development. The primary attachment figure (usually, but not necessarily, the mother) serves as the model for the development of future relationships in later childhood and through adulthood.

Attachment behaviours comprise relevant behaviours directed towards the primary attachment figure, who is the focus of these behaviours (Table 8.1). In early life (typically the first 6 months), the infant does not display selectivity in the direction of relevant behaviours (e.g. seeking closeness), but after this early period these become increasingly directed towards an attachment figure. This represents the formation of an attachment with this individual; interestingly, it depends primarily not on obtaining resources (e.g. food) from that individual but instead on proximity, affection and so on. Therefore, direct survival behaviours such as feeding appear to be distinct from attachment behaviours such as seeking affection.

For example, rhesus monkeys separated from their mother will spend the majority of time clinging to a wool doll rather than a wire doll, even when it is the latter that provides food. This suggests that attachment behaviours are related not to feeding but to proximity, nurturance and so on cued by other stimuli (such as the physical characteristics of the mother).

It has been suggested widely that the initial attachment forms a template for the development of subsequent social and emotional relationships, so that early behaviour may predict later social behaviour.

### Emotional development

Attachment behaviours in early life appear to be highly correlated with subsequent development and behaviour. Secure attachment styles are related to initiative-taking, social competence and the ability to form friendships in later childhood. Insecure attachment styles, on the other hand, are related to subsequent social withdrawal and difficulty in forming friendships. Attachment behaviour seems to be relatively stable, once established, over the lifespan.

### Affect regulation

Insecure attachment behaviours include inability to express affection with the attachment figure, either by being excessively dependent and at the same time irritated by the attachment figure, or by displaying avoidant behaviour, and this may be related to affect regulation in adult life. Generally, insecure attachments have been found to be related to emotional disturbance in adolescence and adulthood, although the strength of the relationship is modest.

### Relationships

The primary attachment figure serves as the model for subsequent relationships, including friendships and romantic relationships. Patterns of adult romantic relationships appear similar to attachment behaviours, with the proportion of adults describing themselves as within each category roughly corresponding to the proportions found in infant attachment styles. Retrospective questionnaires suggest that these styles of romantic affection are related to the perceived or remembered behaviour of the mother towards the individual.

### Secure attachment

Infants who display secure attachment behaviour use the attachment figure as a base from which to explore, occasionally returning to seek affection. Separation from the attachment figure induces anxiety and distress and interaction is sought when reunited, after which anxiety reduces and exploration resumes. This is most evident in the first 36 months of life, after which separation anxiety reduces and attachment substitutes may be accepted.

Secure attachment behaviour is related to early infant temperament, child-focused caring, nurturing behaviour from the attachment figure, encouragement for the child to explore independently, and provision of a secure base by the attachment figure.

### Insecure attachment

Insecure attachment behaviours comprise two distinct categories:

*Insecure-avoidant behaviours* are characterized by muted distress in the absence of the attachment figure and a
minimal response when reunited. What may appear to be secure attachment behaviour may in fact be insecure-avoidant behaviour, due to this apparent independence, and making the distinction may be difficult. The clearest difference lies in the fact that securely attached children still display closeness, balancing a desire for affection with independence, while insecure-avoidant children almost exclusively seek distance and self-sufficiency at the expense of closeness.

Insecure-ambivalent behaviours represent the least common attachment style and represent a mixture of excessively dependent behaviour towards the attachment figure with a lack of obvious affection. Separation results in excessive distress in the child but, when reunited, the child will then resist physical contact. Distress continues for some time after the return of the attachment figure.

There is evidence for a relationship between insecure attachment styles and future antisocial behaviour and affective disorders. If such attachment behaviours are identified in early life, then teaching parenting skills to the parents of the child, specifically to be more caring towards the child, may reduce this risk. However, it is simplistic to attribute attachment behaviours solely to the parenting style of the parents, and other factors such as early infant temperament appear relevant.

Early separation
Given the relationship between attachment behaviour and subsequent behaviour in adolescence and adulthood, separation from initial attachment figures is related to subsequent behavioural problems. This is related to the age at which such separation takes place. For example, selective attachments do not begin to form until 6 months of age, so that separation before this time may have relatively little effect, allowing the formation of attachment behaviours towards the adoptive caregiver. Similarly, after the first few years of life, the child will have developed a pattern of attachment behaviour, and therefore a model or template of relationships, so that separation will not result in excessive disturbance, as the child will be able to accept the adoptive caregiver as a substitute attachment figure.

The critical period appears to be between 6 and 36 months, when the greatest changes occur in the pattern of attachment behaviours. Separation during this period is likely to have the greatest impact on the child’s subsequent behaviour, as it will disrupt the formation of normal attachment behaviour.

Failure to develop selective attachments
Autistic children are characterized by an unwillingness to seek physical contact with parents. This becomes most apparent between 12 and 36 months, when normal, selective attachments would otherwise typically form. This is highly correlated with similar behaviour in adult life and appears to be largely the result of physical and genetic factors rather than social or developmental processes.

The failure to develop selective attachments in autistic children as a result of internal factors should be distinguished from a breakdown of the normal attachment process because of environmental or rearing factors. In this case, the lack of a clear single caregiver results in incomplete development of attachment behaviours, so that strangers and parents are treated similarly, without any apparent stranger anxiety. At the same time, the behaviour towards such figures is superficial and any affection easily terminated, so that separation anxiety also does not occur. It is for this reason that early separation in the critical period is most detrimental to the child, in particular if the child is not placed in a caring adoptive or foster home.

Maternal bonding
The anxiety that results from separation of the child from the attachment figure is a necessary part of the development of secure attachments, since it is the eventual reunion that gives the child confidence in the attachment figure. This, in turn, gives the child confidence in relationships, understanding that they persist over time and distance. The term ‘maternal bonding’ is potentially inappropriate, however, in that, although usual in most Western cultures, it is not necessary that the primary attachment figure be the mother.

Summary
Attachment theory is a framework for understanding the behaviour of infant primates whereby proximity and affection are sought (attachment behaviours) and appear to act as primary drives, in a similar way to hunger and thirst. An attachment relationship develops between the infant and the care provider (attachment figure). This serves as the model for subsequent relationships of all kinds. Infant attachment behaviours appear to relate modestly to adolescent and adult friendships and romantic relationships. Selective attachments usually do not form before 6 months.

Attachment to an attachment figure may be either secure or insecure, with the latter further subdivided into avoidant and ambivalent. Secure attachment represents a relationship where the attachment figure provides a base for independent exploration, and, although separation from the attachment figure results in distress, this rapidly subsides on reunion. Insecure-avoidant attachment is characterized by a relative lack of distress on separation and a general tendency for affection to be muted. Apparent secureness masks an unwillingness to display closeness. Insecure-ambivalent behaviour is characterized by excessive dependence but an unwillingness to display affection towards the attachment figure. There is some evidence for a relationship between attachment style and subsequent antisocial behaviour and affective disturbance.
The development of attachment behaviours occurs between 6 and 36 months. This has implications for the separation of the child from the primary attachment figure (usually the mother), with this critical period being associated with the greatest impact on the child’s behaviour if separation occurs.

A failure to develop selective factors may be the result of internal factors (e.g. autism) or external factors (e.g. disturbed family function). The latter situation may also be related to early separation of the child from the primary attachment figure during the critical period (i.e. the first 3 years of life).

FAMILY RELATIONSHIPS

Parental practices and attitudes

The behaviour of individuals towards their offspring is of primary importance in determining attachment behaviours in infants, with these factors further interacting with temperamental features of the infant. Parenting style is commonly characterized along two dimensions: restrictive-permissive and loving-hostile. Alternatively, three categories of parenting style have been suggested: permissive (warm and caring, while accepting unorthodox behaviour), authoritarian-restrictive (less emotionally close and highly controlling), and authoritative (enforce rules and demand achievement, yet warm and loving).

The development of the child depends greatly on the parenting style adopted by the child’s parents. For example, authoritarian-restrictive parents tend to have highly submissive children, while authoritative parents tend to have independent children (largely as a result of the emphasis placed on expressiveness within set boundaries). The behaviour of the parents is most important in the early development of the child, and this establishes a pattern of behaviour in the child that is sustained over time. In particular, the consistency of the parents’ behaviour towards the child, for example with reference to the rewards and punishments consequent on certain behaviour, is a strong predictor of subsequent emotional and social behaviour in the child. Inconsistent parenting behaviour is associated with negative outcomes along these dimensions, presumably because it inhibits the development of a clear social model to guide behaviour.

The extent to which specific attitudes of parents is mirrored in subsequent attitudes in their children is debatable: any relationship may be weak overall, and there are numerous examples of children adopting opposing attitudes and beliefs, in particular during adolescence.

Distorted family function

There are a variety of ways in which normal family function may be distorted. Such (dysfunctional) families are highly varied in the nature and extent of distorted function, so that care should be taken in making comparisons. Certainly there is no such thing as a ‘typical’ dysfunctional family. Distorted patterns of communication are often at the core of dysfunctional families; for example, positive or neutral remarks may be interpreted in a negative way, leading to potential discord. This situation may be self-sustaining, as individuals attempt to exert their influence in response to perceived insults by reacting in a similar way. Conversely, behaviour that would be useful in reducing discord (e.g. apology) is used rarely and is typically seen by those involved as an admission of defeat.

Overprotection may be the result of enmeshment within a family, in which case it is broadly applicable to all members of the family unit. It may also occur in specific cases; the central feature of overprotection is an unwillingness to allow a member of the family group to display individuality, especially outside of the family group. The characteristic feature of such family behaviour is an apparent excess of closeness that is selfishly motivated.

Rejection may be a specific individual effect, for example where a mother rejects closeness with her child, or a more general family effect. In this latter case, the family will not have a strong sense of collective identity, with individuals showing only weak attachment relationships to other members, often forming stronger attachments outside the family group. Isolation and loneliness commonly result.

Enmeshment refers to families where individual identity and individuality are lost to family status and role, in direct contrast to rejection. A high degree of homogeneity, especially of opinions and beliefs, results in little input in discussions regarding the family. Family structure is tightly defined, and any individual family member attempting to display independence is likely to have this suppressed.

Bereavement

Bereavement may involve the death of a loved one or relative, but more generally (and metaphorically) it can indicate loss of any kind (e.g. moving school, leaving home). This latter use is based on some evidence that the reaction to loss of any kind follows a similar pattern, although the intensity of these reactions will vary. Typical reactions to loss include: disbelief/denial, emotional blunting/numbness, and excessive rumination over the lost object or individual.

Considerable adjustment is required in any case of bereavement, and the effect on the child may be considerable. Behavioural problems are associated with the loss of a parent in children, and this is related to poor adjustment in the surviving parent, although the direction of causation may be complex. Subsequent development of the child may be influenced most by the subsequent behaviour of the surviving parent (e.g. change of parenting style, relative neglect due to increased time demands), rather than the loss of a parent specifically.
Divorce

The effects of divorce on child development are difficult to delineate, as parents who divorce have generally been in conflict for some time before the divorce. In general, in the first year following a divorce, the parents of the child become more permissive and less controlling, and communication between parents and child deteriorates. This behaviour occurs in both the parent without the child and the parent who cares for the child, but usually this change in parenting style resolves after the first year following the divorce. The effects of the divorce on the child depend on the age of the child, the degree of hostility resulting from the divorce, the use of the child by the conflicting parents to achieve their own aims, and the degree of adjustment of the parent who remains caring for the child.

In almost all cases there is a degree of distress in the child, allied to feelings of responsibility or guilt, and subsequent depression or hostility. In most cases, however, this resolves relatively quickly (usually after the first year), provided that the parent with whom the child remains also adjusts over this period.

Intrafamilial abuse

 Abuse of children is most dangerous in the early years of life (under 4 years), not least because this is when the child is physically most vulnerable. This is also the period when the antecedents of self-esteem and self-image are developing. Immediate effects of intrafamilial abuse (either physical or sexual) include sleep disturbance, eating disturbance, depression, phobias or anxiety, behavioural problems and social problems. Longer-term effects are more difficult to delineate, but there is some evidence that initial consequences may persist for several years if abuse continues. In particular, several problems appear to persist, including depression (especially in sexual abuse), self-harm, low self-esteem and impaired relationship formation.

These effects are greatest if the abuse comes from within the family group (which is the most common source), if the abuse is sustained over a substantial period, and if the abused is not believed when help is sought.

Non-orthodox family structures

The most common non-orthodox family structure is the single-parent family, a situation that has increased in prevalence recently. This may be the result of bereavement (uncommon), divorce (common) or single motherhood (also common). The consequences of living with only one parent was present. Similar consequences for child development have been found in other, rare family structures (e.g. children raised by grandparents).

Although the extended family structure found in some cultures and ethnic groups should not be regarded as unorthodox, it is not the common structure in Western cultures. In general, children raised in such families tend to develop high levels of self-esteem and the family structure seems to represent a protective factor (i.e. by providing high levels of social support).

Summary

Parenting style is an important determinant of child behaviour. The behaviour of the parents may be described as either dimensional (e.g. restrictive-permissive/loving-hostile) or categorical (e.g. permissive, restrictive, authoritative). Parenting style correlates with the behaviour of the child. For example, restrictive parents tend to have submissive children. This relationship is statistical, so that it is not possible to accurately predict behaviour in the child from the behaviour of the parents in specific cases.

The impact of bereavement and divorce on family function, in particular children’s behaviour, may be regarded under the more general term of loss. There are certain similarities between bereavement and divorce, although there are also unique characteristics of each. Distress following loss of any kind is normal and only problematic if it becomes chronic in nature and extends beyond the normal time for adaptation and coping to take place.

Specific terms are used to describe different features of distorted family function, such as overprotection, rejection and enmeshment. Although there is no such thing as a typical dysfunctional family, and the causes of dysfunction may vary widely, certain characteristics appear repeatedly (e.g. distorted or impoverished communication between family members).

TEMPERAMENT

Temperament and parent–child relationships

From birth, infants display apparently innate differences in behaviour. They differ in their moods, activity levels,
stability of sleeping and feeding patterns, sociability, and response to novel situations. These early biases are known as differences in temperament. Given that these differences are observed soon after birth, it is reasonable to suggest that differences in temperament are, at least in part, determined genetically.

Temperament also influences the relationship that forms between the child and the parent. A parent of a ‘difficult’ child may display irritability and frustration, which, in turn, increases the irritability of the child. In extreme cases, the stress of dealing with a difficult child may interfere with the natural attachment process, particularly in families where there is limited external support. Conversely, a parent is more likely to engage with a child who is sociable and quick to smile. Consequently, even within the same household, parents may encourage different patterns of development in their children, driven by differences in the children’s temperament. Parenting style itself, however, is subject to change. Parents of a difficult child may learn to adapt and develop new and more fruitful ways of interacting with their offspring, so that even when bonding is initially compromised this can be rectified with appropriate parental adjustment.

**Origins, typologies and stability of temperament**

Early work on temperament identified several dimensions along which young children vary. The analysis of these dimensions resulted in three typologies of temperament: **easy children** (about 40%), characterized as having regular sleeping and feeding patterns, sociability, enjoyment of physical contact, and adaptability to new situations; **difficult children** (about 10%), characterized by irregular sleeping and feeding patterns, irritability, emotional lability and negative responding to new situations; and **slow-to-warm-up children** (about 15%), characterized by relatively low activity, slowness to adapt to new situations, and treating new situations with initial suspicion. A proportion cannot be reliably classified into one of these groups.

Around one-third of the original sample of children studied in this research did not clearly fall into any of these groups, but follow-up work suggested some degree of stability in temperament. Children identified as ‘difficult’ may not always be classified this way but are more likely to have problems in later life.

Temperament theory suggests that the nature and behaviour of a child is not simply a product of his or her environment (e.g. parenting style). Instead, the child interacts with the world and, in doing so, modifies behaviour directed towards them. The goodness-of-fit of the child’s environment should be taken into account – a ‘difficult’ child may prompt negative responses in his or her parents. Alternatively, parents may work hard to overcome the challenges of dealing with a ‘difficult’ child, handling the child with emphasized patience and understanding. The latter case is more likely to result in healthy development of the child.

**Temperament and personality**

A critical question in developmental psychology is the extent to which personality in adulthood may be predicted by infant temperament. Although research has suggested links between early temperament and personality in later life, any continuity that does exist appears to be weak, presumably because of the strong environmental and societal influences on the development of personality. However, temperament does play an important role in the emerging personality of the individual; it sets a framework of behaviour, but personality will be a result of how this basic pattern of behaviour is affected by maturation and experience.

Temperament × environment interactions may serve to strengthen innate dispositions and mould personality. A sociable child, for example, will seek contact with others, in turn promoting sociability and social development. Furthermore, temperament is associated with various long-term outcomes, including the quality of familial and peer relationships, psychopathology and psychological adjustment.

There is some evidence to suggest that temperament of very young children is related to subsequent attachment behaviour (over a relatively short timespan): **easy** with secure attachment, **difficult** with anxious-avoidant attachment, and **slow-to-warm up** with anxious-ambivalent attachment. Attachment behaviour, in turn, has been shown to be weakly associated with adult behaviour. The greater the temporal distance between the temperament and current behaviour, the weaker the relationship.

**Vulnerability and resilience**

Psychosocial adversity and negative life events are associated with higher incidence of psychiatric disorder. However, individuals differ in the extent to which they are vulnerable or resilient to long-term negative impact following adverse experiences. Several factors have been identified that may increase vulnerability, such as family discord, intrafamilial abuse and early bereavement (particularly of the primary attachment figure).

Some children show great resilience to life stressors. Those that demonstrate secure attachment behaviour, for example, are likely to be able to form replacement attachments if the mother is lost (depending on the age at which the loss occurs). It is also possible that experience of early stress may result in resilience to stress in later life in some individuals but an increase in vulnerability in others.

The long-term impact of traumatic events will depend on the temperamental disposition of the child. Difficult and slow-to-warm-up children are more vulnerable to stressors and appear to be more at risk of subsequent deviant
behaviours, including psychiatric problems such as depression, hysteria, neuroticism and psychosis.

Summary

From birth, infants display differences in behaviour that are referred to as individual temperaments. Children with ‘difficult’ temperaments are more irritable, less content and less sociable than children with ‘easy’ temperaments. An intermediate temperament, ‘slow-to-warm-up’, has been identified that describes children who may show initially negative emotional reactions that improve with time and experience. Development of temperment may be related to the development of attachment style in early infancy.

Some psychiatric disorders (e.g. unipolar depression) may develop as a result of certain environmental risk factors. However, individuals differ in the extent to which the presence of these risk factors is likely to result in the expression of psychiatric disturbance: some people seem particularly vulnerable, while others are resilient to these effects. The mechanisms underlying these differences are unclear but are likely to include the coping style of the individual.

COGNITIVE DEVELOPMENT

Jean Piaget developed an epistemological account of intellectual development that transformed our understanding of the way in which children think. He argued that the general pattern of cognitive growth was universal, and interaction with objects and people in the world forced children to follow comparable patterns of development. Piaget was particularly interested in how children think, the processes that underlie cognition, and how these processes change with age. An important feature of his theory, and one that is still largely accepted today, is that children’s thought processes are qualitatively, not just quantitatively, different from adults.

According to this model, children are not merely passive observers of the world. Cognitive development progresses via the interactive processes of assimilation and accommodation. At birth a child inherits relatively primitive mental structures, largely reflexive in nature, which enable basic interaction with the environment and which are modified with experience. First, the child interacts with the environment and interprets information in the context of existing mental structures (assimilation). Then, when presented with new information or objects that do not fit with existing cognitive schema, the child develops his or her repertoire of actions based on the environment (accommodation). Thus, in Piaget’s view, cognitive development comprises a continuous interaction between the child and the environment, in which knowledge is repeatedly constructed and reconstructed in light of new experience.

Piaget argued that cognitive development was not a gradual process but advanced in a step-like fashion. He described specific, qualitatively distinct stages of development in which accomplishment of critical aspects of each stage was required before the child could advance to subsequent stages. These stages described a global process of cognitive development comprising the totality of cognitive growth from birth to maturity and are summarized in Table 8.2.

These transitions between stages suggest that, at critical periods, the child undergoes a comprehensive mental reorganization that encompasses all aspects of cognition. The ages described provide a guide to when these transitions occur, but children may vary considerably in the ages that they progress from one stage to another, with some individuals failing to achieve the final stage entirely.

Some key concepts should be noted that further characterize the different stages in development. Object permanence describes the acquired ability of the child to understand that objects in the environment exist even when

<table>
<thead>
<tr>
<th>Stage</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sensorimotor</td>
<td>Knowledge of the world is acquired primarily through sensory experience and basic motor actions (sucking, grasping, biting), which become more complex and coordinated over time. Only towards the end of this stage does the child begin to form internal mental representations of the world and begin to engage in intentional behaviour.</td>
</tr>
<tr>
<td>Preoperational</td>
<td>Characterized by the child beginning to engage in symbolic thought (imaginative play, drawing), where words/mental images stand for objects and people. Focus on static states rather than transformations. Logical thought and problem-solving ability emerges. Children acquire a number of cognitive operations that were not possible at earlier stages, including ability to see situations from the viewpoint of others, reversible thinking and ability to understand transformations. Abstract conceptualizations, however, are limited.</td>
</tr>
<tr>
<td>Concrete operations</td>
<td>Children can think in terms of abstract and hypothetical concepts. Logical and rational thought develop so that the child can conceive possible outcomes of actions and perform advanced problem-solving by constructing and testing hypotheses systematically. Complex self-identity develops.</td>
</tr>
<tr>
<td>Formal operational</td>
<td></td>
</tr>
</tbody>
</table>
he or she can no longer see them. This ability is one of the most important developments during the sensorimotor stage. Preoperational children have a well-developed sense of object permanence but are largely egocentric – that is, they can only construe the world from their own viewpoint and lack understanding that alternative perspectives exist. Egocentrism is lost by the concrete operational stage, in which the most important acquired skill is conservation. This refers to an understanding that the fundamental nature of an object can remain constant despite changes in appearance. The classic example is that children in this stage understand that a set volume of liquid does not change when poured into different-shaped containers.

A particularly common criticism of Piaget’s model is that he was overly pessimistic when describing the cognitive abilities of children. He believed that biological factors constrained the order and rate at which a child was able to develop. However, abilities such as object permanence have been observed in children much younger than Piaget would have predicted. Underdeveloped motor ability or difficulty in relaying task instructions to young children may have contributed to these underestimations in cognitive capability. In addition, the stage-like nature of development proposed by Piaget has been challenged. It appears that development may be more gradual and continuous than the model suggested. For example, children may show some aspects of object permanence or non-egocentric behaviour in some circumstances but not others, arguing against the abrupt changes in development associated with a stage theory.

Despite these limitations, Piaget’s theory has been hugely influential due to its depth, testable hypotheses, and the observational and empirical basis of much of the theory. It provides a framework of global cognitive and intellectual development that explains the qualitative differences in thinking during development and also how changes occur. The assumption that children are not passive observers of the world has also had important implications for education.

Thought and communication
Piaget claimed that the acquisition of language progresses as part of the natural development of cognition, and therefore the way in which a child communicates with others depends on the developmental stage the child is at.

The first steps on the road to acquiring language occur with the emergence of symbolic thought towards the end of the sensorimotor stage. However, it is during the preoperational period that the child begins to display significant advances in linguistic skills, from single-word utterances, through short sentences, to competent, if unsophisticated, language. Towards the end of the preoperational stage, the child begins to learn and apply the rules of language (language pragmatics) as a means of more sophisticated communication. At this stage, children begin to show adult-like gestures associated with verbal communication and adapt their communication to the situation they are in or the person to whom they are talking. This social skill improves with the reduction of egocentrism, when children can appreciate the perspective of others and thus adapt communication appropriately. A noticeable change that occurs during the preoperational stage is the development of politeness in the linguistic competence of these children. More complex and subtle features of communication, such as indirect questions, hints and sarcasm, require a certain level of cognitive maturity before they can be learned.

The loss of egocentrism during the concrete operational stage characterizes a dynamic change in communication. Understanding the perspective of others means that, for the first time, the child appreciates that another person may not be interested in some topics of conversation and can identify what another person does or does not know. Persuasive communication marks another important development in linguistic ability; during earlier development, children tend to repeat crude requests, while concrete operational children form persuasive arguments that take into account the attitudes or desires of the person to whom the request is directed. During this stage, humour also develops, with children beginning to understand and tell rudimentary jokes.

Finally, the formal operations stage, in the context of communication, represents the final development of the social skills that must be allied to linguistic ability. An increasingly level of subtlety is evident in requests and persuasion, and sophistication in the use of humour (sarcasm, irony) and pragmatics appears. Children also acquire the ability to infer meaning of unfamiliar words by the context in which the word appears, without the need for explicit definition.

Therefore, the linguistic ability and communicative competence of children vary as a function of their level of cognitive development. As the capacity of abstraction develops, egocentrism declines and communicative social skills (pragmatics) develop, spoken language becomes more complex and goal-oriented, particularly in social situations.

Summary
Piaget’s model of cognitive development proposes that children pass through step-like stages of cognitive development that are qualitatively different and proceed in an invariant order. These stages are the sensorimotor, preoperational, concrete operational and formal operational. To understand the model fully, one should be aware of the characteristics that define each stage and the approximate ages at which children move between them.

Although no longer accepted universally, Piaget’s model remains influential. Key concepts include assimilation, accommodation, operations and egocentrism. These represent key mechanisms that allow the child to complete one stage of development and proceed on to the next.
As children progress through Piaget’s stages, they acquire abilities necessary for communication and the development of linguistic ability. For example, with the loss of egocentrism, children develop social communicative skills, such as understanding that other people may not be interested in certain topics of conversation.

**LANGUAGE DEVELOPMENT**

Language develops as children learn to associate symbols with objects or people in the real world. However, language is not merely a collection of words but a coherent system comprising complex rules that the child must master if he or she is to become proficient in its use. Language comprises distinct elements that are achieved competently during different stages of development. Consequently, ascertaining the age at which a child develops language is difficult to determine and depends largely on how ‘language’ is defined. The main aspects of language are summarized in Table 8.3.

Despite the complexities of language, and the considerable cognitive capacity required to learn language, linguistic skills develop quickly. At birth, infants show a preference for the human voice and develop basic phonology during their first year of life. Vocabulary acquisition, although initially slow, increases rapidly between the ages of 18 months and 7 years. First words are universally similar across cultures and languages (including sign language) and are words of particular interest to the child (‘doggie’, ‘mama’, ‘more’). Semantic understanding of newly learned words is initially minimal but becomes refined, with the child quickly learning multiple ways in which a single word can be used.

At around 2 years of age, early sentence structure appears. This is simplistic, comprising the combination of two or three words, and is often grammatically incorrect. However, by 3 years, children learn that simple grammatical manipulations such as changing word order (e.g., from ‘cuddle Mummy’ to ‘Mummy cuddle’) can alter the meaning of a sentence. In addition, children learn to alter sentence structure in order to ask questions and form negative sentences. They also learn to apply grammatical rules such as adding ‘-ed’ to words in order to denote past tense (e.g., ‘wash’ becomes ‘washed’). Once learned, these rules are often overapplied (e.g., ‘drink’ becomes ‘drinked’), suggesting that children do not learn grammatical rules solely through imitation. At approximately 4 years of age children will also start to use future tense, and by 5 years language begins to resemble that of adults.

Contrasting theories of language development exist. Nativists (e.g., Chomsky) argue that language development is predominantly biologically determined, while behaviourists (e.g., Skinner) propose a learning account of language acquisition. Although simple learning accounts are insufficient to account fully for the complexity of language development, it is unquestionable that the learning of language is influenced strongly by the interaction with others.

**Environmental influences**

Whether children are born with innate mental structures that are specific to acquiring and using language is the subject of debate, but, given that language is used to

---

**Table 8.3 Components of language and linguistic competence**

<table>
<thead>
<tr>
<th>Component</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Phonology</td>
<td>Concerns the way in which basic units of sound (phonemes) are used to form words. This develops continuously through early childhood, from crying and cooing in infancy, through simple articulation (consonant sounds) and babbling (combining consonant and vowel sounds), to production of phonologically simple first words (‘mama’). Phonological complexity increases with age, but full phonological competence takes time, and young children often have difficulty with the production of some sounds into school age despite good overall language competence.</td>
</tr>
<tr>
<td>Semantics</td>
<td>Concerns the meaning of words. Early semantic development involves direct association of sounds with objects or people. Children may not, however, understand the meaning of a word in the same way that an adult does. They are prone to overextensions (e.g., the word ‘cat’ used to describe many different animals) and underextensions (e.g., the word ‘cat’ used only to identify black cats). At later ages, more sophisticated semantic understanding develops involving abstract meanings.</td>
</tr>
<tr>
<td>Syntax</td>
<td>Concerns the structure and rules of language and how to combine words to form sentences, understanding grammatical structure of language including word order, use of pronouns, passive sentences, etc. Grammatical learning appears to develop spontaneously without explicit instruction. Furthermore, children show evidence of understanding grammatical rules when listening to the speech of others, even before they have begun to produce meaningful sentences themselves. This is a progressive skill that develops across the lifetime, with many adults never achieving a full understanding of syntax.</td>
</tr>
<tr>
<td>Pragmatics</td>
<td>Concerns the social use of language. Children learn to use language in new ways to communicate effectively with others, e.g., use of tone to convey mood. Furthermore, language can be adapted to suit a particular situation or person (e.g., depending on familiarity or competence of listener).</td>
</tr>
</tbody>
</table>
communicate, it follows that successful language development requires significant exposure to interactions with others. Adults help the child to develop speech by adapting their own speech patterns. Speech is slowed and pauses between words are emphasized, so that words are separated clearly into individual ‘chunks’ of sound. Important words are also stressed and non-verbal gestures (e.g. pointing) often accompany the words to highlight meaning.

Traditional learning theories of language development claim that language is learned through the processes of operant conditioning. Parents will reinforce behaviour by praising the child when he or she produces phonetically (or grammatically) correct speech, which, in turn, shapes behaviour. A more popular approach is that of Albert Bandura, who suggested that children learn through imitation. In the case of language, children learn by listening to the speech of others and attempting to reproduce it. Learning theory accounts of language have been criticized, but nevertheless they identify important ways in which language development can be influenced by the child’s environment.

The importance of environmental influence in language acquisition is also evident in cases of early isolation, where children have had little or no contact with humans during early development. Generally, these children develop elementary language skills, but complete communicative competence is rarely achieved. However, these cases involve a complete absence of social interaction, and the children often display a generally low level of cognitive competence. This has led some theorists to suggest that critical periods exist for language acquisition, referring to a set time period in which certain linguistic skills must be realized: if a child fails to learn these skills within this critical period, learning will never be achieved fully.

Communicative competence

The social conventions of language are known as pragmatics, described earlier. They develop throughout the lifespan and represent a shift from thinking about the meaning and grammatical structure of language to understanding how language is used to communicate. The art of being a good conversationalist requires the ability to engage the listener, to understand non-verbal gestures and to respond appropriately to feedback. By the age of 2 years, children begin to read facial expressions, offering more information, for example, if the listener looks confused. By 3–4 years, children develop a conversational structure more characteristic of adult speech by waiting their turn to speak, maintaining eye contact and adjusting speech to suit the listener. However, at this stage, children have difficulty keeping track of conversations involving two or more people and will often interrupt inappropriately. This may be judged as impolite to the casual observer, but this is a communicative skill that children need time to develop.

Communicative competence will naturally develop when important cognitive milestones are reached. The loss of egocentrism, for example, allows the child to understand that their listener may not know something they do or may have a different opinion to them. Children also learn communicative skills by the moral and cultural lessons of their parents. The use of ‘please’ and ‘thank you’, for example, is a first step towards effective cultural communication.

Although communicative competence, in the conventional sense, requires a substantial degree of linguistic skill and cognitive development, the distinction between language and communication is an important one. In truth, language itself is neither necessary nor sufficient for communication. Many species display communicative competence, but care should be taken when describing these as languages. Furthermore, non-verbal communication (body language) is a powerful means of communication. In sum, an individual may be highly skilled at constructing sentences but lack the social skills to be a good communicator, particularly with unfamiliar others. Although linguistic capability is good, communicative ability is impaired, illustrating the partial dissociation of the two concepts.

Summary

Language is a complex system that can be broken down into separate components – phonetics, semantics, syntax and pragmatics – which refer to the sounds, meanings, structure and social use of language. These components differ in complexity and the age at which they are understood and mastered. Ability in all of these components is required for the child to become a competent user of language.

It is important to distinguish between speaking and communicating. An individual may have relatively strong linguistic ability but be a poor communicator. Language is not necessary for communication, as seen in other animal species.

SOCIAL DEVELOPMENT

Development of social competence and relationships

Early attachment behaviours and styles correspond to the development of an internal model (or schema) of relationship formation. This provides the basis for the development of social competence, but this is by no means the endpoint. Children develop an understanding of their social world and the norms of social behaviour through interactions with peers, the nature of which will change as a function of age. In the first 6 months of life the child will display little interest in other infants, but after 6 months the child will begin to show specific emotional expressions and vocalizations in response to peers. Young children will initially engage in solitary play, but as time progresses the child will begin to play alongside other children, observing their
actions but with little or no direct interaction (parallel play). As motor and cognitive skills develop (including language), he or she will engage in different forms of play that further develop his or her social skills and relationships with other children. Social interactions become more complex and reciprocal in nature, and the child coordinates with their play partner, taking turns in various aspects of play. The first explicit demonstrations of prosocial behaviour are also observed, such as sharing and helping, and the child develops the ability to understand and consider the viewpoint of others. Therefore, the goal of play is not only to have fun; it also enables children to practise the art of social interaction and to develop early peer relationships. In short, play provides the building blocks for the development of social competence. In mid- to late childhood there is a dramatic increase in the amount of time spent with peers, and peer groups grow in terms of both number and diversity. This change is influenced largely by the child’s move into full-time schooling and participation in extracurricular group activities. In adolescence, the trend towards spending an increased amount of time with peers continues, and the child may perceive peer relationships as more influential and important than familial relationships.

Acceptance

There are several common determinants of acceptance within childhood peer groups. Children usually base their first impressions of others on surface characteristics such as names or physical appearance. Physically attractive children are typically accepted more readily by their peers and are more likely to be regarded as having more positive qualities. In some, but not all, cultures, children are most likely to interact and play with children of a similar age to themselves. More universally, children prefer same-sex playmates, particularly in mid- to late childhood, which may be a function of personality and interests, with boys more likely to engage in rough, physical games compared with girls. Generally, children prefer other children similar to themselves, and a child may not be accepted if they are seen to ‘stand out’ or be different from the norm.

Beyond these rather shallow determinants of acceptance, the personality of the child and their cognitive and social skills will also be influential in establishing whether they are viewed positively by their peers. Children who have a well-developed ability to cooperate and communicate will be particularly popular in favour of a child who demonstrates poor social skills.

Group formation

Children do not restrict their relationships to single-pair friendships. As their social skills develop, they forge multiple friendships that merge into friendship groups, within which a hierarchical structure forms. Members of the group assume different roles and form different relationships with other members, depending on their group status. Characteristics of group leaders change with age, with dominance being associated with ‘toughness’ in younger children, and with attractiveness, athletic ability or popularity in older children. Hierarchies in groups develop quickly and serve to facilitate interaction and reduce intra-group conflict.

In adolescence, the development of social groupings or cliques becomes common. Cliques are cohesive, usually same-sex groups that share common interests, attitudes or goals. They play an important part in an individual’s self-identity and psychological wellbeing. Although adolescents may continue to have strong attachment to their parents, they show extraordinarily high levels of conformity to the behaviours and attitudes of their peer group, which often exceeds familial influence. Cliques often combine to produce larger social groups or crowds, which may last a few years in adolescence, but generally disperse back to smaller groups, and then romantic relationships form as the individual advances into adulthood.

Cooperation

The development of social competence includes the emphasis placed on cooperation and competition. There appears to be a strong cultural influence here, with Western cultures being highly competitive and individualistic. In-group/out-group biases may be a result of the internalization of social norms that promote competition rather than cooperation. Nevertheless, cooperation is required in some cases and appears to be one of the major determinants of group behaviour. Cooperative behaviour appears in infants during the preoperational stage of cognitive development, when children will be seen to play together and achieve joint goals or take on individual roles in a broader game.

Friendships

The first experience of peer relationships occurs when children first engage in interactive play. Over repeated encounters with another child, a relationship will form (positive or negative), but the duration and frequency of contact at this stage in life will be dictated predominantly by the parent, and these early relationships do not equate to true friendships. Mutual liking is important for a friendship but not sufficient for its development or maintenance. A friendship additionally requires a level of commitment between individuals, which will not be achievable until a certain degree of cognitive development has been attained.

The function of friendships and conceptions of what constitutes a friendship change across childhood. For younger children friends are predominantly companions and playmates, but in mid-childhood friends begin to take on a supportive role and are more likely to be chosen, based on their personal characteristics. Friendships become more stable and long-lasting and are likely to be based on mutual
liking. Thus, as children age, more intimate relationships are formed, and these friendships become important for emotional growth and wellbeing. There are also interesting differences in the quality of friendships between male and female children. Boys are more likely than girls to gather in groups, and these relationships are less intimate and more competitive. In contrast, friendships between young girls involve more agreement and self-disclosure.

Isolation and rejection

Children who are not readily accepted by their peer groups tend to report loneliness, social exclusion and low self-esteem. Rejected children also demonstrate poorer academic success and are more likely to play truant or drop out of school. However, recent evidence suggests that if a rejected child can secure one high-quality friendship, then the detrimental effects of poor social acceptance are reduced significantly. There is a well-supported association with rejection in childhood and negative outcome in later life. However, the direction of causality is ambiguous—it is unclear whether the rejection in childhood results in subsequent detriment or whether a negative disposition in the individual drives early rejection. Low self-esteem appears to be related closely to isolation and rejection. Children with low self-esteem often display reduced social skills, awkwardness when interacting with others, and general unwillingness to initiate friendships or join in group activities.

It may be important to distinguish between rejected children (who are explicitly ignored or disliked by their peers) and neglected children (who are reasonably well liked but lack individual friendships). Although less well studied, neglected children appear more likely than rejected children to establish friendships over time but will be more at risk of negative outcomes such as loneliness or depression than accepted children.

Popularity

In any group of children, there will be a few who stand out as being particularly well liked and popular among their peers, while others will find themselves on the periphery of the group, with little influence over other members of the group. Although the characteristics that define popularity may differ with age, in general, popular children are those who are physically attractive, friendly, sociable, intelligent and athletic (particularly in boys). For many of these positive traits, however, it is difficult to determine the direction of causation; for example, does extroversion lead to increased popularity, or does popularity result in extroversion?

There is also a strong relationship between popularity and leadership; indeed, popular children tend to be the informal leaders of group activities. One factor that is apparent in leaders rather than those who are simply popular is aggression, although this is highly controlled aggression, used primarily to reinforce the leader’s position when required. Uncontrolled aggression, in contrast, is associated with unpopularity.

Summary

From 6 months, the infant will show interest in other babies and children. As they grow, children begin to play together, and the level of direct interaction that occurs during play increases with age. These interactions enhance social and communicative skills that become important for the formation and maintenance of friendships.

The nature and functions of friendships alter with age. In early to mid-childhood, friends serve as sources of fun (i.e. playmates); however, later friendships become a source of emotional support and acceptance, with greater levels of commitment and self-disclosure (particularly among females). Friendships are extremely important for emotional wellbeing and social fulfilment.

Certain traits are associated with popularity (e.g. physical attractiveness, extroversion, intelligence, sociability), while others are associated with rejection (e.g. social incompetence, excessive aggression). It is often difficult to ascertain the direction of causation—that is, does extroversion create popularity or does popularity create extroversion? Rejected children are more likely to have problems in school and are more at risk of psychiatric disturbance in later life.

MORAL DEVELOPMENT

Kohlberg’s theory

Lawrence Kohlberg emphasized the need to understand how an individual perceives a morally challenging situation and to ascertain the moral reasoning underlying a response. As such, he rejected response-oriented approaches that focused on overt behavioural responding. Instead, he conducted a series of interviews in which subjects were presented with moral dilemmas and were asked to justify what they believed to be the ‘right’ course of action. As a result of this work, Kohlberg proposed a stage theory of moral development comprising three levels of moral reasoning, which each comprised two qualitatively distinct stages:

- Level 1: pre-conventional moral reasoning
  - Stage 1: obedience and avoidance of punishment
  - Stage 2: acquisition of rewards (for self or others)

- Level 2: conventional moral reasoning
  - Stage 3: acquisition of social reward (approval)/avoidance of disapproval
  - Stage 4: maintaining social rules, laws, etc.

- Level 3: post-conventional moral reasoning
  - Stage 5: defined by the ‘public good’, a social contract
  - Stage 6: conscience, individual moral code, abstract personal ethics.
Although ages were not associated explicitly with Kohlberg’s stages of moral reasoning, varying degrees of cognitive competence are necessary to achieve transition through the stages. The first two stages of pre-conventional morality require representational ability and therefore are unlikely to emerge until the child reaches Piaget’s preoperational stage of cognitive development. During early to mid-childhood, moral judgements are made predominantly in reference to punishment and rewards. In this context, the notion of physical punishment will gradually make way for social punishment as social skills develop. However, the concept of the ‘public good’ requires higher-level operational thought and therefore will generally not be realized until adolescence or adulthood. However, Kohlberg himself noted that the highest level of moral reasoning will be achieved by very few people in their lifetime and would be evident only in those regarded as paradigms of morality.

Unfortunately, the correlation between moral development as assessed by Kohlberg’s model and actual behavior is quite weak. This is probably due to the emphasis that the model places on abstract reasoning and the description of moral behavior, as opposed to its actual performance. In addition, the reliability of the interview process, on which the model was based, has been questioned, due to a lack of standardization in both the administration and the scoring of the interview. Moreover, the interviews were conducted only with male subjects, and the imaginary moral dilemmas presented during the interviews were culturally oriented to North America, limiting the generalizability of the findings. Progression through the levels of morality with age may simply result from increased awareness of and ability to describe moral rules, without necessarily being related to any desire to follow these.

Social perspective-taking

The ability to form a detached opinion from another person’s perspective, or from a general ‘social’ perspective, represents a significant advance in the cognitive and moral development of the individual. This requires a strong sense of personal identity, an understanding of the independence of the thoughts and actions of others, and an understanding that morality is not defined simply by one’s own desires and corresponding rewards and punishments. Consequently, it is unsurprising that Kohlberg’s level at which an understanding of social norms for moral behaviour becomes apparent corresponds (roughly) with the development of concrete operational thought and a corresponding decline in egocentrism.

The ability to reason from a perspective other than one’s own, however, is distinct from the desire to act in a moral way. Social perspective-taking is a largely cognitive ability that may be applied to moral dilemmas, so that the stages of Kohlberg’s theory may represent only an increasing ability to reason from perspectives other than one’s own (rather than any actual development of personal morality).

Summary

Kohlberg’s stage theory of moral development comprises three distinct levels, each comprising two stages. It is not as rigid as some stage theories (e.g. Piaget’s cognitive model), and not all individuals accomplish all of the developmental stages fully.

There is some correspondence between moral development and cognitive development, with some level of cognitive capacity being required before specific aspects of morality can be achieved.

DEVELOPMENT OF FEARS

Childhood and adolescence

From around 6 months, an infant will display fear or anxiety in some situations, for example during maternal separation or in the presence of strangers. However, with a few exceptions (e.g. darkness, heights), younger infants are characterized by a general lack of fear, leading to the assumption that the majority of fear responses are learned, particularly in younger children.

There is, however, individual variability in physiological and psychological reactions to a potentially fearful event. For example, some introverted children may display relatively high levels of stress in response to mild environmental stressors. That is not to say that the fear response is consistent across all situations or inevitable in all individuals. For example, fear in response to the presence of a stranger is reduced markedly if the meeting occurs in the infant’s home.

As children grow, their understanding of reality changes, so that fears relating to imaginary figures or unlikely threats to personal safety diminish. Instead, as the child enters late childhood and adolescence, new fears develop, often relating to social concerns, and that begin to resemble the profile of adulthood fears.

Aetiological and maintenance mechanisms

Very young infants show relatively low levels of fear, so that learning models of fear development have proved popular. In particular, associative models of learning have been used to describe how fears are learned and maintained, and have suggested therapeutic interventions that have been successful if also controversial.

Fears are suggested to be the result of the association of neutral objects with fear-evoking objects. For example, when a neutral object is paired with an aversive or frightening stimulus (e.g. shock), that object will acquire the ability to elicit fear through the processes of classical conditioning. Individuals appear to develop fears of certain objects more readily than others (e.g. snakes), and it is suggested that there may be a genetic component to this readiness.
Although valuable in understanding the development and maintenance of phobias, this model is also appropriate in understanding normal fear. In particular, infants appear to learn fearful behaviour from the observation of attachment figures, in particular the mother. This may be described as a form of vicarious classical conditioning or as social learning theory. Note that the two models are not exclusive.

Although classical conditioning models are particularly relevant to the understanding of development of fears, operant conditioning models provide some insight into how these fears (or fear responses) are maintained. Operant conditioning concerns the association of behaviour with either positive or negative reinforcement. In the context of fear, avoidance of fear (i.e. the behavioural response) will be reinforced by reduction in the feelings of fear and anxiety. Thus, once a fear has been established, the fear response serves to maintain the fear, which, in turn, has implications of the treatment of fears.

All learning processes are more powerful in childhood, and this corresponds with the fact that most fears develop early in life and are sustained through it. Adults rarely develop new fears, except in extreme circumstances (e.g. post-traumatic stress disorder).

Summary

Certain fears seem to be innate (e.g. the dark, heights), and there may be an evolutionary component to this. However, the relative lack of fear in infants suggests a strong learning component in the development of fears. The most common fears in babies are separation anxiety and fear of strangers, although the expression of these fears may be affected by factors such as attachment style, temperament and context.

Models of learning, particularly associative learning, have been used to describe how fears develop and are maintained. All also have implications for the treatment of fears.

SEXUAL DEVELOPMENT

Physical sexual development takes place primarily over a 3- to 5-year period, characterized by rapid physical growth and more gradual development of sexual characteristics (e.g. facial hair and deeper voice in males). There is substantial variation in the time of onset of puberty and the rate of development, although in the majority of cases this is complete by the age of 16–17 years.

Physical development is accompanied by increases in emotionality and, importantly, changes in self-identity, self-esteem and social relationships. This is related in part to the hormonal changes associated with sexual development, although this relationship is weak. In particular, sexual development significantly earlier or later than one’s peers can be distressing. Late-maturing boys show greatest distress compared with early-maturing boys, while the reverse pattern is true of girls. Behavioural and emotional problems that exist during puberty and adolescence usually disappear with age.

Sexual identity

The development of personal identity is the central feature of adolescence. A significant component, most closely related to sexual development, is the development of sexual identity. Specifically, sexual identity refers to the elements of self-identity and self-perception that pertain to sexual preference. It is more general than simply the delineation of sexual preference, in that it also encompasses the extent to and way in which an individual’s sexuality is expressed and portrayed to others. Certain behavioural and psychological characteristics may be described as masculine or feminine, with any individual (regardless of sex) displaying both masculine and feminine features. Several theories have suggested ways in which sexual identity develops.

Psychoanalytical theories argue that the sex drive is initially directed towards the father (in females) and blocked by the mother in order to achieve the father (or substitute), leading to appropriate gender roles. The basic mechanism of Freudian theory is identification; incestuous love or sex drive is repressed, resulting in the Oedipus or Electra complex, which culminates around the age of 5 years, with identification leading to the adoption of a gender role.

Social learning theory argues that cultural and societal forces model the behaviour of the child from birth, as well as the behaviour of others towards the child (e.g. girls play with dolls and are dressed in pink), leading to the development of sexual and gender identity. Behaviour, and therefore self-identity, is socially learned, and learning proceeds through reward, punishment and observation, while physical development and sexual characteristics are of minor importance. The child gradually learns appropriate social behaviour, which is internalized, and part of this includes the internalization of appropriate gender behaviour.

Cognitive developmental theories argue that, as the cognitive development of the child progresses, there is an increasing awareness of the self, including important elements of the self-concept such as ‘she’ or ‘he’, which is gradually incorporated into the child’s understanding. Sex and gender concepts are poorly understood in young children, and before the age of about 5 years sex is identified by clothing, hair length and other external characteristics; changing a simple characteristic is enough (e.g. a zebra without stripes becomes ‘a horse’). Around 5 years of age, clearer understanding of concepts develops, and this results in awareness of own sex and corresponding sexual identity and role.

These alternative explanations are not exclusive. Furthermore, similar processes (especially social learning) may account for the development of other elements of
Sexual preference

Sexual preference is the preferred sex of one’s partner and is a behavioural index defined by the usual sex of the partner. It is a relatively recent term, used to distinguish between subjective sexuality, which may not be polarized as either heterosexual or homosexual, and actual sexual behaviour, which usually is. Sexual orientation comprises several components, including attraction, behaviour, affection, and so on. As a result, the classification of individuals as heterosexual, homosexual or bisexual is simplistic. There is substantial current interest in the extent to which sexual orientation and sexual preference are innate or learned.

Evidence to date is equivocal – such research has been more successful at disconfirming hypotheses, so that the following conclusions have been supported to some degree (disconfirming some common hypotheses and popular beliefs). Sexual preference appears to be established relatively early, usually before puberty and adolescence, even if the individual is uncomfortable with this identity, and precedes sexual activity. The nature of the first sexual encounter appears unimportant, with homosexuals being as likely as heterosexuals to have had a first sexual encounter with a partner of the opposite sex. Homosexuals appear to have participated in less sexually stereotyped behaviour as children, so that a lack of conformity appears to be associated with subsequent homosexuality. Parental relationships appear to be of little importance, undermining psychoanalytical theories of the development of sexual preference.

There may be a genetic component to sexuality; for example, increasing genetic similarity is related to an increasing correspondence of sexual behaviour. However, as in the case of intelligence or personality, care must be taken in interpreting these results, given the complex nature of genotype–phenotype correlations. It is possible that certain genetically determined characteristics result in certain behaviour being more or less likely, which, in specific societies, is likely to result in a certain self-identity being developed (i.e. more or less stereotypically masculine), which is likely to be reinforced externally.

Summary

Physical and psychological sexual development are distinct. While the former, to a large extent, drives the latter, it is the latter where there is greater scope for individual variation, and a description of the causal factors is more difficult. Psychological sexual development corresponds broadly to the development of a distinct sexual identity.

Three broad theoretical positions exist for understanding the development of sexual identity and preference: psychoanalytical theories emphasize the role of basic drives and desires; social learning theories focus on the role of social and cultural norms; and cognitive developmental theories suggest that cognitive development results in an increasing awareness of the self, including sexual identity.

The development of sexual identity includes the development of sexual preferences. Preference appears to be established in early life, with parental influence being minimal. Such research is clearly controversial, and care must be taken in interpreting results.

ADOLESCENCE

Pubertal changes

Pubertal changes are those associated with development of the sex organs such that these enable reproduction. These changes are more obvious in females at menarche, while in males the changes are more gradual. Certain physical changes are apparent, in particular in males, such as the development of facial hair and deepening of the voice. The point at which puberty ends is difficult to define, and there is no clear value in attempting to set a period for this, in particular given the wide variation across individuals in onset and rate of development. Primary sexual changes (of the sex organs) are distinct from secondary sexual changes (of other physical characteristics, e.g. facial hair).

It is secondary sexual changes that are most noticeable: males grow significantly in size and body proportions also change, while in females breasts develop. Cognitive differences between males and females also emerge at puberty, with males being more likely to take spatial and mathematical subjects at school and females being more likely to take verbal and literary subjects. Evidence for these differences is somewhat controversial, and the effect may be determined largely by social pressures. Nevertheless, it has been suggested that there are sex-related differences in brain organization.

These physical changes are accompanied by important developments in self-image. For example, drawings of the self change noticeably over the first menstrual period in females, even though this is a short period of time, incorporating far more stereotypically feminine characteristics (not necessarily reflecting actual physical changes).

Task mastery

Physical and cognitive changes associated with puberty and adolescence allow for the development of new abilities. This period is also associated with a high degree of social development, in particular the development of sexual relationships. Social development is also accelerated as a result of the stronger peer relationships that develop, providing a set of group and attitude norms that become internalized. Self-esteem and personal achievements are also highly correlated. This physical, cognitive and social development results in the achievement of autonomy, including
be behavioural autonomy (the ability to select activities and friends independently), emotional autonomy (increasing independence from family members) and value autonomy (value and beliefs determined more by peers than by family).

Adolescence therefore requires mastery of two developmental tasks: development and acceptance of adult sexuality, and development and acceptance of social identity (and autonomy).

**Conflict**

It is a common stereotype that adolescence and puberty are associated with conflict with authority figures, in particular parents and teachers. Although there is some support for this, it appears that such behaviour is also culturally determined. For example, in Western cultures childhood is regarded as unique and the transition to adulthood an important one, while at the same time parental control is high. This results in the characteristic desire of adolescent children to assert their individuality and achieve independence. In contrast, there is evidence that the distinction between childhood and adulthood is less clear in some cultures (e.g. in east Asian), and the degree of parental control sought is less, and that this corresponds to a relatively conflict-free adolescence.

Conflict appears to be not only largely generated by social norms (rather than, say, excessive emotionality related to hormonal changes) but also a function of changes in self-image and self-esteem. Development into an adult is associated with increased self-esteem and confidence and a greater ability to assert oneself. Finally, the stereotype of adolescent conflict is too general, and a large proportion of individuals pass through adolescence without any major conflict or turmoil.

**Affective stability**

The hormonal and other physiological changes associated with adolescence may result in some degree of emotional instability. Although there is some evidence that emotionality is higher during adolescence, this effect is weak. Moreover, the effect is likely to be the result of social conflict as well as physiological factors. The notion of adolescent affective lability has existed in literature at least as far back as the eighteenth century, suggesting a role for social construction. Although there is certainly a degree of conflict associated with adolescence, this is likely to be primarily the result of changing self-image and self-esteem rather than affective instability. Moreover, those adolescents who do experience a high degree of emotional instability are likely to continue to display this in adulthood.

**Normal and abnormal development**

Adolescence should be regarded as a developmental stage characterized by significant physical and psychosocial changes, and these changes require a degree of adaptation on the part of the adolescent. The majority of these changes, while initiated by physical changes and the psychological and social consequences of these, are related to self-image and self-expression. Normal development will be associated with changes in a variety of areas, including values and beliefs, social behaviour, sexual behaviour, cognitive abilities, physical abilities, self-esteem, self-image and self-concept.

Although there is evidence that some adolescents do experience distress and turmoil, this appears to be abnormal and is associated with similar affective instability in later life. Adequate adjustment to the demands of adolescence is a very strong predictor of successful adaptation in adulthood. Adolescent conduct and behavioural problems are associated strongly with criminal behaviour, both in adolescence and later in adulthood. This is in part influenced culturally: the incidence of adolescent criminality is far higher in cultures where pubertal and adolescent turmoil is regarded as normal than in cultures where the emphasis on adolescence is far less.

**Summary**

Physical change in adolescence is marked, and there are correspondingly marked psychological changes, in particular in social and sexual identity. There is an important distinction between primary and secondary sexual changes.

Physical, cognitive and social development results in the accomplishment of specific tasks (task mastery). In particular, the adolescent must develop sexually and socially and, most importantly, be comfortable with and accept these changes.

Changes in self-image, social identity and so on may result in a degree of conflict between the adolescent and, usually, authority figures. This, however, is less common than popularly believed. Although some have suggested that emotionality is elevated during adolescence as a result of hormonal fluctuations, the evidence for this is weak.

Abnormal adolescent development is usually characterized by an inability to accept sexual and social changes associated with this period or by development in this area being impaired in some way.

**ADAPTATIONS IN ADULT LIFE**

Adulthood is not the endpoint of development, and adaptation proceeds throughout life. Certain specific adaptations are common to most individuals, each representing a significant change in lifestyle and an attendant change in self-identity and responsibility. These may include the decision to choose a partner for life, whether or not to have children, and choosing an occupation.

**Pairing**

It is likely that the first significant change in the lifestyle of an adult will be the formation of a romantic relationship
that is intended to be permanent. Although an increasing number of couples do not marry, most still do. Regardless of the exact nature of the relationship with the partner, certain features are common. Several factors appear to be important in the development of romantic relationships, including attractiveness, common attitudes and emotional stability.

There is an association between marriage and health, both physical and mental. A happy and stable relationship is a protective factor, while unhappy relationships have been associated with poorer immune function, depression and other negative health outcomes.

**Parenting**

The transition to parenthood affects the behaviour of both the mother and the father and may change the quality of the marital relationship. Mothers tend to become more sexually stereotype, engaging in more feminine behaviours and fewer masculine behaviours. In contrast, fathers become less sexually stereotype, showing a relative increase in feminine behaviour. Several factors may influence the quality of the marital relationship, including relative reduction in income, potential absolute reduction in income, sleep disturbance and reduction in privacy.

Although these factors suggest that the transition to parenthood should have negative consequences for the marriage, there is also contrasting evidence that intimacy and affection increase between the marital partners, so that the stress of parenthood is reduced. In general, parenthood is likely to be more stressful if the parents are young, the birth takes place before marriage, and the relationship has existed for a long period before the birth (possibly due to greater lifestyle change). The temperament of the child will also have an impact on how stressful the transition to parenthood is, with difficult children representing a greater challenge.

**Illness**

Illness may be regarded as a relatively common but nevertheless serious source of stress in individuals. Beyond the physical effects of the illness, the individual will be required to appraise their condition and, in adults, typically include both current concerns (e.g. loss of income) and concerns about the future.

The nature of illness that individuals have to cope with and adapt to changes with age. With increasing age, illness becomes more common and chronic illness more likely. Illnesses suffered also become more serious and debilitating (e.g. stroke). In the case of chronic illness, individuals may pass through several stages of adjustment: shock (bewilderment and a sense of detachment), encounter (grief, despair and depression), retreat (denial, either of the illness or its implications) and intrusion (the individual comes to terms with the illness and adapts). This model has been criticized for being excessively rigid and prescriptive, but there is some evidence that at least a large proportion of individuals react to the diagnosis of chronic illness in roughly the way described above, although not necessarily as a linear progression through these stages.

**Bereavement and loss**

Bereaved individuals are likely to see their doctor more often, become preoccupied with the object or individual that has been lost, show loss of appetite and general apathy, and exhibit signs of denial. These responses to bereavement are common and should be regarded as normal, provided the individual eventually adjusts to the loss. Mortality also increases in the 6 months following bereavement, in particular among married men who have lost their wife. Several factors have been associated with poor adjustment, including lower socioeconomic status, several concurrent stressful life events, self-blame, severe depression, and lack of forewarning and preparation. Although in some cases adjustment to the loss may be difficult and lengthy, the majority of individuals eventually do adapt effectively.

Although the term ‘bereavement’ is generally used to refer to the loss of a relative, close friend or loved one, it may also be used metaphorically to refer to other forms of loss, such as limb amputation or loss of a job. The common feature of these cases is that a considerable degree of adjustment is required after the loss, although there will be variation in severity and reaction across individuals.

**Summary**

Adaptations in adult life are characterized by the requirement to interact in specific socially defined ways with others. One example is the search for a partner and subsequent parenting. It is common, although not universal, to follow a fairly clearly defined path through life, punctuated by periods of adaptation (e.g. marriage, parenthood, bereavement, death).

No definitive list of the adaptations required in adulthood exists, but in general these include major events that require a significant change in lifestyle. In such cases there will be a role played by self-image, self-esteem and so on, and also by others (e.g. social support).

**PREGNANCY AND CHILDBIRTH**

The 9 months of pregnancy represent a gradual build-up to the stresses of childbirth and parenthood, while also representing a stressful episode itself.

**Physiological stresses**

The physical changes associated with pregnancy are (perhaps paradoxically) not regarded as particularly feminine, in particular by women themselves. The increase in weight,
and the hormonal and dietary changes that result from pregnancy, represent a significant source of physiological stress, with consequent problems such as low back pain and morning sickness. The physiological consequences also contribute to a great extent to the feeling of unattractiveness common in many pregnant women.

At the time of birth, the most important consideration of the mother is the pain associated with childbirth. Relaxation and focused-attention techniques do allow significantly improved tolerance of pain, while other methods of childbirth have broader objectives such as the maintenance of contact between the mother and child.

**Psychological stresses**

The onset of pregnancy will have consequences not only for the mother but also for the father. For example, the preoccupation of the mother with the fetus may result in feelings of alienation and separation in the father. Although there is no reason why sexual contact should be reduced during pregnancy, it commonly is. There is some evidence that sexual behaviour during pregnancy is related to the ease of labour. Several stereotypes and attitudes exist towards pregnancy: pregnancy as illness (the substantial medical intervention in births may result in a conception that the birth is a medical rather than a natural process), pregnancy as crisis (the professional consequences of pregnancy for employed women may be substantial, in particular if the pregnancy is unplanned or unexpected), and pregnancy as a task (there is substantial pressure, in some cases, from other family members for a couple to begin a family, which may not correspond to the couple’s wishes).

These stereotypes and attitudes tend to be strongest during the first pregnancy; contact with the realities of pregnancy and childbirth tend to modify the attitudes of mothers having a second child. However, this may also have negative consequences if the events during pregnancy are particular distressing, such as prolonged labour, so that the mother may expect a difficult labour again, even if this is relatively unlikely.

Anxiety is a common feature of pregnant women and may be focused on several potential risks or outcomes, such as possible handicap of the child, preoccupation with cleanliness, one’s own abilities as a mother, the financial consequences of a child, and the risk of miscarriage. Although some degree of anxiety is perhaps to be expected, there is evidence that excessive stress during pregnancy may influence fetal development in several ways and has also been shown to be related to the risk of miscarriage and low birth weight. The incidence of miscarriage is significant and results in very strong grief reactions from both parents, especially the mother, being associated with subsequent depression for several weeks or months following the event.

**Summary**

The physiological and psychological stresses of pregnancy and childbirth are distinct, although they interact. Postnatal depression, for example, is likely to include a strong physiological (i.e. hormonal) component.

Specific social stereotypes contribute to the stress of pregnancy and childbirth (e.g. the pathologization of pregnancy).

A degree of anxiety is normal in pregnant women (and in their partner), generated by a variety of potential negative outcomes or consequences (e.g. financial burden, doubt in one’s ability to act as a good parent).

**DEVELOPMENT OF PERSONAL IDENTITY**

Erik Erikson suggests a stage model of psychosocial and personal development, with each stage being characterized by a particular crisis that the individual must overcome in order to develop (Table 8.4).

Although Erikson specifies favourable outcomes, the result of each psychosocial crisis may not in fact be favourable (e.g. anxiety, insecurity, loneliness). The ability to face each crisis depends to a large extent on the outcome...
of the previous crisis, so that a child who develops secure attachments and a strong sense of self-control in early life will be well prepared to face future challenges and crises.

**Various social identities**

Social identities derive largely from the membership of groups, although these groups need not be explicit (e.g. football team) and may be more implicit (e.g. recognition of occupying a certain socioeconomic position). Individuals will possess a number of social identities that may overlap and, in some cases, conflict.

Group membership appears to be a fundamental need. Individuals will very rapidly regard themselves as belonging to a group, even on the basis of random and meaningless criteria, and display a preference for other members of the group. Individual identity (self-concept) depends to a large extent on social identities, intergroup comparisons contribute to self-esteem, and the need for a positive self-concept results in intergroup prejudice and bias.

The question ‘Who am I?’, asked of subjects and repeated several times, results in an interesting and insightful hierarchy of self-descriptions, many of which are related to social identities and group membership. This is influenced by cultural factors also, so that in Western cultures there is a bias towards individual characteristics while in Eastern cultures there is more emphasis on group membership.

Social identities need not necessarily be related to group membership (although the majority are) and may instead relate to perceived relationships and interactions with other (e.g. a strong component of self-concept may be ‘father’).

**Adaptations in adult life**

Typical adaptations in adult life include the development of permanent romantic relationships, the birth of the first child, the onset of serious illness and bereavement. Nevertheless, the development of the individual, in particular social support, self-esteem and self-efficacy beliefs, will influence the degree to which the individual adapts to various life crises. Therefore, factors that influence the extent to which adaptations in adult life will be successful include self-esteem, self-efficacy, locus of control, attributional style and social support.

Erikson’s model of the development of personal identity makes it clear that developmental experiences, in particular those in early and middle childhood, will influence these factors and directly influence coping responses to stressful events. An individual with a strong, coherent and positive sense of self will be better prepared to cope with major life events requiring adaptation.

The ‘mid-life crisis’ represents the generativity versus stagnation crisis of middle adulthood suggested by Erikson. The proposal is that adults at this stage question their achievements to date and what they will achieve in the remainder of their life. Priorities tend to be restructured and greater emphasis is placed on the development of children rather than the self. Nevertheless, the term ‘crisis’ is debatable, as the evidence that individuals in middle adulthood are particularly distressed is weak. As such, it is perhaps more valuable to examine specific crises (i.e., adaptations) separately, with middle adulthood simply representing a period when several of these are likely to occur close together (e.g. illness, children leaving home, etc.).

**Summary**

The basic structure of Erikson’s model of personal development is important, in particular the crises that characterize different stages of the model. For each of these there is a generally favourable (or unfavourable) outcome. These outcomes are appropriate at different stages in the lifespan, and the model is therefore distinct in that it covers the entire lifespan, from birth to death. Concern for the future and society in general, for example, is appropriate by this model in middle age but inappropriate in adolescence, where personal development and self-identity are paramount.

The stages of Erikson’s model correspond to an extent to the different social roles adopted by individuals over the lifespan. Parenthood in adult life corresponds to the development, in Erikson’s model, of a commitment to others.

**AGEING**

**Individual functioning and ageing**

The physical, physiological and cognitive changes related to ageing result in corresponding changes in functioning. For example, speed of performance generally becomes slower, although this is not uniform across tasks, and corresponds to a decline of less than 10 per cent between 20 years and 70 years of age for aimed movement, a roughly 25 per cent decline for simple sensorimotor decision tasks, and approximately a 50 per cent decline for complex sensorimotor decision tasks. Sensory function, in particular vision and hearing, also declines. The most significant changes begin after 40 years of age, when decline in function becomes more rapid.

**Memory and learning**

Learning of new skills declines, while longer explicit recall also declines with age. Some memory tasks show improvement (possibly due to greater use of memory aids, such as diaries and notes).

**Personality**

Erikson regards development through the lifespan as continual (see above), and norms for psychometric personality
questionnaires (e.g. measures of extraversion and neuroticism) change with age. Individuals generally become less extroverted and less neurotic, and emotionality is often more stable and easily controlled in older adults.

**Sexuality**

The nature of sexual function changes greatly, although pleasure derived from intercourse commonly remains. It has been argued that sexuality in the elderly is often not socially accepted, and there is a common misconception that elderly people cannot (or should not) remain sexually active.

**Social functioning and ageing**

Social contact generally reduces with age. Although this is in part due to a reduction in the number of friends, the changes in individual functioning associated with age also lead to a reluctance or inability to maintain social contact. Social situations may be frightening if hearing or vision is impaired (e.g. on busy streets), for example, while difficulties in performing certain tasks may reduce social contact (e.g. walking to a bus stop). In particular, society may not allow for the differences in individual functioning found in elderly people (objects are designed by young and healthy people, usually without consideration for elderly people).

Nevertheless, there are certain gains associated with age, such as reduced emotional lability, which may allow certain losses to be compensated for. Selective optimization with compensation refers to the ability of individuals to select appropriate and realistic goals, focus on goals of primary importance, and use alternative strategies to compensate for declining abilities (e.g. memory aids). This conceptualization is universal, although clearly the pattern of behaviour and compensation will vary widely across individuals.

**Summary**

The normal ageing process has both physical and psychological consequences. The physical consequences are relatively straightforward, including a gradual decline in sensorimotor ability, memory and so on. Apparent improvements in certain types of memory with age may be ascribed to increasing use of memory aids.

Psychological consequences of ageing include changes in the sexual behaviour of individuals. This is due primarily to social norms rather than to any decline in the desire for or pleasure derived from intercourse. Social contact also changes, as a consequence of a declining social network and an inability to perform certain social tasks as a result of physical changes.

**KEY POINTS**

- Development is the result of the interaction between innate behaviours and the environment and may entail progression through a series of stages. It is distinct from maturation, where less emphasis is placed on this interaction.
- Key models of the development of cognitive (e.g. Piaget), social (e.g. attachment theory) and moral (e.g. Kohlberg) abilities exist, which are separate but may be mutually compatible (e.g. a certain degree of development may be necessary to understand certain moral concepts).
- Attachment theory describes the need for proximity and nurturance as separate from the need for sustenance, and suggests distinct types of attachment behaviour (secure, insecure-avoidant, insecure-ambivalent), which may relate to behaviour in adult life.
- The development of personal identity accelerates in adolescence, as personal autonomy increases and puberty brings results in important physical and psychological changes. This results in changes in self-image and self-identity.
- Although most developmental theories focus on infancy, childhood and adolescence, there are developmental changes throughout the lifespan, and these are sometimes characterized by challenges that need to be met (c.f. Erikson).
- Other developmental models exist for linguistic and sexual development and for the development of fears. Many of these share core features, such as the role of cognitive development, learning processes and social learning theory.
IS PSYCHOLOGY A SCIENCE?

Throughout psychology’s history as a separate discipline and field of study, psychologists, as well as philosophers of science and other interested parties, have continued to ask this question. One feature of psychology that makes it special is that its scientific status is part of its subject matter: it’s as though we need to know what kind of discipline it is before we can evaluate and apply the research findings that are published under the name of psychology.

Behind the question ‘Is psychology a science?’ is the fundamental assumption of scientism:...

... the borrowing of methods and a characteristic vocabulary from the natural sciences in order to discover causal mechanisms that explain psychological phenomena.¹

For much of its history, psychology has taken physics and chemistry as the ‘model’ it aspired to; this perhaps suggests that we might rephrase the original question and ask: ‘How successful is psychology in identifying causal mechanisms that explain psychological phenomena?’ This, in turn, begs all sorts of questions about the aims or goals of psychology, how psychology has changed during its near-130-year history, and the appropriateness and viability of studying human beings using the methods of natural science.

The scope of this chapter doesn’t allow for discussion of these issues, but for a detailed account, see Gross²,³ and Gross et al.⁴

A BRIEF HISTORY

The word ‘psychology’ is derived from the Greek psyche (= mind, soul, spirit) and logos (= knowledge, discourse, study). Literally, then, psychology is the ‘study of the mind’:

The emergence of psychology as a separate discipline is generally dated at 1879, when Wilhelm Wundt, a German physiologist, opened the first psychology laboratory at the University of Leipzig. Wundt and his co-workers were attempting to investigate ‘the mind’ through introspection (observing and analysing the structure of their own conscious mental processes). The aim of introspection was to analyse conscious thought into its basic elements and perception into its constituent sensations, much as chemists analyse compounds into elements. This attempt to identify the structure of conscious thought is called structuralism.

Wundt and his fellow researchers recorded and measured the results of their introspections under controlled conditions, using the same physical surroundings, the same stimulus (such as a clicking metronome), the same verbal instructions to each participant, and so on. This emphasis on measurement and control marked the separation of the ‘new psychology’ from its parent discipline of philosophy.

Philosophers had discussed ‘the mind’ for thousands of years. For the first time, scientists applied some of the basic methods of scientific investigation to the study of mental processes. This was reflected in James’s definition of psychology as...

... the Science of Mental Life, both of its phenomena and of their conditions... The Phenomena are such things as we call feelings, desires, cognitions, reasoning, decisions and the like.⁵

However, by the early twentieth century, the validity and usefulness of introspection were being seriously questioned, particularly by the American psychologist John B Watson. Watson believed that the results of introspection could never be proved or disproved, since, if one person’s introspection produced different results from another’s, then how could we ever decide which was correct? Objectively, of course, we cannot, since it is impossible to ‘get behind’ an introspective report to check its accuracy. Introspection is subjective, and only the individual can observe his or her own mental processes.

Consequently, Watson proposed that psychologists should confine themselves to studying behaviour, since only this is measurable and observable by more than one person.⁶ Watson’s form of psychology was known as behaviourism. It largely replaced introspectionism and advocated that people should be regarded as complex animals to be studied using the same scientific methods as those used in
chemistry and physics. For Watson, the only way psychology could make any claim to being scientific was to emulate the natural sciences and adopt its own objective methods (i.e. scientism). He defined psychology as:

\[ \text{... that division of Natural Science which takes human behaviour – the doings and sayings, both learned and unlearned – as its subject matter.}\]

The study of inaccessible, private, mental processes was to have no place in a truly scientific psychology.

Especially in the USA, behaviourism in one form or another remained the dominant force within psychology for the next 40 years or so. The emphasis on the role of learning (in the form of conditioning) was to make that topic one of the central areas of psychological research as a whole (see Chapter 14). Box 9.1 outlines psychoanalytic theory and Gestalt psychology, two major European alternatives to American behaviourism.

In the late 1950s, many British and American psychologists began looking to the work of computer scientists to try to understand more complex behaviours, which, they felt, had either been greatly oversimplified or neglected altogether by learning theory (conditioning). These complex behaviours were what Wundt, James and other early scientific psychologists had called ‘mind’ or mental processes. They were now referred to as cognition or cognitive processes and denote all the ways in which we come to know the world around us – how we attain, retain and regain information through the processes of attention, perception, memory, problem-solving, language and thinking in general.

Cognitive psychologists see people as information-processors, and cognitive psychology has been heavily influenced by computer science, with human cognitive processes being compared to the operation of computer programs (the computer analogy). Cognitive psychology now forms part of cognitive science, which emerged in the late 1970s (Figure 9.1). The events that together constitute the ‘cognitive revolution’ are described in Box 9.2.

**Box 9.2 The 1956 ‘cognitive revolution’**

At a meeting at the Massachusetts Institute of Technology (MIT), Noam Chomsky presented his theory of language (see Gross\(^2\)), George Miller presented a paper on the ‘magical number seven’ in short-term memory (see Chapter 5), and Newell and Simon presented a paper on the logical theory machine (or logic theorist), with a further paper by Newell et al.\(^9\), which Newell and Simon extended into the general problem-solver (GPS)\(^9\) (see Gross\(^3\)).

The first systematic attempt to investigate concept formation (in adults) from a cognitive psychological perspective was reported.\(^1\)

At Dartmouth College, New Hampshire (the ‘Dartmouth Conference’), ten academics met to discuss the possibility of producing computer programs that could ‘behave’ or ‘think’ intelligently. These academics included McCarthy (generally attributed with having coined the term ‘artificial intelligence’), Marvin Minsky, Simon, Newell, Chomsky and Miller.

**Box 9.1 Psychoanalytic theory and Gestalt psychology**

In 1900, Sigmund Freud, an Austrian neurologist living in Vienna, first published his psychoanalytic theory of personality, in which the unconscious mind plays a crucial role. In parallel with this theory, he developed a form of psychotherapy called psychoanalysis. Freud’s theory (which forms the basis of the psychodynamic approach) represented a challenge and a major alternative to behaviourism (see Gross\(^2\) and Chapter 8).

A reaction against both structuralism and behaviourism came from the Gestalt school of psychology, which emerged in the 1920s in Austria and Germany. Gestalt psychologists were interested mainly in perception and believed that perceptions could not be broken down in the way that Wundt advocated. They identified several ‘laws’ or principles of perceptual organization (such as ‘the whole is greater than the sum of its parts’), which have made a lasting contribution to our understanding of the perceptual process (see Chapter 10).

Although mental or cognitive processes can only be inferred from what a person does (i.e. they cannot be literally or directly observed), they are now accepted as being valid subject matter for psychology, provided that they can be made ‘public’ (as in memory tests or problem-solving tasks). Consequently, what people say and do are perfectly acceptable sources of information about their cognitive processes, although the processes themselves remain inaccessible to the observer, who can study them only indirectly.

The influence of both behaviourism and cognitive psychology is reflected in Clark and Miller’s definition of psychology as:

\[ \text{... the scientific study of behaviour. Its subject matter includes behavioural processes that are observable, such as gestures, speech and physiological changes, and processes that can only be inferred, such as thoughts and dreams.}\]

Similarly, Zimbardo states:

**Psychology is formally defined as the scientific study of the behaviour of individuals and their mental processes.**\(^13\)
CLASSIFYING THE WORK OF PSYCHOLOGISTS

Despite behaviourist and cognitive psychology’s influence on psychology’s general direction during the past 90 years or so, much more goes on within the discipline than has been outlined so far. There are other theoretical approaches or orientations (such as the humanistic, social constructivist and evolutionary), other aspects of human (and non-human) activity that constitute the special focus of study, and different kinds of work that different psychologists do.

A useful, although not hard and fast, distinction can be made between the academic and applied branches of psychology (Figure 9.2). Academic psychologists conduct research and are attached to a university or research establishment, where they also teach undergraduates and supervise the research of postgraduates. Research may be pure (done for its own sake and intended, primarily, to increase our knowledge and understanding) or applied (aimed at solving a particular problem). Applied research is usually funded by a government institution, such as the Home Office, National Health Service (NHS) or Department for Education and Skills (DfES), or by a commercial or industrial institution. The range of topics that may be investigated is as wide as psychology itself, but they can be classified as focusing either on the processes or mechanisms underlying various aspects of behaviour, or more directly on the person.14

The process approach

This is divided into three main areas: physiological, cognitive and comparative psychology.

Physiological (or bio-) psychology

Physiological (or bio-) psychologists are interested in the physical basis of behaviour, how the functions of the nervous system (in particular, the brain) and the endocrine (hormonal) system are related to and influence behaviour and mental processes. For example, are there parts of the brain concerned specifically with particular behaviours and abilities (localization of brain function)? What role do hormones play in the experience of emotion, and how are these linked to brain processes? What is the relationship between brain activity and different states/levels of consciousnessconsciousness/awareness (including sleep)?

A fundamentally important biological process with important implications for psychology is genetic transmis-
Figure 9.2 Some of the main areas of academic and applied psychology open to psychology graduates

**Educational psychologist**

**Qualifications**
- Accredited Doctorate in educational psychology or Accredited Masters in educational psychology
- BPS Award in educational psychology (Scotland only)

**Works in**
- LEAs = schools, colleges, child and family centre teams, schools psychological service, hospitals, day nurseries, nursery schools, special schools, residential children’s homes

**Occupational (work or organizational) psychologist**

**Qualifications**
- Either accredited MSc in occupational psychology (1 year, full-time) + 2 years supervised work experience
- Or at least 3 years’ full-time supervised work experience, including BPS PG cert. in occupational psychology

**Works in**
- Factories, offices, shops, supermarkets, advertising, large organizations/corporations

**Health psychologist**

**Qualifications**
- Either accredited MSc in health psychology (1 year, full-time) and stage 2 of BPS qualification in health psychology
- Or stages 1 and 2 of BPS qualification in health psychology

**Works in**
- Hospitals, academic health research units, health authorities, university departments

**Pure research**

Carried out largely for its own sake

**Clinical psychologist**

**Qualifications**
- Work experience as assistant psychologist/research assistant
- Plus
- Doctorate in clinical psychology (3 years, full-time)

**Works in**
- Hospitals, health centres, community health teams, child and adolescent mental health services, social services; mainly in NHS; some private

**Academic/research psychologist**

Teaching post in university plus research in one or more of the following areas:
- Physiological (or bio-) psychology
- Cognitive psychology
- Comparative psychology
- Evolutionary psychology
- Social psychology
- Developmental psychology
- Individual differences

**Works in**
- Universities and research

**Counselling psychologist**

**Qualifications**
- Either accredited MSc or diploma or doctorate in counselling psychology (3 years, full-time/equivalent part-time)
- Or BPS qualification in counselling psychology (3 years, full-time independent study and practice)

**Works in**
- General and psychiatric hospitals, GP surgeries (NHS), private hospitals, schools, colleges and universities, industry (public and private companies)

**Forensic psychologist**

**Qualifications**
- Either accredited MSc in forensic psychology (1 year, full-time) and stage 2 of BPS diploma in forensic psychology
- Or stages 1 and 2 of BPS diploma in forensic psychology

**Works in**
- HM Prison Service (prisons, Home Office Research and Development Unit), health service (including rehabilitation units, special/secure hospitals for criminally insane people), police force, young offender units, probation service

**Psychology teaching**

In schools, sixth-form centres, colleges of further education

**Applied research**

Carried out in order to solve a problem (e.g. social, educational)
sion. The heredity–environment (or nature–nurture) issue draws on what geneticists have discovered about the characteristics that can be passed from parents to offspring, how this takes place, and how genetic factors interact with environmental ones (see Gross\textsuperscript{2,3}).

Other topics within physiological psychology include motivation (see Chapter 11), stress (which is commonly discussed as part of health psychology; see below and Chapter 13) and sensory processes, which are connected closely with perception (see Chapter 16).

**Cognitive psychology**

As we saw earlier, cognitive (or mental) processes include attention, perception, memory, language, thinking, problem-solving, decision-making, reasoning and concept-formation (higher-order mental activities). Although these are often studied for their own sake, they may also have important practical implications, such as understanding the memory processes involved in eyewitness testimony (see Gross\textsuperscript{2}).

Social psychology (classified here as belonging to the person approach) is heavily cognitive in flavour: for example, many social psychologists study the mental processes that we use when trying to explain people’s behaviour (social cognition). Also belonging to the person approach is the Swiss psychologist Jean Piaget’s influential theory of cognitive development (see Gross\textsuperscript{2}).

**Comparative psychology**

Comparative psychology is the study of the behaviour of non-human animals, aimed at identifying similarities and differences between species. It also involves studying non-human animal behaviour in order to gain a better understanding of human behaviour.

The basis of comparative psychology is evolutionary theory. Areas of research include classical and operant conditioning (see Chapter 14), animal communication, language and memory (see Gross et al.\textsuperscript{19}), and evolutionary explanations of human behaviour (see Clamp\textsuperscript{16} and Gross\textsuperscript{3}).

**The person approach**

**Social psychology**

Some psychologists would claim that all psychology is social psychology, because all behaviour takes place within a social context and, even when we’re alone, our behaviour continues to be influenced by others. However, other people usually have a more immediate and direct influence upon us when we are actually in their presence (as in conformity and obedience).

Social psychology is also concerned with interpersonal perception (forming impressions of others) and interpersonal attraction (why we like some people more than others, both friends and romantic partners), which forms a part of interpersonal relationships. Other areas of research interest include prejudice and discrimination, and pro- and antisocial behaviour (especially altruism and aggression, respectively).

**Developmental psychology**

Developmental psychologists study the biological, cognitive, social and emotional changes that take place in people over time. One significant change within developmental psychology during the past 40 years or so is the recognition that development is not confined to childhood and adolescence but is a lifelong process (the lifespan approach). It is now generally accepted that development continues beyond childhood and adolescence into adulthood and old age.

Developmental psychology is not an isolated or independent field, and advances in it depend on progress within psychology as a whole (such as behaviour genetics, (neuro)physiological psychology, learning, perception and motivation). Although Piaget’s theory of cognitive development was meant to map the changes that take place up to about 15 years of age, he is considered to have made a major contribution to psychology as a whole.

**Individual differences**

This is concerned with the ways in which people can differ from one another, including personality, intelligence and psychological abnormality. Other examples are age, gender and cultural/ethnic background. Another source of individual differences is criminal behaviour. Major mental/psychological disorders include schizophrenia, depression, anxiety disorders, sexual and eating disorders, and addictive behaviours.

Abnormal psychology is linked closely with clinical psychology, one of the major applied areas of psychology (see below). Clinical psychologists and psychologists who study abnormality are also concerned with the effectiveness of different forms of treatment and therapy. Each major theoretical approach (such as the behavioural, psychodynamic and cognitive-behavioural) has contributed to both the explanation and the treatment of mental disorders.

**Comparing the process and person approaches**

In practice, it is very difficult to separate the two approaches, even if it can be done theoretically. However, there are important relative differences between them (Box 9.3).

**Areas of applied psychology**

Discussion of the process/person approaches has been concerned largely with the academic branch of psychology. Since the various areas of applied psychology are all concerned with people, they can be thought of as the applied aspects of the person approach.
According to Hartley and Branthwaite, most applied psychologists work in four main areas: clinical, educational and occupational psychology, and government service (such as forensic psychology). In addition, Coolican and colleagues identify forensic (or criminological), sport and exercise, health, and environmental psychology. Hartley and Branthwaite argue that the work psychologists do in these different areas has much in common: it is the subject matter of their jobs that differs, rather than the skills they employ. Consequently, they consider an applied psychologist to be a person who can deploy specialized skills appropriately in different situations (Box 9.4).

Clinical psychology

Clinical psychologists are the largest single group of psychologists, in both the UK and the USA. Clinical psychology represents the largest single division within the British Psychological Society (BPS) and probably the largest number of Chartered Psychologists holding a Practising Certificate within the UK (see below). In 2005, those belonging to the Division of Clinical Psychology (DCP) constituted approximately 52 per cent of the entire register of Chartered Psychologists.

According to Coolican, clinical psychology can be defined as:

... the application of psychological theory to human distress, manifested as psychological problems. Therefore, clinical psychology is a profession primarily concerned with the alleviation of psychological problems ...

Even within psychology, clinical psychologists cannot claim to be the only practitioners concerned with the alleviation of psychological problems. Counselling and health psychologists also play a vital role in the application of psychological therapy. Outside psychology, psychotherapists, counsellors, specialist nurses and psychiatrists are all

Box 9.3 Some important differences between the process and person approaches

- The process approach is typically confined to the laboratory (where experiments are the ‘method of choice’). It makes far greater experimental use of non-human animals and assumes that psychological processes (particularly learning) are essentially the same in all species; any differences between species are only quantitative (differences of degree).
- The person approach makes much greater use of field studies (such as observing behaviour in its natural environment) and of non-experimental methods (such as correlation studies; see Coolican). Typically, human participants are studied, and it is assumed that there are qualitative differences (differences in kind) between humans and non-humans.

Box 9.4 Seven major skills (or roles) used by applied psychologists

- The psychologist as counsellor: helping people to talk openly, express their feelings, explore problems more deeply, and see these problems from different perspectives. Problems include school phobia, marriage crises and traumatic experiences (such as being the victim of a hijacking). The counsellor can adopt a more or less directive approach.
- The psychologist as colleague: working as a member of a team and bringing a particular perspective to a task, namely drawing attention to the human issues, such as the point of view of the individual end user (be it a product or a service of some kind).
- The psychologist as expert: drawing upon psychologists’ specialized knowledge, ideas, theories, and practical knowledge to advise on issues ranging from incentive schemes in industry to appealing to an ‘expert witness’ in a court case.
- The psychologist as toolmaker: using and developing appropriate measures and techniques to help in the analysis and assessment of problems. These include questionnaire and interview schedules, computer-based ability and aptitude tests and other psychometric tests (tests of mental measurement, such as intelligence quotient (IQ) tests and personality tests).
- The psychologist as detached investigator: many applied psychologists carry out evaluation studies to assess the evidence for and against a particular point of view. This reflects the view of psychology as an objective science, which should use controlled experimentation whenever possible. The validity of this view is a recurrent theme throughout psychology.
- The psychologist as theoretician: theories try to explain observed phenomena, suggesting possible underlying mechanisms or processes. They can suggest where to look for causes and how to design specific studies that will produce evidence for or against a particular point of view. Results from applied psychology can influence theoretical psychology, and vice versa.
- The psychologist as agent for change: applied psychologists are involved in helping people, institutions and organizations, based on the belief that their work will change people and society for the better. However, some changes are much more controversial than others, such as the use of psychometric tests to determine educational and occupational opportunities, and the use of behaviour therapy and modification techniques to change abnormal behaviour.
involved in the same overall aim; the main difference between these professional groups lies in the methods and techniques used to achieve it (as well as the theories and research on which they are based).

Clinical psychologists work largely in health and social care settings, including hospitals, health centres, community mental health teams, child and adolescent mental health services, and social services (Box 9.5). They usually work as part of a team, with, for example, social workers, medical practitioners and other health professionals. In the UK, most clinical psychologists work in the NHS, but some work in private practice.

### Box 9.5 Major functions of the clinical psychologist

A clinical psychologist has had work experience as an assistant psychologist/research assistant, plus 3 years’ postgraduate training (doctorate in clinical psychology). The clinical psychologist’s functions include:
- assessing people with learning difficulties, administering psychological tests to brain-damaged patients, devising rehabilitation programmes for long-term psychiatric patients, and assessing elderly people for their fitness to live independently;
- planning and carrying out programmes of therapy, usually behaviour therapy/modification or psychotherapy (group or individual) in preference to, or in addition to, behavioural techniques;
- conducting research into abnormal psychology, including the effectiveness of different treatment methods (‘outcome studies’); patients are usually adults, many of whom are elderly, or in psychiatric hospitals, psychiatric wards in general hospitals or psychiatric clinics;
- involvement in community care, as psychiatric care in general moves out of the large psychiatric hospitals (‘asylums’);
- teaching other groups of professionals, such as nurses, social workers and psychiatrists.

### Counselling psychology

Counselling psychology as an applied field of psychology

... aims to facilitate personal and interpersonal functioning across the life span with a focus on emotional, social, educational, health-related, developmental and organizational concerns. Through the integration of psychological theory, research and practice, counselling psychology includes a broad range of practices that help people improve their well-being, alleviate distress, resolve crises, and increase their ability to live more fulfilling lives.

Counselling psychology is a relatively new division within the BPS. Counselling psychologists work within the NHS (in general and psychiatric hospitals and primary care settings), in private hospitals and in private practice, in schools, colleges and universities, in public and private corporate institutions, and, most recently, within the prison service.

### Forensic (or criminological) psychology

Forensic psychology is a branch of applied psychology that applies psychological principles to the criminal and civil justice system. It is very much rooted in empirical research, theory and practice, and it is one of the fastest-growing areas of applied psychology, following a funded expansion of psychologists working with offenders in prison in 1996.

Drawing on cognitive, developmental, social and clinical psychology, a major focus of forensic psychology is the study of criminal behaviour and its management, but in recent years research interests have expanded to include other areas, most notably those with a high media profile (such as stalking) (Box 9.6).

The largest single employer of forensic psychologists in the UK is HM Prison Service (which includes the Home Office Research and Development Unit as well as prisons). Forensic psychologists also work in the health service (including rehabilitation units and special/secure hospitals for criminally insane people, such as Broadmoor and Rampton), the police service, young offender units and the probation service. Some work in university departments or in private consultancy.

### Educational psychology

According to Coolican, educational psychology is an... area of applied psychology, linking knowledge about the development of children and young people to education. It is concerned with how children feel, interact, learn and behave. It involves the application to education of psychological theories, research and techniques, with the aim of establishing a body of

### Box 9.6 Recent areas of research interest among forensic psychologists

- Jury selection
- Presentation of evidence
- Eyewitness testimony (see Chapter 17 and Gross)
- Improving the recall of child witnesses
- False memory syndrome and recovered memory (see Chapter 17)
- Offender profiling
- Crime prevention
- Devising treatment programmes, such as anger management
- Assessing the risk of releasing prisoners
- Falling convictions for rape.

From Coolican and Coolican et al.
knowledge about the psychological and educational development of children within the context of home, school and the community.\footnote{19}

Educational psychologists in England, Wales and Northern Ireland must have a first degree, followed by 3 years’ full-time professional training leading to a doctorate in educational psychology.\footnote{23}

Educational psychologists are mostly employed by local education authorities (LEAs), working in schools, colleges, child and family centres (previously called ‘child guidance’), the Schools Psychological Service, hospitals, day nurseries, nursery schools, special schools (day and residential) and residential children’s homes. Clients are aged up to 18 years, but most fall into the 5–16 years age group. Educational psychologists regularly liaise with other professionals from the departments of education, health and social services. A growing number work as independent or private consultants.\footnote{22} Box 9.7 lists some of the responsibilities of educational psychologists.

**Health psychology**

Health psychology is one of the newer fields of applied psychology, having become a separate division in 1997.

Health psychologists work in a variety of settings, such as hospitals, academic health research units, health authorities and university departments (Box 9.8). They may deal with the problems identified by healthcare agencies, including NHS trusts and health authorities, health professionals (such as general practitioners (GPs), nurses and rehabilitation therapists), and employers outside the healthcare system.

**Chartered psychologists**

Calling yourself a ‘psychologist’ even if you have never formally studied psychology is not illegal (unlike calling yourself a ‘doctor’ or a ‘psychiatrist’), and the BPS has long sought some kind of statutory status for practising psychologists of the type that doctors and nurses enjoy.\footnote{19}

Since 1987, the BPS, the only professional body for British psychologists incorporated by Royal Charter, has been authorized under its charter to keep a register of chartered psychologists. Entry to the register is restricted to members of the BPS who have applied for registration and who have the necessary qualifications or experience to have reached a standard sufficient for professional practice in psychology without supervision.\footnote{24}

All of the applied areas described above (as well as occupational) lead to chartered status, entitling the individual to take the title CPsychol. As yet, sport psychology and psychotherapy do not grant chartered status.\footnote{18} Now, not just anyone can call themselves a ‘chartered psychologist’ without facing prosecution: chartered status is a form of Kitemark for psychologists that should reassure members of the public that they are consulting a competent, experienced and professional practitioner.\footnote{19}

In spring 2005, the UK government issued a consultation document on statutory regulation, which proposed that psychologists should be regulated by the Health Professions

**Box 9.7 Some of the responsibilities of the educational psychologist**

- Administering psychometric tests, particularly intelligence quotient (IQ) tests, as part of the assessment of learning difficulties (LDs)
- Planning and supervising remedial teaching; research into teaching methods, the curriculum, interviewing, and counselling methods and techniques
- Planning educational programmes for people with mental and physical impairments (including visual impairment and autism), and other groups of children and adolescents not attending mainstream schools (special educational needs)
- Advising parents and teachers on how to deal with children and adolescents with physical impairments, behaviour problems and LDs
- Teacher training.

---

**Box 9.8 Breadth of health psychology**

Health psychology involves the use of psychological principles to promote changes in people’s attitudes, behaviour and thinking about health and illness. This may involve:

- the use of psychological theories and interventions to prevent damaging behaviours (e.g. smoking, drug abuse, poor diet), and to change health-related behaviour in community and workplace settings;
- promoting and protecting health by encouraging behaviours such as exercise, healthy diet, teeth-brushing, health checks and self-examination;
- health-related cognitions – investigating the processes that can explain, predict and change health and illness behaviours;
- processes influencing healthcare delivery – the nature and effects of communication between healthcare practitioners and patients, including interventions to improve communication, facilitate adherence (such as taking medication) and prepare for stressful medical procedures;
- psychological aspects of illness – looking at the psychological impact of acute and chronic illness on individual families and carers.

Based on British Psychological Society.\footnote{22}
Council (HPC). The BPS raised several serious objections, not least being the fact that most psychologists work outside the NHS. The BPS continues to argue for a new, more appropriate, regulatory body.

Psychology and common sense

In a sense we are all psychologists (see Gross). This is a theme explored at length by Joynson in *Psychology and Common Sense.* He begins by stating that human beings are not like the objects of natural science – we understand ourselves and can already predict and control our behaviour to a remarkable extent. This creates for the psychologist a paradoxical task: what kind of understanding can we seek of a creature that already understands itself?

For Joynson, the fundamental question is: ‘If the psychologist did not exist, would it be necessary to invent him?’ Conversely, for Skinner, ‘it is science or nothing’, while Broadbent also rejects the validity of our everyday understanding of ourselves and others (what Joynson calls ‘the behaviourists’ prejudice’). But given our cognitive abilities, and the nature of social interaction, we cannot help but try to make sense of our own and other people’s behaviour, and, to this extent, we are all psychologists. Heather points to ordinary language as embodying our ‘natural’ understanding of human behaviour: as long as human beings have lived, they have been psychologists, and language provides us with an ‘elaborate and highly refined conceptual tool, developed over thousands of years of talking to each other’.

Formal versus informal psychology

Legge and others resolve this dilemma by distinguishing between formal and informal psychology (or professional versus amateur/scientific versus non-scientific).

Our common-sense, intuitive or ‘natural’ understanding is unsystematic and does not constitute a body of knowledge. This makes it very difficult to ‘check’ an individual’s ‘theory’ about human nature, as does the fact that each individual has to learn from his or her own experience. So, part of the aim of formal psychology (or ‘Psychology’ – the scientific discipline – as opposed to ‘psychology’ – every individual’s cognitive, emotional, behavioural make-up) is to provide such a systematic body of knowledge, which represents the unobservable basis of our ‘gut reactions’.

Yet it could be argued that informal psychology *does* provide a ‘body of knowledge’ in the form of proverbs or sayings or folk wisdom, handed down from generation to generation, for example ‘birds of a feather stick together’, ‘too many cooks spoil the broth’ and ‘don’t count your chickens until they’re hatched’. Although each of these may contain at least a grain of truth, for each one there’s another proverb that states the opposite: ‘opposites attract’, ‘many hands make light work’ or ‘two heads are better than one’, and ‘time and tide wait for no man’ or ‘nothing ventured, nothing gained’.

However, formal psychology may help us to reconcile these apparently contradictory statements. For example, there is evidence to support both proverbs in the first pair. Formal psychology tries to identify the conditions under which each statement applies; they appear to be contradictory only because we assume that only one or the other can be true. In this way, scientific psychology throws light on our everyday informal understanding, rather than negating or invalidating it (see Gross and Rolls).

Legge believes that most psychological research should indeed be aimed at demonstrations of ‘what we know already’, but that it should also aim to go one step further. Only the methods of science, he argues, can provide us with the public, communicable body of knowledge that we’re seeking. According to Allport, the aim of science is ‘Understanding, prediction and control above the levels achieved by unaided common sense’, and this is meant to apply to psychology as much as to the natural sciences.

**CONCLUSIONS**

Psychology is a diverse discipline. Psychologists investigate a huge range of behaviours and mental or cognitive processes. There is a growing number of applied areas, in which theory and research findings are brought to bear in trying to improve people’s lives in various ways.

During the course of its life as a separate discipline, definitions of psychology have changed quite fundamentally, reflecting the influence of different theoretical approaches. Rather than having to choose between our common-sense understanding of people and the ‘scientific’ version, psychology as a scientific discipline can be seen as complementing and illuminating our ‘everyday’ psychological knowledge.

**KEY POINTS**

- The question as to whether psychology is a science has been part of its subject matter throughout its history as a separate discipline.
- Early psychologists, such as Wundt, attempted to study the mind through introspection under controlled conditions, aiming to analyse conscious thought into its basic elements (structuralism).
- Watson rejected introspectionism’s subjectivity and replaced it with behaviourism. Only by regarding people as complex animals, using the methods of natural science, and studying observable behaviour could psychology become a true science.
- Gestalt psychologists criticized both structuralism and behaviourism, advocating that ‘the whole is greater than the sum of its parts’. Freud’s psychoanalytic theory offered another major alternative to behaviourism, stressing the role of the unconscious mind.
Following the cognitive revolution, people came to be seen as information-processors, based on the computer analogy. Cognitive processes, such as perception and memory, became an acceptable part of psychology’s subject matter.

Academic psychologists are concerned mainly with conducting research (pure or applied), which may focus on underlying processes/mechanisms or on the person.

The process approach comprises physiological (bio-), cognitive and comparative psychology, while the person approach covers developmental and social psychology, and individual differences.

The process approach is confined largely to laboratory experiments using non-humans; the person approach makes greater use of field studies and non-experimental methods involving humans. The two approaches see species differences as quantitative and qualitative respectively.

Most applied psychologists work in clinical, counselling, forensic (criminological) and educational psychology. Newer fields include health psychology.

In a sense we are all psychologists, creating a dilemma for psychologists: are they necessary? One solution is to distinguish between informal/common-sense and formal/scientific psychology. The latter aims to go beyond common-sense understanding and to provide a public, communicable body of knowledge.

REFERENCES

INTRODUCTION

For the first 30 years or so of its life as a separate discipline, pioneered by figures such as William James and Wilhelm Wundt, psychology took conscious human experience as its subject matter. As described in Chapter 9, introspection – the observation of one’s own mind – was the primary method used to study it. This interest in consciousness should not come as a surprise, given how fundamental it is to everything we do.¹

And yet it is the very subjectivity of our experience that led Watson to reject introspectionism in favour of a truly scientific (i.e. objective) approach to the study of psychology, namely behaviourism. Writing from the perspective of a modern neuroscientist, Greenfield states:

Any scientific explanation of consciousness must be objective and embrace physical properties of the brain: but at the same time it must, nonetheless, somehow take account of the subjective. This is why consciousness has been such an anathema to scientists, because the whole essence of science is objectivity. And yet we are going to deal with a phenomenon that is subjective …²

However, as part of the ‘cognitive revolution’ in the 1950s (which removed behaviourism from its dominant position within psychology), ‘the mind’ once more became an acceptable, respectable focus of psychological research. Reflecting the current interest in consciousness among neuroscientists, philosophers and psychologists, one of the questions we will ask is: how might the brain generate consciousness?

There has been a considerable amount of research since the 1950s into sleep as a state of consciousness, much of which involves trying to find correlations between objective measures of physiological activity and subjective experience, in particular dreaming. Sleep is increasingly discussed in relation to bodily rhythms; disruption of these through our modern lifestyle is increasingly seen as a risk to health. According to Hobson, the rhythm of rest and activity, ‘... the primordia of sleeping and waking …’, represents one of the most universal and basic features of life.³ So, the study of sleep is of interest to biologists as well as to psychologists.

WHAT IS ‘CONSCIOUSNESS’?

Are only human beings ‘conscious’?

In Edelman’s terms, non-humans possess primary consciousness;⁴ this comprises sensory awareness, attention, perception, memory (or learning), emotion and action. What makes human beings distinct is their additional possession of secondary consciousness; that is, self-consciousness or awareness. This, according to Singer, is the experience of one’s own individuality, the ability to experience oneself as an autonomous individual with subjective feelings.⁵ It is considered to be ‘... the result of social interactions, and hence of cultural evolution’. This suggests that it is a rather human thing to have.

Singer also claims that when we say we are conscious, we usually mean that we perceive and remember in a way that makes it possible to report about the perceived and remembered content, or to make it the object of intentional deliberations. As Hobson puts it:

Consciousness may be defined as our awareness of our environment, our bodies, and ourselves. Awareness of ourselves implies an awareness of awareness, that is, the conscious recognition that we are conscious beings.⁶

Given the crucial role of language in these processes, and given that language is regarded by many as unique to humans, the rest of this chapter focuses on consciousness as a characteristic of human beings.

Some other definitions

- When we are awake, we are conscious; but when we are asleep, are in a coma or have been ‘knocked out’ by a punch to the head, we are unconscious. The term ‘unconscious’ is often reserved for the latter two examples, but, as we shall see, when we fall asleep we do ‘lose consciousness’.
- When we do something consciously, we do it deliberately or knowingly; but to do something unconsciously means doing it automatically or without having to think about it (e.g. an experienced driver or typist; see Chapter 13).
• Public-health campaigns (such as those promoting safe sex) are aimed at increasing public consciousness or awareness of the dangers of certain types of behaviour.

Freud’s theory of consciousness

Freud saw consciousness as a whole comprising three levels:
• The conscious: what we are fully aware of at any one time.
• The preconscious: what we could become aware of quite easily if we switched our attention to it.
• The unconscious: what we have pushed out of our conscious minds, through repression, making it extremely inaccessible, although it continues to exert an influence on our thoughts, feelings and behaviour (see Chapters 15, 17 and 61).

Most psychologists agree that thoughts, feelings, memories and so on differ in their degree of accessibility. But most would not accept Freud’s formulation of the unconscious (based on repression). Indeed, other psychodynamic theorists, in particular Jung, disagreed fundamentally with Freud’s view of the unconscious.

CONSCIOUSNESS, AROUSAL AND ALERTNESS

Objective physiological measures, such as the electroencephalogram (EEG), electromyogram (EMG), electrooculogram (EOG) (see below), breathing and heart rates, and other correlates of consciousness, are often described as measures of level of arousal or alertness. Both subjectively and in terms of overt behaviour, there is an obvious difference between being sleepy and being wide awake regarding the degree of arousal or alertness. Less obvious are the smaller changes that occur during normal wakefulness and that are of two kinds – tonic and phasic. These are mediated by different brain systems.7

Tonic alertness

Changes in tonic alertness reflect intrinsic (and usually quite slow) changes of the basic level of arousal throughout a 24-hour period (or even across a lifetime). They are related closely to various biological rhythms, in particular the circadian rhythm (see below). It was originally thought that the reticular formation (RF)/reticular activating system (RAS) was solely responsible for arousing and maintaining consciousness (it has been called a ‘consciousness switch’). For instance, if the brainstem is severed below the RAS, then the animal is paralysed but remains fully alert when awake and shows normal sleep–wake EEG patterns. However, if the brainstem is sectioned above the RAS, then the animal falls into a state of continuous slow-wave sleep (see below).

It is known that other brain structures (in both the thalamus and the hypothalamus) are involved in the sleep–wake cycle, and the coordination of all these systems is necessary for the initiation and maintenance of conscious awareness. Both during wakefulness and sleep, there are periodic, fairly predictable changes in the degree of alertness: the daytime changes are governed by a diurnal rhythm and the sleep (night-time) changes by an ultradian rhythm.

Phasic alertness

Changes in phasic alertness involve short-term, temporary variations in arousal, over a period of seconds, initiated by novel and important environmental events. An important component of these changes is the orienting response to arousing stimuli. It involves a decrease in heart rate and breathing rate, pupil dilation, tensing of the muscles and characteristic changes in the EEG, which becomes desynchronized.

If the stimuli are continuously presented, then the orienting response is replaced by habituation: the person or animal stops responding to the stimuli. Habituation is, in fact, a form of adaptation. It is more important from a survival point of view to respond to novel stimuli rather than constant stimuli, and, since most stimuli are relatively constant, we need to be able to attend selectively to those that are different or unexpected. It is the changing aspects of the environment that demand, and usually receive, our attention, and the nervous systems of animals and humans have evolved so as to make them especially responsive to change.

CONSCIOUSNESS AND ATTENTION

Although consciousness is difficult to describe because it is fundamental to everything we do,1 one way of trying to ‘pin down’ consciousness is to study what we are paying attention to – that is, what is in the forefront of our consciousness. According to Allport, ‘attention is the experimental psychologist’s code name for consciousness’.8

Focal attention

Focal attention/awareness is what we are currently paying deliberate attention to and what is in the centre of our awareness (this corresponds to Freud’s conscious). All those other aspects of our environment, or our own thoughts and feelings, that are on the fringes of our awareness but that could easily become the object of our focal attention are within our peripheral attention/awareness (corresponding to Freud’s preconscious).

We seem to be capable of doing many things quite unconsciously or automatically, without having to think about what we are doing. A good illustration of this is perception. It is difficult to imagine what it would be like if we were aware of how we perceive (Box 10.1).
Consciousness and brain activity

Part 2: Developmental, behavioural and sociocultural psychiatry

itive explanations) is illusory, because what really guides our behaviour is not available to consciousness. We do not have direct or privileged access to our cognitive processes, only to the products/outputs of those processes. Joynson,\(^{10}\) Heather\(^{11}\) and other psychologists present an opposing view, arguing that people are psychologists and that common-sense explanations may be as valid as theoretical, scientific explanations (see Gross\(^{12}\)).

CONSCIOUSNESS AND BRAIN ACTIVITY

Passingham at Oxford University and his colleagues from the Institute of Neurology in London (see McCrone\(^{13}\)) conducted a finger-tapping experiment, which may have revolutionary implications for our understanding of what it means to consciously experience something (Box 10.2).

McCrone believes that Passingham and colleagues’ results are not especially surprising. After all, we would expect the brain to be capable of automating motor tasks such as typing or riding a bike. However, McCrone refers to other imaging studies that have shown that a similar

Conversely, something we normally do quite automatically, such as walking down stairs, might be disrupted if we try to bring it into focal awareness (e.g. thinking about each step as we take it – but don’t try this at home!). In general, being able to do things automatically makes sense in terms of freeing us to attend to those environmental events that are unfamiliar or threatening in some way. If we had to think about our bodily movements when walking, this would add to the long list of sources of stimulation competing for our attention (see Chapter 13).

Even with skills that definitely do require focal attention when first acquired, such as driving or playing the piano, once they have been mastered, they become automatic. As Lloyd and colleagues put it, unconscious processes seem to be ‘precipitates’ of earlier conscious processes.\(^{7}\)

Nisbett and Wilson go so far as to claim that all psychological activities (including social behaviour) are governed by processes of which we are unaware.\(^{9}\) If people are asked about what they think governed their behaviour after participating in a social psychology experiment, then the answers they give do not usually correspond very well with the explanations that psychologists offer for the same behaviour (and that they believe are the real reasons).

Nisbett and Wilson argue that our belief that we can account for our own behaviour (‘common-sense’ or intu-

Box 10.1 Perception as an automatic process: doing what comes naturally

If you haven’t seen the picture shown in Figure 10.1 before, what do you see? If you have seen it before, try to explain how you saw what you saw when you first saw it.

Figure 10.1 Duck or rabbit?

- To consciously select one version of the ambiguous duck/rabbit figure, we must either know that there is a duck and a rabbit in the picture, or we must have already perceived both versions (in which case, how did the original perception come about?).
- You may have had difficulty perceiving the duck if your immediate perception was of the rabbit, even though you consciously searched for, and tried to see, the alternative version.
- This illustrates the very important difference between conception and perception; most of the time, perception is something that we ‘just do’ (see Chapter 16).

Box 10.2 Could finger-tapping be the key to conscious experience?

- Participants positioned their head into the centre of a brain scanner and rested one hand on a keypad. Then, by trial and error, they started to work out an unknown sequence of eight finger-taps.
- A tick flashed up on a screen whenever they pressed the correct key. Once they knew the sequence, their instruction was to keep drumming out the pattern until it became an unthinking rhythm. After an hour, their fingers were skipping through the complex routine almost of their own accord and they were barely conscious of what they were doing.
- In the learning phase, having to remember what they had just discovered while groping for the next step, regions all over the brain were clearly very active. These regions included a range of high-level cognitive areas in the forebrain (such as those involved with planning and memory), as well as other, lower brain areas that regulate movements (such as the basal ganglia and the cerebellum).
- Yet, within minutes of ‘getting’ the sequence, this wash of activity began to fade. The job of moving the fingers became confined to a small set of motor areas:

... It seems, having used the whole brain consciously to establish the individual finger movements, just the bare bones of the routine are left. The brain now has a template or habit that can produce the same behaviour ‘as if’ it were still going through all the hoops of being consciously aware.\(^{13}\)
process occurs when we learn more cognitive skills, such as matching verbs to nouns (e.g. ‘hammer’ and ‘hit’), learning to play a computer game, and learning a path through a drawn maze. Studies using these various tasks show that paying focal, effortful attention to something calls large regions of the brain into action. The brain does not behave like a collection of isolated pathways, each doing their own thing, but as a coherent system.13

There seem to be general-purpose planning centres that come into play whenever the brain is dealing with any kind of novel or difficult mental situation. These planning centres guide the more specialist language and motor centres to an appropriate output. Once the brain has found an optimal way to respond to a certain situation, the ‘wider scaffolding’ quickly falls away. It is not a case of practice making more efficient use of the pathways that were active during conscious learning, but rather the response can be reduced to its bare essentials. When Passingham and colleagues asked their participants to pay close attention to their finger-tapping rhythm (after this had become automatic), the participants’ prefrontal cortex immediately became active again. Just as significantly, their actual performance became more ragged, as if the brain were being put back into exploratory mode.

How might the brain generate consciousness?

Greenfield suggests that consciousness may have three properties:2

- Where might a ‘consciousness centre’ in the brain be? She claims that a recurring problem in neuroscience in general is the difficulty of ‘location of function’. Vision, memory, movement and other brain/mind functions seem almost certainly not to be related in a modular way to single respective brain regions. Many different regions play parallel roles, analysing the outside world in various ways and reintegrating it into a connected whole. This is likely to be true of consciousness: it could be spatially multiple but also temporally unitary (i.e. we are usually conscious of only any one state at a time). This view is consistent with Passingham and colleagues’ research discussed above.

- Rather than being all or nothing (either you are conscious or you are not), a more plausible scenario is that consciousness is more like the light on a dimmer switch that grows as the brain does. The more complex the brain, the greater the consciousness, with a continuum running from minimal to profound. This view can accommodate non-human animal consciousness, children’s consciousness, and differences between the same individuals on different occasions (e.g. changes in consciousness induced by drugs [see Chapters 58 and 70], religious experience and listening to music).

- We are always conscious of something; there is always some kind of focus, epicentre or trigger (Box 10.3).

How might this happen? Greenfield cites an experiment by Libet, in which he pricked participants’ skin and recorded the activity of large parts of the brain surface using the EEG. There was a huge amount of activity in the somatosensory cortex, but participants reported no conscious experience of tingling or any other sensations. They felt nothing, although their brain was registering signals of the touch to the skin, via the spinal cord. In Greenfield’s model, it is this early component in the response that is equivalent to the ‘epicentre’. But then, after about 500 ms, the activity evoked by the skin-prick spread away from the somatosensory cortex to a much larger area of the brain. Only at this stage did participants report feeling a tingle.

Because we never have the same conscious experience on two separate occasions, the same number of neurons will never be stimulated to exactly the same extent or in exactly the same way more than once. Greenfield’s model, therefore, needs a neuronal mechanism that can bias a large number of neurons to become activated simultaneously, and she believes that neuromodulators fit the bill. These chemicals ‘prime’ (bias or modulate) neurons for stimulation by neurotransmitters.

THE FUNCTIONS OF CONSCIOUSNESS: WHAT IS IT FOR?

Like perception, many cases of problem-solving seem to involve processes that are ‘out of consciousness’. For example, answers often seem to ‘pop into our head’, but we do not know how we reached them. If what is important is the
solution (as opposed to the process involved in reaching it),
then consciousness may be seen as incidental to information-
processing (consistent with Nisbett and Wilson’s view: see
above). But although perception and other basic cognitive
and behavioural processes may not require consciousness,
they are at least usually accompanied by consciousness.
Assuming that most other species lack our kind of con-
sciousness, we can infer that consciousness evolved in
human beings for some purpose.

The complexity of our nervous system, which makes our
consciousness possible, provided our ancestors with the
flexibility of behaviour that helped them to survive.
However, it is less obvious whether consciousness was itself
adaptive or simply a side effect or by-product of a complex
nervous system. Some psychologists and biologists believe
that consciousness is a powerful agent for controlling
behaviour, which has evolved in its own right. Accordingly,
non-conscious problem-solving systems are seen as the
‘servants of consciousness’ (Box 10.4).

TWO KINDS OF CONSCIOUSNESS

According to Hilgard’s ‘neo-dissociation’ theory of hypno-
sis (see Gross17), the consciousness that solves a problem
may be different from the consciousness that reports the
solution: neither is ‘higher’ or ‘lower’ than the other, they’re
simply different.18 This is consistent with the work on split-
brain patients (e.g. see Sperry19) – that is, people who have
undergone surgery (usually for intractable epilepsy) that
involves cutting the corpus callosum linking the two
hemispheres.

Some psychologists believe that the two cerebral hemi-
spheres are specialized (although they share the potential
for many functions and both participate in most psycholog-
ical activities), so that each is dominant with respect to par-
ticular functions. The most common way of distinguishing
between them has been the claim that the left is specialized
for verbal processes, while the right is specialized for visuo-
spatial processes. But this is rather oversimplified, and the
distinction is most accurate in relation to higher-order cog-
nitive processes within these domains. For example,
although the basic processes of language may be present in
both hemispheres, only the left has the specialized neural
processes needed to carry out the complex linguistic func-
tions of everyday life.20 In the vast majority of intact brains,
only the left hemisphere retains the person’s ability to
speak, enabling verbal report of conscious experience.21

Ornstein believes that these two modes of operation rep-
resent two distinct modes of consciousness.22 In daily life,
we normally just alternate between them and, although
they might complement each other, they do not readily sub-
stitute for one another (as when you try to describe a spiral
staircase or how you tie a shoelace). Is there any evidence
to support these claims (Box 10.5)?

CONSCIOUSNESS AND THE ELECTROENCEPHALOGRAM

A major method (since the 1930s) of studying the working
of the brain is to monitor its electrical activity. Exactly the
same information can be used to throw light on conscious-
ness, because particular patterns of electrical activity are
correlated with other measures of arousal and alertness
(Box 10.6).

Electroencephalography (literally, ‘electric-in-head writ-
ing’) detects the output of minute electrical ‘ripples’ caused
by changes in the electrical charges in different parts of the brain (usually the synchronized activity of large groups of neurons). Although there are characteristic patterns common to all individuals of a particular age or developmental stage, an individual’s brain activity is as unique and distinctive as their fingerprints.

Computerized electroencephalography has recently been used to detect evoked potentials (EPs), minute voltage changes induced in the brain by fairly specific visual and auditory stimuli. Often the average of a number of responses to similar kinds of stimuli is used (the average evoked potential – AEP) in order to amplify the signal-to-noise ratio. AEPs are used to study newborns, some children with learning difficulties, people in coma, people who have had a stroke, people with tumours and people with multiple sclerosis. However, for certain brain conditions, brain scanning has largely replaced the EEG (see Chapter 32).

## SLEEP

### Sleep and the circadian rhythm

According to Blakemore:

> For all the advances of modern society, we cannot afford to ignore the rhythms of the animal brain within us, any more than we can neglect our need to breathe or eat. Without the biological clocks in our brains, our lives would be chaotic, our actions disorganized. The brain has internalized the rhythms of Nature, but can tick on for months without sight of the sun ...  

Most animals display a circadian (from the Latin 
\textit{circa dies} = about one day) rhythm. This is a periodicity or rhythmical alternation of various physiological and behavioural functions, synchronized to the 24-hour cycle of light and dark. So, during a 24-hour period, there is a cycle of several physiological functions (heart rate, metabolic rate, breathing rate, body temperature, hormonal secretion, urine excretion, immune function, alertness and so on), which all tend to reach maximum values during the late afternoon and early evening and to reach minimum values in the early hours of the morning. (The disruption of circadian rhythms is discussed in Box 10.7 and in Chapter 11 as a source of stress.)

### Box 10.5 Alpha rhythms and hemispheric lateralization

Galin and Øistein (1972; see Øistein 23) recorded changes in participants’ electroencephalograms (EEGs) when presented with either verbal or spatial tasks.

- Verbal tasks, alpha rhythms (associated with a waking adult with the eyes closed) in the right hemisphere increased relative to the left; on spatial tasks, the reverse was true (see Box 10.6).

The appearance of alpha rhythms indicates a “turning off” of information-processing in the area of the brain involved. So, on verbal tasks, information-processing is turned off in the right hemisphere. This is the side of the brain not being used (as if to reduce the interference between the two conflicting modes of operation of the two hemispheres).

Similarly, people with damage to the left hemisphere have greater problems with consciously executed writing, while those with right hemisphere damage have greater problems with more automatic writing, such as signing their name.

This suggests that the left hemisphere may be more involved in highly conscious processes that require intentional behaviour and the focusing of attention. The right hemisphere may be more involved with automatic or unconscious actions, and may be more sensitive to material outside the conscious focus of attention.

### Box 10.6 The four major types of brain wave (measured in frequency)

- **Delta** (1–2 Hz): found mainly in infants, sleeping adults and adults with brain tumours.
- **Theta** (3–7 Hz): found mainly in children aged 2–5 years and in psychopaths. May be induced by frustration.
- **Alpha** (8–12 Hz): found mainly in adults who are awake and relaxed, and whose eyes are closed. Most reliably recorded from the back of the scalp.
- **Beta** (≥ 13 Hz): found mainly in adults who are awake and alert, whose eyes are open, and who may be concentrating on some task or other. Most reliably recorded from the middle of the scalp and related to activity in the somatosensory and motor cortex.

*See also Box 10.8.*

### Box 10.7 Siffre and the 25-hour day

In 1972, Michel Siffre, a young French cave explorer, spent 7 months underground with no cues as to the time of day. He had adequate food, water, books and exercise equipment. His only contact with the outside world was via a telephone, which was staffed permanently. He was linked up to a computer and video camera, by which scientists on the surface could monitor his physiological functions and state of mind. He organized his life into a fairly normal pattern of alternating periods of activity and sleep, and his ‘day’ was broken up by a normal meal pattern. The remarkable finding was that he chose to live a 25-hour (rather than 24) day. For every real day that passed, he rose an hour later—the clock in his brain was running a little slow.

From Blakemore.24
The internal or biological clock
Rats, like humans, have an inherent rhythm of about 25 hours, which dictates their cycle of sleep and waking if they are put in the dark. This internal clock is as reliable and regular as most manufactured ones – the rhythm deviates by no more than a few minutes over several months. So how is the internal (biological) clock reset each day to the cycle of the real world, and where is the clock to be found?

The internal clock is thought to be a tiny cluster of neurons, the suprachiasmatic nucleus (SCN), situated in the medial hypothalamus. For example, damage to the SCN in rats produces complete disappearance of the circadian rhythm: the sleep–wake cycle, eating and drinking, hormone secretion and so on become completely random during the course of the 24-hour period. Most of what is known about the SCN is based on experiments with non-human animals, and we cannot make direct electrophysiological recordings from the human brain. But anatomical studies show that humans have an SCN. The function of the SCN is to synchronize all the bodily functions that are governed by the circadian rhythm.

The SCN is situated directly above the optic chiasma (the junction of the two optic nerves en route to the brain). A tuft of thin nerve fibres branches off from the main nerve and penetrates the hypothalamus above, forming synaptic connections with cells in the SCN. This anatomically insignificant pathway is the link between the outside world and the brain’s own clock. So, the retina projects directly onto the SCN, which ensures that the sleep–wake cycle is tuned to the rhythm of night and day. If this connection with the retina is severed, then the cycle goes ‘haywire’.

The effects of disrupting the biological clock
In human adults at least, it appears that the circadian rhythm does not depend primarily on external cues, although it is surprisingly easy to outsmart our body clock by external means such as alarm clocks.

According to Melton, scientists are warning that we ignore our natural bodily rhythms at our peril:

... Fighting our natural sleep tendencies ... may be grinding away at our health, triggering a string of maladies... Giving up the late nights and weekend lie-ins in favour of a strict daily routine and a regular bedtime might be as important to our health as quitting smoking or cutting back on saturated fat.

How much sleep do we need?
We are biologically ill-prepared to function on minimal sleep: our prehistoric genetic blueprint for sleep has not evolved fast enough to keep up with the pace of twenty-first-century life. Humans are more likely to need an average of 10 hours of sleep a night than the 4 hours that Margaret Thatcher famously claimed to get by on. In the sleep laboratory, people who average 8 hours of sleep a night and maintain that they are fully alert during the day, and who then get an extra hour’s sleep at night, find their productivity levels increase by 25 per cent.

It has been suggested that each of us maintains a personal sleep bank account. We need enough sleep in the account in order to be able to function properly during the day. This means at least 8 hours of sleep for most people, in order to cancel out the sleep debt incurred by 16 hours of continuous alertness. Similarly, Dement, one of the pioneers of sleep research and the founder of the world’s first sleep disorders centre (see below), proposes a rough rule of thumb: most people require about an hour’s sleep for every two waking hours.

We live in a sleep-deprived society. For example, in the past 20 years, we’ve added about 158 hours to our annual working and commuting time – equal to a full month of working hours. (The British work longer hours compared with any other nation in Europe). Young mothers with children have added an astonishing 241 hours since the 1960s. According to the National Sleep Survey, we have just 6.5 hours’ sleep per night (rather than 8 hours), although the almost 2000 respondents were mainly younger than in other surveys. This is more than 2 hours less every night than our grandparents slept. In our 24-hour society, the pace of life is becoming faster and harder, and the stresses and pressures of work are leading to longer working hours and disrupted sleep. But, as Griffey says: ‘... sleep isn’t a social inconvenience, it’s a physical necessity and more and more studies are showing that sleep deprivation is a growing problem.’

How does sleep deprivation produce negative effects on health?
Dement believes that most of us carry a heavy ‘sleep debt’, a deficit of sleep built up over days, weeks and months. Sleep debt is dangerous, and it is potentially lethal. Examples are drivers who fall asleep at the wheel, pilots who are too sleepy to land planes safely, and surgeons who botch surgical procedures because they are exhausted. Both the Exxon Valdez and the Challenger space shuttle disasters were attributed to human error caused by extreme sleep deprivation. Dement also links high blood pressure, heart attacks and strokes to sleep apnoea, a chronic failure to sleep well because of problems breathing during sleep (see Chapter 54).

According to Melton, reduced sleep can interfere with the regulation of the immune system (see Chapter 11). Griffey reports on the findings of several studies showing why sleep deprivation is so harmful. The metabolic and endocrine changes resulting from a significant sleep debt mimic many of the hallmarks of ageing. Chronic sleep loss could not only speed up the onset but also increase the severity of age-related diseases such as diabetes, hypertension, obesity and memory loss. This might happen through chronic increases in the level of cortisol, a stress-related hormone, which in large quantities acts as a neurotoxin, killing billions of brain cells. Cortisol is also associated with increased risk of heart disease (see Chapter 11). Shift workers are especially at risk.
The physiology of sleep

When darkness falls, the eyes indirectly inform the pineal gland (the ‘third eye’). This is a tiny structure at the top of the brainstem, which keeps track of the body’s natural cycles and registers external factors such as light and darkness. The pineal gland secretes melatonin in response to darkness, making us drowsy. Downing calls melatonin ‘nature’s sleeping draught’. Melatonin is a hormone that affects brain cells that produce serotonin, concentrated in the raphe nuclei (situated near the pons), which secrete a substance that acts on the RAS to induce light sleep. Jouvet found that lesions of the raphe nuclei in cats produced severe insomnia, and naturally occurring lesions in humans seem to have a very similar effect.

Another important sleep centre is the locus coeruleus (LC), a tiny structure on each side of the brainstem whose cells are rich in noradrenaline, thought to be involved in inducing active (rapid eye movement – REM) sleep (see below). The LC may well serve many of the functions previously attributed to the RAS. Studies with rats suggest that the LC regulates the animal’s level of vigilance to environmental stimuli.

There is also evidence that a substance called factor S accumulates gradually in the brain of animals when they are awake. If this factor is removed from the fluid surrounding the brain and transferred into another animal, then sleep is induced. It is likely that factor S contributes to our feelings of sleepiness.

Varieties of sleep and the ultradian rhythm

In the typical sleep laboratory, a volunteer settles down for the night with not only EEG wires attached, but also with wires from an EOG (‘oculo’ = eye) and an EMG (‘myo’ = muscle) (Figure 10.3).

A typical night’s sleep comprises a number of ultradian cycles (lasting approximately 90 min), and each cycle consists of a number of stages (Box 10.8).

The cycle then goes into reverse, so we re-enter stage 3 and then stage 2. Instead of re-entering stage 1, however, a different kind of sleep (active sleep) appears. Pulse and respiration rates increase, as does blood pressure, and all three processes become less regular. The EEG begins to resemble that of the waking state, showing that the brain is active, supported by increases in oxygen consumption, blood flow and neural firing in many brain structures. But it is even more difficult to wake us from this kind of sleep than from the deep stage 4 sleep, hence the term paradoxical sleep.
Another characteristic of active sleep are the rapid eye movements (the eyeballs moving back and forth, and up and down, together) under the closed lids (hence the term ‘rapid eye movement sleep’). Finally, although the brain may be very active, the body is not. REM sleep is characterized by muscular paralysis (especially of the muscles of the arms and legs), so that all the tossing and turning and other typical movements associated with sleep occur only during stages 1–4 (non-rapid eye movement (NREM) sleep). The distinction between REM and NREM sleep was originally made by Dement and Kleitman.34

Another feature of REM sleep is the appearance of pontine-geniculo-occipital (PGO) spikes/waves, which are generated in the pons and travel through the lateral geniculate nucleus (LGN). These were discovered by Jouvet working with cats in the 1960s. PGO spikes typically occur in bursts, often preceding individual eye movements. According to the activation-synthesis model of dreaming (see below), PGO activity is the prime source of dreaming experience.25

After 15 minutes or so in REM sleep, we re-enter NREM sleep (stages 2–4), and so another ultradian cycle begins (Figure 10.4). However, with each 90-minute cycle (of which

---

**Box 10.8 Typical night’s sleep: the four stages of non-rapid eye movement (NREM) sleep**

After we shut our eyes and prepare to sleep, alpha waves begin to punctuate the high-frequency beta waves of active wakefulness. The transition from being awake to entering stage 1 sleep is called the hypnagogic period, and is sometimes included in stage 1.

- **Stage 1:** When we first fall asleep, the electroencephalogram (EEG) is irregular and lacks the pattern of alpha waves that characterizes the relaxed waking state. At first, there is a reduction in frequency of alpha waves, which are then replaced by low-voltage, slow theta waves, accompanied by slow rolling eye movements. The heart rate begins to slow down and the muscles relax, but we can still be woken up easily.

- **Stage 2:** This is a deeper state of sleep, but it is still fairly easy to wake the person. The EEG shows bursts of activity called sleep spindles (1- to 2-second waxing and waning bursts of 12- to 14-Hz waves). There are also occasional sharp rises and falls in amplitude of the whole EEG (K complexes), which last for up to 2 seconds.

- **Stage 3:** Sleep is becoming deeper, and the spindles disappear and are replaced by long, slow delta waves for up to 50 per cent of the EEG record. We are now quite unresponsive to external stimuli, and so it is difficult to wake us up. Heart rate, blood pressure and body temperature continue to drop.

- **Stage 4:** We now enter delta sleep (deep or ‘quiet’ sleep: 50% or more of the record consists of delta waves) and will spend up to 30 minutes in this stage. About an hour has elapsed since stage 1 began. As in stage 3, it is difficult to wake us unless something happens of great personal significance, such as our baby crying.

Stages 2–4 collectively are called slow-wave sleep (SWS). As we pass through stages 1–4, the frequency of the waves decreases, and the amplitude and voltage increase. Also, muscle tone steadily declines.

---

![Figure 10.4 Typical night’s sleep stages. NREM, non-rapid eye movement; REM, rapid eye movement.](image-url)
there are four to five on average per night), the duration of the REM sleep increases and that of NREM sleep decreases. The first cycle normally provides the deepest sleep and the shortest REM period. As the night goes on, we spend relatively more time in REM and less in NREM sleep. In later cycles, it is quite common to go from REM to stage 2, and then straight back into REM sleep (bypassing stages 3 and 4). Natural waking usually occurs during a period of REM sleep.

According to Empson:

While most all-night recording experiments are over brief periods (of up to a week), some very extended studies have been done and there is no evidence that the patterns of sleep we observe over short periods (after the first night) are in any way peculiar to the unfamiliarity of the laboratory environment.25

Sleep and dreaming

People woken from REM sleep commonly report that they have been dreaming,35 and dreaming is associated primarily with REM sleep.36 Rapid eye movements seem to be a very reliable indicator that a person is dreaming (especially in combination with the fairly high-frequency and low-amplitude brain waves). However, it is now generally agreed that there is no one-to-one correspondence between dream action and eye movement, although cues about the general nature of the dream can often be gleaned from the REM record.37 Faraday notes that research has shown that movements of the inner ear also occur during sleep and may be correlated with the auditory content of dreams.

REM sleep has been called ‘dream sleep’ or the ‘D-state’, and some writers have gone so far as to call it the ‘third state of existence’, because it is in many ways as different from NREM sleep (the ‘S-state’) as it is from waking. Since brain activation is most intense in REM, dreaming is most highly correlated with that brain state,6 and dream reports from REM sleep have remained the principal focus of empirical investigations of dreaming.38

Blackmore gives figures of 70–95 per cent and 5–10 per cent, respectively, for the (vivid) dreaming that is reported when people are woken from either kind of sleep.39 Mentation (mental activity) of some sort is reported in about 50 per cent of NREM awakenings. The figures vary according to the criteria used.40 So, being in REM sleep does not guarantee dreaming; conversely, dreaming can and does occur in NREM sleep (Box 10.9). Human fetuses spend about 15 hours per day in REM sleep – but they cannot be ‘dreaming’, since experience of the world is the ‘raw material’ of dreams. From what we know about REM sleep in other species, and from what we believe about their dreams and state of consciousness, we must conclude that dreaming and REM sleep are not the same thing.39

The effects of sleep deprivation

As far as rats are concerned, long-term sleep deprivation is definitely not good for their health: it causes impaired thermoregulation, metabolic dysfunction and eventually death.3

In the case of human beings, studies have been remarkably consistent in failing to show any marked changes in heart and breathing rates, blood pressure, skin conduction, body temperature, EMG or EEG, even when deprivation continues for up to 200 hours.41 But as we have seen, this is very different form the chronic sleep deprivation that is symptomatic of a modern Western lifestyle.

Webb and Bonnet limited participants to 2 hours’ sleep on one particular night.44 The participants suffered no ill effects the following day, but that night they fell asleep more quickly and slept for longer than usual. Longer periods of sleep deprivation may result in some unpleasant psychological effects, but people are remarkably able to do without sleep. Webb and Bonnet gradually reduced the length of sleep in a group of volunteers from 8 hours to 4

</tr>
</tbody>
</table>

Beaumont argues that being awoken from NREM sleep may lead to the dream being forgotten before the participant is sufficiently awake to report it (since this is a deeper kind of sleep, in which the brain is much less active).42 By contrast, being woken from REM sleep may allow the ongoing dream to be remembered and then reported (as the brain is much more active).

Clearly, if this is so, then we have stumbled upon a major confounding variable that challenges the very basis of much of the sleep/dream research. An appreciable amount of mental activity occurs during NREM sleep, and there are no completely consistent differences between dream reports obtained when participants are woken from either kind of sleep.

Research in the 1990s indicated that REM sleep may not be the driving force behind dreams. Dreaming seemed to be more of a continuous process, not confined to periods of REM sleep. Rather than seeing NREM sleep as ‘dream-free’, research suggested that NREM dreams are relatively short and rationally constructed in terms of facts and logic, compared with the more visual, emotional and detailed REM dreams.42

Participants woken from NREM sleep tend to report dreams that are shorter, less vivid and less visual than REM dreams and, in fact, they often describe themselves as having been ‘thinking’ rather than dreaming. NREM sleep is also associated with sleepwalking (somnambulism), sleeptalking and some types of nightmare.

However, evidence from studies of sleep deprivation seems to support the view of REM sleep as a dream-state sleep quite independently of the sleeper’s report of having dreamed (or not).
hours per night over a 2-month period, with no detectable effect. Box 10.10 describes the sleep rebound.

Theories of sleep

According to Blakemore:

Our planet is a dangerous place; there is ruthless competition for limited resources and only the fittest survive. And yet all the most advanced animals, normally alert, shrewd, watchful, drop their defences to sleep. Even human beings, the most spectacularly successful species, spend one-third of their lives more or less paralysed and senseless. If sleep is so risky, it must bestow a huge benefit on animals that indulge in it, or it would have been eliminated by the powerful forces of natural selection. Animals that did not need sleep would surely have evolved and prevailed over their sleepy competitors ... sleep must surely be valuable ...

Empson maintains that, even though physiologists have made great strides in understanding sleep mechanisms, this has not helped greatly in understanding what sleep is for. Sleep has the features of a primary drive (such as hunger and sex), but what makes it unique as a primary biological drive is that the need for sleep is reflected in decreased levels of arousal, and its satisfaction is associated with further decreases. Sleep, therefore, represents a serious exception to the view that organisms seek a single optimal level of (non-specific) arousal (see Chapter 11).

The restoration theory

Oswald maintains that both REM and NREM sleep serve a restorative, replenishing function. NREM restores bodily processes that have deteriorated during the day, while REM sleep is a time for replenishing and renewing brain processes, through the stimulation of protein synthesis (Box 10.11).

An evaluation of restoration theory

- Patients who survive drug overdoses and withdrawal, and other brain ‘insults’, such as intensive electroconvulsive therapy (ECT) (see Chapter 59), experience prolonged increases in REM sleep. These increases are consistent with the estimated time for the half-life of proteins in the brain; that is, in a 6-week period, about half the brain’s total protein is replaced, and this is the approximate length of the increased REM period.
- Nocturnal secretion of growth hormone (which produces bodily protein synthesis) depends on uninterrupted stage 4 sleep. In adults, a chronic lack of normal stage 4 is found in people with fibrositis, whose EEG during sleep is characterized by ‘alpha–delta’ patterns, a mixture of sleeping and waking EEG (typically experienced as fitful, unrestorative sleep). The disturbance of stage 4 in healthy volunteers produces the symptoms of fibrositis.
- According to Empson, all this evidence is consistent with a general anabolic function for sleep: REM sleep underlies brain growth, repair and memory functions, and slow-wave (stage 4) sleep promotes bodily growth and repair. However, cell repair goes on 24 hours a day (even though it reaches a peak at night).
- A more serious objection is that REM sleep is an active process, through the stimulation of protein synthesis (Box 10.11).

Box 10.10 The rapid eye movement rebound

<tbody>
<tr>
<td>When sleep is reduced abruptly (e.g. in the case of hospital doctors, who may be on duty for 50 hours at a stretch), the effects may be serious and may include irritability, intellectual inefficiency, and an intense fatigue and need for sleep.</td>
</tr>
<tr>
<td>These effects mirror those produced by depriving participants of approximately 2 hours of rapid eye movement (REM) sleep (but otherwise allowing them to sleep normally). The following night, there is an increase in REM sleep (to compensate for the previous night’s loss). This is called the REM rebound.</td>
</tr>
<tr>
<td>When volunteers are able to get by on greatly (but gradually) reduced amounts of sleep, it is apparently because they pack their 2 hours of REM sleep tightly into their sleeping time (thus reducing the amount of non-rapid eye movement (NREM) sleep in between their dreams). When sleep is reduced abruptly, there is no time to adopt this alternative dreaming-sleep pattern.</td>
</tr>
<tr>
<td>Dement woke participants from their REM sleep on five successive nights (a control group were woken only during NREM sleep periods). When the participants were allowed to sleep uninterrupted, they did 60 per cent more dreaming until they had made up their lost REM time. For as many as five nights following their REM deprivation, they spent more time in REM sleep than usual, and on some nights they doubled their REM time.</td>
</tr>

</tbody>
</table>
state (at least as far as the brain is concerned) and probably burns up a substantial amount of energy. Indeed, blood flow to the brain increases during REM sleep, and this would actually prevent high levels of protein synthesis. In view of this kind of evidence, Oswald maintains that both types of sleep are involved in the process of restoring bodily tissue.47

- However, Oswald may have been a little premature. According to Siegel, although most brain cells are at least as active during REM sleep as in waking, there is a specific group of cells that goes against this trend.48 These are the cells that produce the monoamine neurotransmitters (noradrenaline, serotonin, histamine). These key neurotransmitters inhibit body movement and reduce awareness of the environment, and the cells that produce them stop discharging completely during REM sleep. This cessation of neurotransmitter release is vital for the functioning of these neurons and their receptors on recipient neurons. This interruption may allow the receptor systems to ‘rest’ and regain full sensitivity, which may be crucial during waking for mood regulation. The monoamines also play a part in rewiring the brain to respond to new experiences. So, turning them off during REM may help to prevent changes in brain connections that might otherwise be ‘accidentally’ created as a consequence of the activation of other neurons during REM sleep. The REM rebound might result from the need to rest monoamine systems and other ‘off’ systems.48

Evolutionary theory

Different species characteristically sleep for different periods. Those at risk from predators, that cannot find a safe place to sleep or that spend large parts of each day searching for and consuming food and water (such as herd animals) sleep very little (e.g. zebras sleep for only 2–3 hours per day). Predators that sleep in safe places and can satisfy their food and water needs fairly quickly sleep for much of the day (e.g. lions often sleep more or less continuously for 2–3 days after gorging themselves on a kill).

According to Meddis, sleep is an advantage because it keeps the animal immobilized for long periods, making it less conspicuous to would-be predators and, therefore, safer.49,50 The safer the animal from predators, the longer it keeps the animal immobilized for long periods, making it

Evidence from sleep-deprivation experiments (both partial and total) shows that accumulated sleep ‘debts’ are made up to some extent on recovery nights, but never entirely. For example, REM rebound accounts for approximately 50 per cent of the REM sleep lost during selective awakenings. This suggests that only the first 3 hours of sleep are truly necessary (core sleep), and the rest is optional (having no physiological function).

- A weaker version of the ‘waste of time’ theory was proposed by Horne, who distinguishes between core sleep (which is necessary) and optional sleep (which is not).51

Empson concludes by saying:

... sleep appears to be ubiquitous and necessary; it is a complex function of the brain involving far-reaching changes in body physiology as well as brain physiology. It is difficult to believe that it does not have an important function and the restorative theories provide a coherent account of what this might be.25

Hobson’s levels

Although not a discrete theory, Hobson proposes that the function of sleep can be analysed at different levels.1

- At the behavioural level, sleep suppresses activity at a time (night-time/darkness) when the chances of finding food or a mate are relatively low. Also, such activities have a high energy cost in warm-blooded animals when the temperature is low. This makes sleep behaviourally very efficient. In addition, the enforced nature of sleep and its relation to resting activity serves to unite animals in a family or pair-bonded situation, which may encourage sexual behaviour and promote care and development of the young.

- At the developmental level, a function of REM sleep for developing organisms could be the guaranteed activation of neural circuits underlying crucial, survival behaviours (see Box 10.11). From an evolutionary point of view, there would be great advantages gained from ensuring the organized activation of the complex systems of the brain before the organism has developed the ability to test them in the real world. In both the developing and the adult animal, REM sleep could constitute a form of behavioural rehearsal.
At the metabolic level, the recurring cycles of NREM/REM sleep are accompanied by major changes in all the body’s physiological systems. NREM sleep involves decreased blood pressure, heart rate and breathing rate, as well as the release of growth and sex hormones from the pituitary (consistent with the restoration theory), while REM sleep involves increased blood pressure, heart rate and breathing rate, as well as penile erection and clitoral engorgement.

DREAMING

Although dreaming and REM sleep are not the same thing, dreaming is associated with REM sleep, and psychologists have developed reliable techniques for establishing when a person is likely to be dreaming. But there has been no equivalent progress in understanding the nature of dreams. According to Empson, a starting point must be to establish clearly how dreaming differs from waking consciousness. Empson identifies four such differences:

- Dreams happen to us as opposed to being a product of our conscious control: ‘When dreaming we are the spectators of an unfolding drama, and only rarely does one have the impression of being in control’...
- Lucid dreaming, in which the dreamer ‘knows’ that he or she is dreaming and decides how the dream plot should develop, is very rare.
- The logic of waking consciousness is suspended (see Freud’s theory in Chapter 61).
- Dreams reported in the laboratory tend to be mundane and lack the bizarre quality of ‘normal’ dreams, probably because only the strangest experiences are remembered when we wake normally after a night’s sleep.

Dreams have a single-mindedness: the imagery of the dream totally dominates the dreamer’s consciousness. But when we are awake, we normally reflect on the stream of consciousness as it goes on, and we can be aware of one thing but simultaneously imagine something else. (Recall that Greenfield claims that waking consciousness is single-minded: recall above).

Hobson describes dreams as typically including:

- hallucinations (predominantly visual, although auditory, tactile and movement sensations are also prominent, with taste and smell underrepresented and pain extremely rare);
- delusions (believing that the events are real);
- cognitive abnormalities (such as the occurrence of events that would be physically impossible in the real world);
- emotional intensification and amnesia (we forget over 95 per cent of our dreams).

These characteristics have led to a comparison between dreams and abnormal states of mind, as in schizophrenia and organic mental disorders, in particular delirium (see Chapters 37 and 38).

Theories of dreaming

Reorganization of mental structures

According to Ornstein, REM sleep and dreaming may be involved in the reorganization of our schemas (mental structures), so as to accommodate new information. People placed in a ‘disturbing and perplexing’ (asked to perform difficult tasks with no explanation) atmosphere for 4 hours just before sleep spend longer in REM sleep than normal. REM time also increases after people have had to learn complex tasks.

This may explain why REM sleep decreases with age. As we have seen, newborns spend 50 per cent of their (approximately) 18 hours of sleep in REM sleep, compared with 25 per cent spent by adults in their (approximately) 8 hours of sleep. Oswald suggested that babies’ brains need to process and assimilate the flood of new stimuli pouring in from the outside world (as part of the very construction of the brain), and that this is achieved (partly) through REM sleep (see above). However, we go on throughout our lives needing to reconstruct our brains and our minds.

Activation-synthesis model

The cortex is highly active during REM sleep (activation), although it receives little external stimulation. While the motor cortex is highly active (generating activity that would normally produce bodily movement), these commands do not reach the muscles of the limbs but are ‘switched off’ at a relay station at the top of the spinal column: we are effectively paralysed (output blockade).

Not only is the cortex isolated (unable to control muscles), but also there is inhibition of incoming signals produced by the sensory systems. Consequently, perceptions of the ‘real’ world are selectively attenuated (input blockade). Hindbrain and midbrain structures, normally associated with relaying sensory information to the cortex, spontaneously generate signals (PGO waves; see above) responsible for cortical activation. These are indistinguishable from signals that would normally have been relayed from the eyes and ears. This activity is under the control of a periodic triggering mechanism in the pontine brainstem (the top of the spinal column, at the base of the brain).

What we call a dream is the simplest way of interpreting these internally produced signals, by combining them into some meaningful whole (i.e. synthesis). The cognitive system, which organizes sensory information into the simplest meaningful interpretation when we are awake, processes all the internally generated signals as if they came from the outside world. In combination with oculomotor activity, PGO waves are sent to the visual and association cortex and the thalamus.

It is the unusual intensity and rapidity of brain stimulation (often involving simultaneous activation of areas not usually activated together during waking) that account for the highly changeable and sometimes bizarre content of dreams. According to Hobson: ‘... the now autoactivated
and autostimulated brain processes these signals and interprets them in terms of information stored in memory. 57

Many dream experiences do seem to reflect the brain’s and body’s state, and so they can be thought of as interpretations of these physical states. For example, being chased, locked up or frozen with fear may well reflect the blocked motor commands to the muscles; floating, flying and falling experiences may reflect vestibular activation; and the sexual content of dreams may reflect vaginal engergment and penile erection. 23

**Evaluation of the activation-synthesis model**

- In a sense, we dream instead of acting (perhaps suggesting the need for rest and restoration for the body). Cats with brainstem injury act out their dreams by, for example, chasing the mouse of their dreams while ignoring the real mouse in their cage: they are not paralysed in the normal way during REM sleep.

- Crick and Mitchison proposed a modified version of the model, which they called reverse learning. 55 The basic idea is that we dream in order to forget. The cortex (unlike other parts of the brain) is composed of richly interconnected neuronal networks. The problem with such a network system is that it malfunctions when there is overload of incoming information. To deal with such overload, the brain needs a mechanism to ‘debug’ or ‘clean up’ the network, and REM sleep is that mechanism. In this way, we awake with a cleaned up network, and the brain is ready for new input. According to Crick and Mitchison, trying to remember our dreams may not be a good idea: they are the very patterns of thought that the system is trying to tune out.

- For others, especially psychoanalysts and other psychodynamic psychologists, it is essential that we do remember our dreams, so that we can try to understand their meaning. For example, Freud saw dreams as wish fulfilments. Both he and Jung saw symbolism as being of central importance in dreams, which put the dreamer in touch with parts of the self usually inaccessible during waking life (see Chapter 61). Hall saw dreams as ‘a personal document, a letter to oneself’ and, like Jung, advocated the study of dream series rather than single isolated dreams. 56

**CONCLUSIONS: INTEGRATING NEUROBIOLOGICAL, EVOLUTIONARY AND PSYCHOLOGICAL ACCOUNTS OF DREAMING**

Winson, a neuroscientist, argues that neural and psychological theories of dreams are not mutually exclusive. 57 While Crick and Mitchison argue that we need to forget our dreams, Winson claims that:

---

**KEY POINTS**

- Since the cognitive revolution dislodged behaviourism from its dominant position in psychology, cognitive processes and consciousness have once more become important areas of psychological research.

- Freud distinguished three levels of consciousness: conscious, preconscious and unconscious. Most psychologists do not accept Freud’s view of the unconscious as based on repression, but they would accept that there is a continuum of consciousness.

- Arousal/alertness can be defined objectively in terms of various physiological measures, such as EEGs, ECGs, EMGs, breathing rate and heart rate. These are correlates of consciousness.

- Changes in tonic alertness are linked closely to various biological rhythms, especially the circadian rhythm. The RF/RAS plays an important role in arousing/maintaining consciousness. Alertness changes in fairly predictable ways both during wakefulness (controlled by a diurnal rhythm) and sleep (ultradian rhythm).

- Changes in phasic alertness involve changes in the orienting response to arousing stimuli. This is complemented by habituation, a form of adaptation. Human and non-human nervous systems have evolved such that they are especially responsive to change.

- Consciousness can be experimentally pinned down by studying attention (focal or peripheral). Perception seems to take place largely unconsciously, and many behaviours are carried out quite...
According to the activation-synthesis model, dreams are the simulation that occurs during REM sleep. This activation of the brain is consciously interpreted (synthesis) in the form of a dream. Psychological theories of dreams, such as those of Freud, Jung and Hall, focus on the synthesis component, stressing their significance for the dreamer.

According to Crick and Mitchison’s reverse learning theory, dreams are a way of ‘cleaning up’ the cortex’s neural networks and preparing them for new input – so, we need to forget our dreams. Psychological theories, on the other hand, stress the need to remember our dreams.

Different theories of dreaming are not mutually exclusive. REM sleep may have evolved in order to help animals’ biological survival, but dreams continue to serve a vital function for individuals, helping them to survive psychologically.

- Most animals display a circadian rhythm that is synchronized to the 24-hour cycle of light and dark, involving a rhythmic alternation of various physiological and behavioural functions.
- The internal/biological clock is thought to be the SCN, part of the hypothalamus. The retina projects directly on to the SCN, ensuring that the sleep–wake cycle is tuned to the rhythm of night and day.
- When darkness falls, the pineal gland begins to secrete melatonin, making us drowsy. It affects the brain cells that produce serotonin concentrated in the raphe nuclei; these secrete a substance that acts on the RAS to induce light sleep. The LC is rich in noradrenaline, which induces REM sleep.
- Modern living increases the likelihood that the circadian rhythm will be disrupted, and people are sleeping less than human beings are designed for by evolution. This has harmful effects on people’s mental and physical health.
- Sleep is measured in the laboratory using an EEG, EOG and EMG. A typical night’s sleep comprises four to five ultradian cycles, each consisting of several stages. Stages 2–4 are collectively called SWS or ‘deep’ sleep; stages 1–4 are collectively called NREM sleep.
- REM or active sleep replaces stage 1 at the beginning of the next cycle. Physiological processes increase and EEGs begin to resemble those of the waking state, and yet it is more difficult to wake someone from stage 4 sleep (making it paradoxical). With each ultradian cycle, the duration of REM sleep increases.
- Depriving people of REM sleep produces the REM rebound, suggesting that dreaming associated with REM sleep is perhaps the most important function of sleep. But psychologists are still very unclear about the functions of sleep. It is unique as a primary biological drive designed for by evolution. This has harmful effects on people’s mental and physical health.
- The sleep–wake cycle is tuned to the rhythm of night and day. The retina projects directly on to the SCN, ensuring that the need for sleep is reflected in decreased levels of arousal.
- According to Oswald’s restoration theory, REM and NREM sleep help to replenish bodily and brain processes, respectively. However, the fact that cell repair goes on 24 hours a day, and that the brain is highly active during REM sleep, led Oswald to claim that both REM and NREM sleep are involved in restoration of bodily tissue.
- Meddis’s evolutionary theory claims that both longer and shorter periods of sleep are associated with greater safety from predators, and that longer sleep is also characteristic of certain predators such as lions. This makes the theory unfalsifiable. Hibernation theory is a variant of evolutionary theory.
- According to the activation-synthesis model, dreams are the simplest way of interpreting all the internal, brain-produced signals that occur during REM sleep. This activation of the brain is consciously interpreted (synthesis) in the form of a dream. Psychological theories of dreams, such as those of Freud, Jung and Hall, focus on the synthesis component, stressing their significance for the dreamer.
- According to Crick and Mitchison’s reverse learning theory, dreams are a way of ‘cleaning up’ the cortex’s neural networks and preparing them for new input – so, we need to forget our dreams. Psychological theories, on the other hand, stress the need to remember our dreams.
- Different theories of dreaming are not mutually exclusive. REM sleep may have evolved in order to help animals’ biological survival, but dreams continue to serve a vital function for individuals, helping them to survive psychologically.

INTRODUCTION

According to Bartlett:

... the notion that stress is bad for you and can make you ill has become a modern cultural truism. However, there is also a significant body of research evidence which lends support to this idea... The study of stress must ... be central to ... health psychology which concerns, at its most basic level, the role of psychosocial processes in health and disease.¹

Definitions of stress fall into three categories:¹,²

- Stress as a stimulus
- Stress as a response
- Stress as interaction between an organism and its environment.

In turn, this classification corresponds very closely to three models of stress identified by Cox: the engineering model (which is concerned mainly with the question ‘what causes stress?’), the physiological model (‘what are the effects of stress?’) and the transactional model (both of these questions, plus ‘how do we cope with stress?’).³

Although stressors are faced by everyone (especially, perhaps, people living in constantly changing Western cultures), some people face greater demands than others. As a group, patients (both in and out of hospital) face sources of stress that they did not have to deal with before becoming ill. Similarly, although all occupations are stressful, some occupations are more stressful than others. Several studies have suggested that health workers experience more stress than comparable groups of non-health workers.⁴ In terms of Warr’s vitamin model, which identifies several environmental factors that affect mental health, nurses and other health professionals are likely to suffer from organizational stressors that are common to many other occupations (e.g. lack of clarity, conflicting roles, work overload, lack of control).⁵ However, doctors and nurses often suffer additional stressors that are intrinsic to the job (e.g. providing terminal care, counselling bereaved parents, dealing with disturbed and violent patients).

MODELS OF STRESS

The engineering model sees external stresses giving rise to a stress reaction, or strain, in the individual.³ The stress is located in the stimulus characteristics of the environment: stress is what happens to a person, and not what happens within a person. Up to a point, stress is inevitable and can be tolerated; moderate levels may even be beneficial (eustress⁶).

The physiological model is concerned primarily with what happens within the person as a result of stress (the ‘response’ aspects of the engineering model), in particular the physiological changes. The impetus for this view was Selye’s definition of stress as ‘... the individual’s psychophysiological response, mediated largely by the autonomic nervous system and the endocrine system, to any demands made on the individual’.⁶

As a medical student, Selye noticed a general malaise or syndrome associated with ‘being ill’, regardless of the particular illness. The syndrome was characterized by (i) a loss of appetite, (ii) an associated loss of weight and strength, (iii) loss of ambition and (iv) a typical facial expression associated with illness. Further examination of extreme cases revealed major physiological changes (confirmed by Cox³). This non-specific response to illness reflected a distinct phenomenon, which Selye called the general adaptation syndrome (GAS; see below).

The transactional model represents a kind of blend of the first two models. It sees stress as arising from an interaction between people and their environment, in particular when there is an imbalance between the person’s perception of the demands being made of them by the situation and their ability to meet those demands. Because it is the person’s perception of this mismatch between demand and ability that causes stress, the model allows for important individual differences in what produces stress and how much stress is experienced. There are also wide differences in how people attempt to cope with stress, psychologically and behaviourally.
WHAT CAUSES STRESS?

The causes of stress do not exist objectively, and individuals differ in what they see as a stressor in the first place. In this section we identify potential stressors – the kinds of event or experience that most people are likely to find exceed their capacity to handle the demands that are involved.

Disruption of circadian rhythms

The word ‘circadian’ (‘about 1 day’) describes a particular periodicity or rhythm of a number of physiological and behavioural functions that can be seen in almost all living creatures (see Chapter 10). Many studies have shown that these rhythms persist if we suddenly reverse our activity pattern and sleep during the day and are active during the night. This indicates that these rhythms are controlled internally (endogenous).

However, our circadian rhythms are kept on their once-every-24-hours schedule by regular daily environmental (exogenous) cues called zeitgebers (German = ‘time-givers’). The most important zeitgeber is the daily cycle of light and dark. If we persist with our reversal of sleep and activity, the body’s circadian rhythms reverse (after a period of acclimatization) and become synchronized to the new set of exogenous cues.

Individual differences and the effects of shift work

Some people take 5–7 days to adjust, while others take up to 14 days and some never achieve a complete reversal. Not all physiological functions reverse at the same time: body temperature usually reverses within a week for most people, while the rhythms of adrenocortical hormone take much longer to reverse. During the changeover period, the body is in a state of internal desynchronization. This is very stressful, and shift workers often report experiencing insomnia, digestive problems, irritability, fatigue and even depression when changing work shifts. In shift work, the zeitgebers stay the same, but workers are forced to adjust their natural sleep–wake cycles in order to meet the demands of changing work schedules (Box 11.1).

Coffey et al. examined the influence of day, afternoon, night and rotating shifts on the job performance and job-related stress of 463 female nurses at five US hospitals. Using a structured questionnaire, they found that job performance was highest for nurses on the day shift, followed by the night, afternoon and rotating shifts. Rotating-shift nurses reported the highest job-related stress, followed by afternoon-, day- and night-shift nurses. These results contrast with those of mainly male factory workers, where individuals are doing essentially the same type of work regardless of the shift. The type of work carried out by nurses differs considerably depending on their particular shift, and so performance by shift may be affected by both the social organization of hospital work and circadian rhythm synchronization.

Rotating-shift nurses may suffer the most stress and have the least successful job performance due to both the disturbance of circadian rhythms and the fact that they often work with different colleagues and patients on each shift. This may make it more difficult to establish working relationships. Although day-shift nurses suffer the least from circadian rhythm disruption, they are responsible for the instrumental activities of supervising patient preparation for diagnostic testing, treatment and therapy. The pace is rapid and the nurse is interacting with a maximum number of colleagues, both nursing and non-nursing. This can be very stressful (see below).

Conversely, the pace is slower and interaction with others considerably reduced on night shift, helping to reduce stress levels. Concentration is on the expressive activities of making patients comfortable and ensuring rest and sleep.

In the afternoon shift, circadian rhythm disruption is moderate, but nurses face the stress of both instrumental and expressive functions. The nurses are responsible for continuing and monitoring the medical treatment initiated during the day shift, while at the same time dealing with the social and psychological aftermath of the medical regimen. This may account for their high stress levels.

According to Singer (see Brown), who compared rota systems in different countries, there is a very high error and accident rate among people working an early-morning shift that follows a late-afternoon/evening shift. This combination should be avoided at all costs. However, a late shift followed by an early shift is the staple diet of the internal rotation duty pattern in the UK.

Jet lag

Other occupational groups affected by disruption to their circadian rhythms are airline pilots and cabin crew, who experience jet lag because they cross time zones during the course of a flight. If you have travelled across a time zone, you will know what it is like to have your biological rhythms ‘out of sync’ with your surroundings. If you arrive in Washington, DC, at 7 p.m., after an 8-hour flight from London, you may want to start your evening’s entertainment – but as far as your body is concerned, it is time to sleep, because back in London it is 1 a.m.
Most people suffer much less jet lag when travelling in an east–west direction compared with a west–east direction. When going west (‘chasing the sun’), the day is temporarily lengthened. Because the natural circadian rhythm cycle is 25 hours (see Chapter 10), an increase in day length is much easier to deal with than a decrease. Secretion of melatonin reaches a peak during the night, helping to make us sleepy. After a long flight, the cyclical release of melatonin stays locked into the day/night pattern of the home country for some days. This could account for the fatigue felt during the day and the insomnia experienced at night. If jet-lagged volunteers are given melatonin during the evening, far fewer report feeling jet-lagged than controls who receive only a placebo.13

Cabin crew flying across time zones had significantly raised salivary cortisol (one of the glucocorticoid stress hormones; see Figure 11.1) compared with when the same cabin crew flew short distances, and compared with ground crew. In a response-time test, the jet-lagged crew performed more poorly when there was a 25-second delay between presentation of the target symbol and having to recognize the symbol (but not when the delay was only 1 or 5 seconds).14 De Quervain et al. found poorer recognition memory among non-flight crew participants given cortisol (another glucocorticoid).15 The researchers believe that raised glucocorticoid levels may cause impairments in memory retrieval in stressful situations such as exams, job interviews, combat and courtroom testimony (see Chapter 17).

Life changes: the Social Readjustment Rating Scale

Holmes and Rahe examined 5000 patient records and made a list of 43 life events, of varying seriousness, that seemed to cluster in the months preceding the onset of the patients’ illnesses.16 Out of this study grew the Social Readjustment Rating Scale (SRRS). Several studies have shown that people who experience many significant life changes (a score of 300 or more life change units – LCUs) are more susceptible to physical and mental illness than people with lower scores. The range of health problems includes sudden cardiac death, heart attacks (non-fatal), tuberculosis (TB), diabetes, leukaemia, accidents and athletics injuries (Table 11.1).

Evaluation of the Social Readjustment Rating Scale

The SRRS assumes that any change, by definition, is stressful; that is, certain events are inherently stressful, but the undesirable aspects of events are at least as important as the fact that they change people’s lives.17 A quick glance at Table 11.1 suggests that life changes have a largely negative feel, especially those in the top ten, which receive the highest LCU scores; so, the scale may be confusing ‘change’ and ‘negativity’.

Similarly, life changes may be stressful only if they are unexpected and, in this sense, uncontrollable. In other words, it may not be change as such that is stressful, but rather change that we cannot prevent or reverse. Studies have shown that if people are asked to classify the undesirable life events on the SRRS as either ‘controllable’ or

The amount of stress a person has experienced in a given period of time, say 1 year, is measured by the total number of life change units (LCUs). These units result from the addition of the values (shown in the right-hand column) associated with events that the person has experienced during the target time period. The mean values (item weightings) were obtained empirically by telling 100 judges that ‘marriage’ had been assigned an arbitrary value of 500 and asking them to assign a number to each of the other events in terms of ‘the intensity and length of time necessary to accommodate ... regardless of the desirability of the event relative to marriage’. The average of the numbers assigned to each event was divided by 10 and the resulting value became the weighting of each life event.

‘uncontrollable’, then only the latter are correlated significantly with subsequent onset of illness.\textsuperscript{18}

Some of the items are ambiguous (e.g. those that refer to ‘changes in’ could be positive or negative changes). Others (e.g. items 6 and 12) refer to states of health, and so the total LCU score is already contaminated with the individual’s current health status.\textsuperscript{19}

The list of events is incomplete. For example, the list does not include death of a child, there is no reference to the problems of old age, and there is no mention of natural or ‘man-made’ disasters.\textsuperscript{20} The list also fails to take into account individual circumstances. For example, the impact of the death of a spouse is generally affected by the partner’s age at the time, the nature of their relationship and the cause of death.\textsuperscript{21} The SRRS was developed over 40 years ago. This makes some of the original LCU scores associated with particular life events potentially out of date.

Evaluation of studies using the Social Readjustment Rating Scale
Although many studies have found statistically significant correlations between LCUs and subsequent illness, the correlations are typically too low to be of any practical value.\textsuperscript{20} Since the data produced by these studies are correlational, it is possible that, instead of life events causing illness, some life events (e.g. being fired from work, sexual difficulties, trouble with in-laws, change in sleeping habits) are themselves early manifestations of an illness that is already developing.\textsuperscript{18,19,22}

Many of these studies are also retrospective: people are asked to recall both the illnesses and the stressful life events that occurred during the specified period, which is likely to produce distorted, unreliable data (see Chapter 17). For example, what people say about a past illness may be different from what the illness was actually like.\textsuperscript{22}

The need for control
According to Parkes, the psychosocial transitions that are most dangerous to health are those that are sudden and allow little time for preparation.\textsuperscript{23} The sudden death of a relative from a heart attack, in an accident or as a result of crime are examples of the most stressful kind of life changes (see Chapter 57).

Using Rotter’s Locus of Control Scale,\textsuperscript{24} and devising a new scale – the Life Events Scale – Johnson and Sarason found that life events stress was related more closely to psychiatric symptoms (in particular, depression and anxiety) among people rated as high on external locus of control than among those rated as high on internal locus of control.\textsuperscript{25} In other words, people who believe that they do not have control over what happens to them are more vulnerable to the harmful effects of change than those who believe they do. This is related to Seligman’s concept of learned helplessness (see Chapter 14).\textsuperscript{26}

The hassles and uplifts of everyday life
By definition, most of the 43 changes included in the SRRS are not everyday occurrences. Kanner \textit{et al.} designed a hassles scale comprising 117 items, and an uplifts scale containing 135 items.\textsuperscript{27} They define ‘hassles’ as:

… the irritating, frustrating, distressing demands that to some degree characterize everyday transactions with the environment. They include annoying practical problems, such as losing things or traffic jams and fortuitous occurrences such as inclement weather, as well as arguments, disappointments, and financial and family concerns.\textsuperscript{27}

Daily uplifts are:

... positive experiences such as the joy derived from manifestations of love, relief at hearing good news, the pleasure of a good night’s rest, and so on.\textsuperscript{27}

In a study of 100 men and women aged 45–64 years over a 12-month period, Kanner \textit{et al.} confirmed the prediction that hassles are related positively to undesirable psychological symptoms; but the effect of uplifts was unclear, and research interest waned.\textsuperscript{1} Kanner and colleagues also found that hassles are a more powerful predictor of symptoms than life events (as measured by the SRRS). ‘Divorce’, for example, may exert stress by any number of component hassles, such as cooking for oneself, handling money matters and having to tell people about the situation. So, daily hassles may intervene between major life events and health: it is the cumulative impact of these day-to-day problems that may prove detrimental to health.

An evaluation of the hassles and uplifts scales
According to Lazarus, life events (as measured by the SSRS) are \textit{distal} (remote) causes of stress.\textsuperscript{20} We need to know the psychological meaning that a person attaches to an environmental event – the personal significance of what is happening (the \textit{proximal} cause). This is what makes Kanner and colleagues’ scales a more valid approach. According to Lazarus:

\textit{Although daily hassles are far less dramatic than major life changes ... and what constitutes a hassle varies greatly from person to person, our research has suggested that, especially when they pile up or touch on special areas of vulnerability ... they can be very stressful for some people and very important for their subjective well-being and physical health ...}\textsuperscript{20}

Bartlett claims that implicit in the concept of hassles is a stimulus-based definition of stress.\textsuperscript{7} This is inconsistent with the transactional approach advocated by Lazarus (see above). This apparent contradiction stems from focusing on the hassles themselves while simultaneously believing that it is their psychological meaning that causes stress.

Occupation-linked stressors
Along with social work, teaching and the police force, nursing is identified as a high-stress occupation. A study by
Borrill et al. (see Carson et al.29) of 11 000 National Health Service (NHS) staff found that nurses had the second-highest stress score among seven staff groups. We have already seen how shift work, although not unique to nurses, is an inherently stressful aspect of the job; this is common to doctors and to all people working in the emergency services (e.g. police, fire, ambulance, emergency medical teams, mountain rescue). These staff groups share routine encounters with death, tragedy and horror, are required to deal with people in pain and distress and to handle dead bodies, and may face personal danger and injury.

Mental health nurses

O'Donnell reported the findings of a survey in which nurses were asked about 16 different stressors.29 Overall, most of these stressors were perceived as being more extensive in mental health nursing (MHN) than in nursing as a whole. Violence was found to be substantially more extensive than average, as were job insecurity, not being involved in decision-making and career uncertainty.

According to Sullivan (see Nolan et al.30), a growing body of research evidence suggests that nursing in general, and MHN in particular, is a stressful occupation. All those professionals working in mental health may be at greater risk of stress than their colleagues working in physical healthcare; for example, psychiatrists have the highest suicide rate among doctors. As MHN is often carried out against a background of risk-taking and uncertainty because of the volatile and potentially aggressive nature of some psychiatric patients, nurses inevitably experience stress.30

According to Burnard et al., psychological distress, emotional exhaustion and increased alcohol consumption are just some of the consequences of increased workplace stressors among community mental health nurses (CMHNs).31 These nurses see themselves as overworked, struggling with too much paperwork and administration, having too many clients, and having serious concerns about their client groups. As many as 20 per cent feel they have no job security. These are among the key findings of a survey into stress among CMHNs in Wales, the largest of its kind in the UK. The survey included nurses working in a wide range of urban and rural settings. The findings describe burnout, which Cherniss (see Firth et al.32) defines simply as ‘negative changes in work-related attitudes and behaviour in response to job stress’. Burnout is an ‘occupational hazard’ in a variety of healthcare professionals, especially those caring for terminally ill patients.33

WHAT ARE THE EFFECTS OF STRESS?

The general adaptation syndrome

According to Selye, GAS represents the body’s defence against stress.6 The body responds in the same way to any stressor, whether the stressor is environmental or arises from within the body itself. The GAS comprises three stages: the alarm reaction, resistance and exhaustion.

Alarm reaction

When a stimulus is perceived as a stressor, there is a brief, initial shock phase. Resistance to the stressor is lowered. This is followed quickly by a countershock phase. The sympathetic branch of the autonomic nervous system (ANS) is activated, which, in turn, stimulates the adrenal medulla to secrete increased levels of adrenaline and noradrenaline (catecholamines). These are associated with sympathetic changes, collectively referred to as the fight-or-flight syndrome (the individual’s instinctive, biological preparation for confronting or escaping danger). The catecholamines mimic sympathetic arousal (sympathomimetics), and noradrenaline is the transmitter at the synapses of the sympathetic branch of the ANS. Consequently, noradrenaline from the adrenals prolongs the action of noradrenaline released at synapses in the ANS. This prolongs sympathetic arousal after the stressor’s removal. This is referred to as the ANS–adrenal medulla system or sympatho-adrenomedullary axis.

Resistance

If the stressor is not removed, there is a decrease in sympathetic activity but an increase in output from the other part of the adrenal gland, the adrenal cortex. This is controlled by the amount of adrenocorticotropic hormone (ACTH) in the blood. ACTH is released from the anterior pituitary (the ‘master’ endocrine gland) upon instructions from the hypothalamus. The adrenal cortex is essential for the maintenance of life and its removal results in death.

The effect of ACTH is to stimulate the adrenal cortex to release corticosteroids (or adrenocorticoid hormones), one group of which are the glucocorticoid hormones (chiefly, corticosterone, cortisol and hydrocortisone). These control and conserve the amount of glucose in the blood (gluconeogenesis), which helps to resist stress of all kinds. The glucocorticoids convert protein into glucose, make fats available for energy, increase blood flow and generally stimulate behavioural responsiveness. In this way, the anterior pituitary–adrenal cortex system (or hypothalamic-pituitary–adrenal axis) contributes to the fight-or-flight syndrome.

Exhaustion

Once ACTH and corticosteroids are circulating in the bloodstream, they tend to inhibit the further release of ACTH from the pituitary. If the stressor is removed during the resistance stage, then blood sugar levels will gradually return to normal. But if the stress situation continues, the pituitary–adrenal excitation continues. The body’s resources are now becoming depleted, the adrenals can no longer function properly, blood glucose levels drop and, in extreme cases, hypoglycaemia could result in death.
At this stage psychophysiological disorders develop, including hypertension, coronary artery disease (CAD), coronary heart disease (CHD), asthma and peptic ulcers. Selye calls these ‘diseases of adaptation’ (Figures 11.1 and 11.2).

**Evaluation of the general adaptation syndrome**

Lazarus cites a study of patients dying from injury or disease. Postmortem examination showed that those patients...
who remained unconscious had normal levels of corticosteroids, while the opposite was true for those who were conscious, presumably aware that they were dying. Lazarus infers from this that:

... some psychological awareness – akin to a conscious perception or appraisal – of the psychological significance of what is happening may be necessary to produce the adrenal cortical changes of the GAS.20

Although Selye helped us to understand how stressors affect the body, in order to understand what makes a psychological event stressful, we must put the person into the equation. In effect, says Lazarus: ‘... it takes both the stressful stimulus conditions and a vulnerable person to generate a stress reaction ...’

**HOW DOES STRESS MAKE US ILL?**

**An evolutionary perspective**

The sympathetic branch of the ANS responds as a unit, causing a state of generalized, undifferentiated arousal. This was probably of crucial importance in our evolutionary past, when our ancestors were frequently confronted by life-threatening dangers. This is precisely what the fight-or-flight syndrome is for. But although an increase in heart rate may be necessary to supply more blood to the muscles when facing a hungry-looking bear, it may be quite irrelevant to most of the stressors we face in modern life, which involve a far higher psychological element.

Most stressors do not pose a physical threat, but our nervous and endocrine systems have evolved in such a way that we typically react to stressors as if they did. What may have been adaptive responses for our ancestors have become maladaptive today. So, what happens to all that internal activity?

In the case of heart rate and blood pressure, chronic stress involves repeated episodes of increases in heart rate and blood pressure, which in turn produces increases in plaque formation within the cardiovascular system. Stress also produces an increase in blood cholesterol levels, through the action of adrenaline and noradrenaline on the release of free fatty acids. This produces a clumping together of cholesterol particles, leading to clots in the blood and in the artery walls, and occlusion of the arteries. In turn, raised heart rate is related to a more rapid build-up of cholesterol on artery walls. High blood pressure results in small lesions on the artery walls, and cholesterol tends to get trapped in these lesions.34

**Stress and the immune system**

The immune system (Figure 11.3) is a collection of billions of cells that travel through the bloodstream and move in and out of tissues and organs, defending the body against invasion by foreign agents such as bacteria, viruses and cancerous cells. The immune cells are produced mainly in the spleen, lymph nodes, thymus and bone marrow. The study of the effect of psychological factors on the immune system is called psychoneuroimmunology (PNI; see Ogden35).

Many people catch a cold soon after a period of stress because stress seems to reduce the immune system’s ability to fight off cold viruses (we become ‘run down’). Goetsch and Fuller refer to studies that show decreases in the activity of lymphocytes among medical students during their final exams (e.g. Kiecolt-Glaser et al.36). Lymphocytes (natural killer cells) are a particular type of white blood cell that normally fight off viruses and cancer cells. Levels of immunoglobulin A (IgA) increase immediately after an oral exam (if it appeared to go well) but not after a written exam, suggesting that the stress is not relieved until much later, when the exam results are known.37

Of course, none of these findings means that stress actually causes infections. Stress makes us more susceptible to infectious agents by temporarily suppressing immune function (the immunosuppressive effects of stress). Stressors that seem to have this effect include exams (see above) and the death of a spouse (see Chapter 57). For example, Schiefer et al. found that the immune systems of men whose wives had died from breast cancer functioned less well than before their wife’s death.38

Interleukin-b (see Figure 11.3) is produced soon after tissue damage, helping to remodel connective tissue in wounds and to form collagen (scar tissue). Kiecolt-Glaser et al. compared the rate of wound healing in two groups: (i) a group of 13 ‘high-stress’ women, caring for relatives with Alzheimer’s disease and (ii) a ‘stress-free’ matched control group.39 All the women underwent a 3.5-mm full-thickness punch biopsy on their non-dominant forearm. Healing took significantly longer in the caregivers than in the controls (48.7 days v. 39.3 days). Box 11.2 describes another study investigating psychological techniques to boost the immune system.

**Moderators and mediators of stress**

*Moderator variables* are antecedent conditions (e.g. personality, ethnic background, gender) that interact with exposure to stress to affect health outcome. *Mediator variables* intervene in the link between stress exposure and health outcome (e.g. appraisal38). If a mediator variable reduces the impact of a stressful event, then it is a ‘protective’ or ‘buffering’ variable (it softens or cushions the impact).

**Personality**

What is now referred to as *type A behaviour pattern (TABP)* was originally called ‘type A personality’ (a stable personality trait42). TABP is now conceptualized as a stereotypical set of behavioural responses, including:
• competitiveness and achievement orientation;
• aggressiveness and hostility;
• sense of time urgency.

Many early studies showed that people who display TABP were at much greater risk of high blood pressure and CHD, compared with type B people. However, these risks are only relative: the vast majority of type A people do not develop CHD, and many type B people do develop CHD.\(^{17}\) Also, most studies have found that TABP assessed immediately following a heart attack does not predict future attacks. This suggests that TABP is not a distinct risk for CHD in people already at risk for the disorder.\(^ {19}\)

However, there seem to be clear physiological differences between type A people and type B people in response to stress, even when the person is not conscious.\(^ {41}\) Krantz \textit{et al.} (see Fletcher\(^ {43}\)) found that, compared with type B patients, type A patients undergoing coronary bypass surgery showed greater blood-pressure changes while anaesthetized (by as much as 30 mmHg) and were much more likely to have complications during surgery, which could be attributed to enhanced sympathetic nervous system activity.

According to Temoshok, people with type C personalities are cancer-prone.\(^ {44}\) People with the type C personality have difficulty expressing emotion and tend to suppress or inhibit emotions, particularly negative emotions such as...
anger. Although there is no clear-cut evidence to show that these personality characteristics can actually cause cancer, it does seem likely that they influence the progression of cancer and, hence, the survival time of people with cancer.45

Greer and Morris found that women diagnosed with breast cancer showed significantly more emotional suppression than women with benign breast disease (especially among those aged under 50 years).46 This emotional suppression had been a characteristic for most of their life. Cooper and Faragher reported that experiencing a major stressful event is a significant predictor of breast cancer.47 This was especially so in women who did not express anger but who used denial as a form of coping (Box 11.3).

Self-esteem
This is an important factor in moderating stress (see Burnard et al.31). The study of CMHNs in Wales described above found that those with high self-esteem/self-worth used a wide range of coping skills to deal with work stress. However, 40 per cent of respondents reported low self-esteem and felt that others had little respect for them. Low self-esteem scores were associated with higher levels of psychological distress, greater emotional exhaustion, lower use of coping skills and increased alcohol consumption.

A positive and resilient self-esteem is a crucial resource in combating the negative implications for an individual that often accompany stressful events (see Carson et al.28). Research has shown a significant inverse relationship between self-esteem and symptoms of depression (the lower the self-esteem, the greater the symptoms of depression; see Carson et al.28). Although self-esteem has not featured much in the literature on nursing stress, Carson et al. believe that it is reasonable to predict that nurses with high self-esteem will have lower levels of stress and burnout, and better coping skills, than those with low self-esteem.

The Claybury community psychiatric nurse (CPN) study was a survey of stress, coping and burnout in 245 MHNs and 323 ward-based nurses in five large mental hospitals and two district hospital psychiatric units.28 A range of standardized measures were used, including the modified Rosenberg Self-Esteem Scale, the General Health Questionnaire (a well-validated measure of psychological distress) and the Maslach Burn-Out Scale.52 Overall, the results confirmed the prediction that levels of stress, burnout and use of coping skills are related to levels of self-esteem in MHNs.

**COPING WITH STRESS**

**What do we mean by ‘coping’?**

Lazarus and Folkman define coping as ‘... constantly changing cognitive and behavioural efforts to manage external and/or internal demands that are appraised as taxing or exceeding the resources of the person’.53

This mirrors the definition of stress as the individual’s belief that his or her available biological, psychological and social resources are not sufficient to meet the demands of the situation.
Different kinds of coping

According to Roger and Nash, the term ‘coping’ conjures up ideas about being able to handle any situation that comes our way. But in relation to stress, they distinguish between maladaptive and adaptive coping styles:

- **Maladaptive styles** involve failing to adjust appropriately to our environment and experiencing misery and unhappiness as a result. They can take the form of emotional and avoidance coping styles.
- **Adaptive styles** involve an appropriate adjustment to the environment and gaining from the experience. These can be either detached or rational.

In fact, the term ‘maladaptive coping’ is a contradiction in terms (Table 11.2).

Cohen and Lazarus classified all the coping strategies that a person might use into five general categories:

- **Direct action response**: the individual tries to directly change or manipulate his or her relationship to the stressful situation, such as escaping from or removing it.
- **Information-seeking**: the individual tries to understand the situation better and to predict future events related to the stressor.
- **Inhibition of action**: doing nothing. This may be the best course of action if the situation is seen as short-term.
- **Intrapsychic or palliative coping**: the individual reaps the situation (e.g. through the use of psychological defence mechanisms; see Chapter 19) or changes the internal environment (e.g. through drugs, alcohol, relaxation, meditation).
- **Turning to others**: for help and emotional support.

These five categories of coping overlap with the distinction between problem-focused coping (PFC) and emotion-focused coping (EFC) (Box 11.4).

An evaluation of different methods of coping

- Many researchers simply assume that EFC and avoidant coping are a less adaptive way of dealing with stress. But, as Lazarus and Folkman state, the effectiveness of coping depends on the situation. For example, a situa-

| Table 11.2 Maladaptive and adaptive coping and their short- and long-term consequences |
|-----------------------------------------------|---------------|-----------------------------------------------|---------------|
| Maladaptive coping                          | Adaptive coping                                      |                             |
| Emotional                                   | Feeling overpowered and helpless                      | Detached                     | Not seeing the problem or situation as a threat |
|                                              | Becoming miserable, depressed, angry                 | Keeping a sense of humour    |                                             |
|                                              | Taking out frustrations on other people              | Taking nothing personally and seeing the problem as separate from yourself |                                             |
|                                              | Preparing for the worst possible outcome and seeking sympathy from others | Resolving the issue by getting things into proportion |                                             |
|                                              | *Short-term benefits: expression of emotion*         | *Short-term benefits: able to stand back and take stock of problem* |                                             |
|                                              | *Long-term consequences: increasingly overwhelmed by problem* | *Long-term consequences: prevents overidentification with problem* |                                             |
| Avoidance                                   | Sitting tight and hoping it all goes away            | Rational                     | Using past experience to work out how to deal with the situation |
|                                              | Pretending there is nothing the matter if people ask |                                             | Taking action to change things               |
|                                              | Thinking about something else and talking about it as little as possible | Taking one step at a time and approaching the problem with logic |                                             |
|                                              | Trusting in fate and believing things will sort themselves out | Giving the situation full attention and treating it as a challenge to be met |                                             |
|                                              | *Short-term benefits: temporary relief as problem blocked out* | *Short-term benefits: logic determines resolution of problem* |                                             |
|                                              | *Long-term consequences: blocking out cannot be sustained* | *Long-term consequences: problems put into perspective* |                                             |

Adapted from Roger and Nash.
Stress management

Much of what we have said about coping with stress refers to what people do in a largely spontaneous way. In this informal sense, we all ‘manage’ our stress more or less effectively. More formally, the term ‘stress management’ refers to a range of physiological and psychological techniques used in a quite deliberate way, in a professional setting, to help people reduce their stress. These techniques may be used singly or in combination.

Psychotherapeutic drugs act directly on the ANS, and anxiolytic drugs are commonly used in cases of chronic stress. The benzodiazepines (a group of anxiolytic drugs) usually succeed in reducing the physiological effects of stress, but they may produce side effects, tolerance and physical dependence (see Chapter 58).

With biofeedback (see Chapter 14), the focus is on treating the symptoms of stress rather than the stressor itself. Biofeedback is based on the principle that stress can be reduced by gaining control over autonomic functions about which we normally have little knowledge, let alone control. The same is true for a number of procedures used to bring about a state of relaxation, in particular progressive muscle relaxation, meditation and hypnosis.

Cognitive restructuring refers to a number of specific methods aimed at trying to change the way the individual thinks about their life situation and self, in order to change their emotional responses and behaviour. This approach is based largely on the work of Beck (treatment of automatic thoughts) and Ellis (rational emotive therapy), two major forms of cognitive-behaviour therapy (CBT; see Chapter 66). This approach provides information to reduce uncertainty and to enhance the individual’s sense of control.

**KEY POINTS**

- Stress has been defined as a stimulus (corresponding to the engineering model), a response (corresponding to the physiological model) and an interaction between an organism and its environment (corresponding to the transactional model).
- The physiological model is based on Selye’s GAS, which comprises the alarm reaction, resistance and exhaustion.
- The alarm reaction involves changes in the sympathetic branch of the ANS, which are collectively called the fight-or-flight syndrome. This is associated with the ANS-adrenal-medulla system/sympathoadrenomedullary axis.
- Resistance is associated with the anterior pituitary-adrenal cortex system/hypothalamic-pituitary-adrenal axis.
- Exhaustion is related to psychophysiological disorders (‘diseases of adaptation’).
- Potential causes of stress (stressors) include disruption of circadian rhythms (e.g. shift work, jet lag), life changes (as measured by the SRRS) and occupation-linked stressors.
- Burnout is an occupational hazard for a variety of healthcare professionals, especially those working with terminally ill people.
- Chronic stress makes us ill through repeated increases in heart rate and blood pressure, increased blood cholesterol, and suppression of the functioning of the immune system (the immunosuppressive effects of stress).
- Personality and self-esteem represent moderators of the effects of stress.

**Box 11.4 Problem-focused and emotion-focused coping**

- **Problem-focused coping (PFC)** involves taking direct action in order to solve the problem, or seeking information that is relevant to a solution.
- **Emotion-focused coping (EFC)** involves trying to reduce the negative emotions that are part of the experience of stress.

Lazarus and Folkman claim that effective coping depends on the situation; sometimes using both kinds of coping might offer the best solution.53

- **Effectiveness must also take into account how long the stressor lasts.** With short-term stressors, avoidant strategies are preferable, while long-term stressors require more focused attention. This implies (i) that men would be better at coping with short-term problems (because of their predominant use of avoidant coping) and (ii) women would adjust better to less frequent but more extreme events (e.g. death of a spouse; see Stroebe57 and Chapter 57) because of their more frequent use of attentional strategies, which provides them with timely warning signs to take action.

- **Although many studies report that women engage more often than men in EFC, the majority of female coping is PFC:** the observation that women are emotion-oriented copers is a relative one and does not support the stereotype of all women as emotional copers.56

- **Stanton et al. have questioned the very concept of EFC.**58 They found that women worked through their emotions more often than men and that this greater effort to understand and express their emotions was more adaptive for them. Similarly, Stroebe has suggested that widowers may be more vulnerable to physical illness and depression compared with widows because widowers find it easier to avoid confrontation with feelings and to deal with the problems that are created by their wife’s death, rather than dealing with their grief.57 Widows can access their emotions and express them more easily.
○ Type A behaviour is associated with an increased risk of high blood pressure and CHD, while people with type C personalities may be cancer-prone.
○ So-called coping with stress can be both adaptive and maladaptive.
○ All coping strategies can be classified as direct action response, information-seeking, inhibition of action, intrapsychic/palliative coping, or turning to others for emotional support. These overlap with the distinction between problem-focused and emotion-focused coping.
○ Formal stress management refers to physiological and psychological techniques used by professionals to reduce people’s stress.
○ Physiological techniques include the use of anxiolytic drugs and biofeedback.
○ Many psychological techniques involve cognitive restructuring, which forms the basis of various types of CBT.

INTRODUCTION

Mr Spock in *Star Trek* often points out to Captain Kirk how much energy human beings waste through reacting emotionally to things, when a more logical and rational approach would be more productive. But would we be human if we did not react in this way? This is not to advocate ‘being emotional’ in the sense of losing control of our feelings, or being unable to consider things in a calm and detached way; but it is the richness of our emotions, and our capacity to both have feelings and think things through and reason that makes us unique as a species. Emotions set the tone of our experience and give life its vitality. Emotions are internal factors that can energize, direct and sustain behaviour.¹

At the same time, we often respond emotionally to events and situations that we believe make demands on us that we cannot meet, either because we do not have the necessary abilities or resources or because they force us to make very difficult choices and decisions. We describe these negative kinds of events as ‘stressful’ and our emotional responses to them as the experience of ‘stress’ (see Chapter 11).

One of the key issues running through research into the nature of emotional experience is to what extent it is a physiological phenomenon. Related to this is the question of whether different subjective emotions (feeling angry, afraid and so on) are also physiologically distinct. More recent theories have emphasized the role of cognitive factors in our experience of emotion and are collectively referred to as cognitive appraisal theories.

WHAT IS EMOTION?

Wundt, one of the founders of scientific psychology (see Chapter 9), believed that emotional experience can be described in terms of combinations of three dimensions – pleasantness/unpleasantness, calm/excitement and relaxation/tension (based on introspection). Schlosberg² also identified pleasantness/unpleasantness, together with acceptance/rejection and sleep/tension, based on photographs of posed facial expressions.

Ekman et al.³ and Ekman and Friesen⁴ identified six primary emotions: surprise, fear, disgust, anger, happiness and sadness, based on photos of posed facial expressions (Figure 12.1). These primary emotions are taken to be universal; that is, they are expressed facially in the same way, and are recognized as such, by members of diverse cultures. This suggests very strongly that the emotions are innate.

Plutchik proposed an ‘emotion wheel’ (Figure 12.2), in which eight basic or primary emotions (composed of four pairs of opposites) are shown inside the circle, with a further eight complex emotions on the outside.⁵ The primary emotions correspond to Ekman and Friesen’s six emotions, except that the terms ‘joy’ and ‘sorrow’ are used instead of ‘happiness’ and ‘sadness’, respectively, plus ‘acceptance’ and ‘expectancy’ are also included. Plutchik believes that the primary emotions are both biologically and subjectively distinct.
Basic or primary emotions

Ekman uses the term ‘basic’ to emphasize the role that evolution has played in shaping both the unique and the common features that emotions display, as well as their current function. Emotions evolved for their adaptive value in dealing with fundamental life tasks: they helped species to survive. Three major characteristics of emotions follow from this adaptive function:

- There are certain common elements in the contexts in which emotions are found to occur, despite individual and cultural differences in social learning.
- The emotions are likely to be observable in other primates (although it is possible that there are certain emotions that are unique to humans, there is no convincing evidence that this is so).
- The emotions can be aroused so quickly that they start to happen before we are even aware of them:

Quick onset is central to the adaptive value of emotions, mobilizing us quickly to respond to important events.

Emotions can occur with very rapid onset, through automatic appraisal (see below), with little awareness, and with involuntary changes in expression and physiology. Indeed, we often experience emotions as happening to us rather than chosen by us.

Evidence exists of distinctive patterns of autonomic nervous system (ANS) activity for different emotions (see below). Ekman believes that these patterns are likely to have evolved because they support patterns of motor behaviour that were adaptive for each of these emotions, preparing the organism for quite different actions. For example, fighting may have been the adaptive action in anger (which is consistent with the finding that blood flow increases to the hands when we are angry). There may also be unique patterns of central nervous system (CNS) activity for each emotion, which is not found in other mental activity.

Averill also recognizes the influence that an evolutionary approach has had in the study of emotions, defining basic emotions as those ‘that fulfil vital [to the survival of the species] biological functions.’ Like Ekman, Averill believes that basic emotions should be universal, be seen (at least in rudimentary form) in non-human primates and be heritable.

However, what is considered ‘basic’ varies between cultures and within the same culture over time. For example, in the Middle Ages, hope was classified as a basic emotion, but today hope is regarded as a secondary emotion (if it is considered an emotion at all) by most emotion theorists (Box 12.1).

**Figure 12.2 The emotion wheel**

---

**Box 12.1 The social construction of emotions**

According to social constructionism (see Gross), emotions are the products of culture. Human cultures influence the emotions by influencing their members’ beliefs, values, and social environments.

Emotions may be understood as enmeshed within an entire system of beliefs and values, so they cannot exist independently of the culture. For example, accida is an emotion that existed in Western cultures in medieval times but seems to have become extinct by about 1400. It involved a mixture of boredom with one’s religious duties, attempting to put off carrying them out, sadness about one’s religious failings, and a sense of loss of one’s former religious enthusiasm. It disappeared during the Renaissance, when values started to change. Today, someone facing the same religious ‘crisis’ is likely to feel guilt, an emotion related to a culture based on individual responsibility rather than spiritual duty.

According to Markus and Kitayama, ‘ego-focused’ emotions (e.g. anger, frustration, pride) are experienced more by people in individualist cultures with more independent selves. ‘Other-focused’ emotions (e.g. shame, belongingness, sympathy) are more common in collectivist cultures with more interdependent selves.

Most basic of all are emotions that are psychologically basic: when people are asked to recount emotional episodes that evoked their ‘true feelings’, they typically describe incidents that reinforce or transform or enhance their sense of self.

**Components of emotion**

For each distinct emotion, there are three components:

- The subjective experience of happiness, sadness, anger and so on
• **Physiological changes**, involving the ANS and the endocrine system, over which we have little if any conscious control; however, we may become aware of some of their effects (e.g. ‘butterflies in the stomach’, gooseflesh, sweating)

• **Associated behaviour** such as smiling, crying, frowning, running away or being ‘frozen to the spot’.

The latter two components are sometimes categorized together as ‘bodily reactions’, with the physiological changes being described as ‘visceral’ and the associated behaviour ‘skeletal’. This distinction relates to the ANS and CNS, respectively. However, although running away is largely under voluntary (CNS) control, crying and sweating definitely are not; and yet in all three cases, we infer another person’s emotional state from this observable behaviour.

Different theories of emotion are distinguished by:

- how they see the relationship between three components;
- the relative emphasis given to each component;
- how they see the relationship between the components and our cognitive appraisal or interpretation of the emotion-producing stimulus or situation.

Consistent with this is Parrott’s definition of an emotion as:

... a reaction to personally significant events, where ‘reaction’ is taken to include biological, cognitive and behavioural reactions, as well as subjective feelings of pleasure or displeasure.\(^9\)

---

**THEORIES OF EMOTION**

### The James–Lange theory

If there is a common-sense theory of emotion, it is that something happens that produces in us a subjective emotional experience and, as a result of this, certain bodily and/or behavioural changes occur. James (originally in 1878 and then in 1890) and Lange (at first quite independently of James) turned this common-sense view on its head. They argued that our emotional experience is the result, not the cause, of perceived bodily changes.

To give an example used by James, the common-sense view says that we meet a bear, are frightened and run. The James–Lange theory maintains that we are frightened because we run. Similarly, ‘We feel sorry because we cry, angry because we strike, afraid because we tremble ...’ According to James: ‘... the bodily changes follow directly the perception of the exciting fact, and ... our feeling of the same changes as they occur is the emotion.’\(^13\)

The crucial factor in the James–Lange theory is feedback from the bodily changes (Figure 12.3). We label our subjective state by inferring how we feel based on perception of our own bodily changes (‘I’m trembling, so I must be afraid’).

You may be able to think of situations in which you have reacted in a fairly automatic way. For example, if you slip while walking down stairs, only after you’ve grabbed the banister do you become aware of feeling frightened and a little shaken. It is almost as if the sudden change in your behaviour – rather than your reason for grabbing the banister in the first place – has caused the fear.

### Evaluation of the James–Lange theory

The theory implies that by deliberately altering our behaviour, we can control our emotional experiences. Try smiling – do you feel any happier? A crucial test (which James admitted would be very difficult to perform) would be to examine the emotional experience of a completely anaesthetized, but not intellectually or motor impaired, individual.

In the examples that James gives of inferring emotion from bodily changes, such as running away from the bear, he clearly attaches much more importance to skeletal rather than visceral changes. Parrott calls this the ‘peripheral’ approach.\(^9\) In this respect, the James–Lange theory probably differs from other theories, which usually mean ‘visceral’ when they say ‘physiological’. Given this emphasis on skeletal changes, there are two important studies that support the James–Lange theory (Box 12.2).

The Valins\(^14\) and Laird\(^15\) studies suggest that overt behaviour may cause subjective feelings without there being any

---

*Figure 12.3 James–Lange theory of emotion. (ANS: autonomic nervous system).*
obvious physiological arousal taking place: visceral changes may not be necessary. But neither Valins nor Laird attempted to measure any accompanying visceral changes. What if smiling triggers certain physiological changes? Might these changes, rather than the change in our facial muscles, be the real cause of our feeling happy? And, if so, is this quite damaging to the James–Lange theory, which places so much stress on behavioural (skeletal) changes?

Levenson et al. asked participants to move particular facial muscles, in order to simulate the emotional expression of fear, anger, surprise, disgust, sadness and happiness. The authors also monitored several physiological responses controlled by the ANS while this was going on. They found that the simulated expressions did alter ANS activity; for example, anger increased heart rate and skin temperature, fear increased heart rate but decreased skin temperature, and happiness decreased heart rate without affecting skin temperature.

In the James–Lange theory, these bodily changes occur spontaneously, rather than consciously and deliberately. This makes it difficult to draw any firm conclusions from experiments like those of Valins and Laird. However, both studies strongly suggest that physiological arousal is not sufficient to account for emotional experience. The fact that participants in the Valins study were prepared to infer emotion on the basis of (false) information about their reactions to stimuli suggests that physiological arousal may not even be necessary, and that cognitive factors may be sufficient. According to Parrott, for the body to ‘know’ how to respond appropriately, more than simply ‘perception of the exciting fact’ must be involved. The event (e.g. the bear) must be interpreted or evaluated (or appraised) as a threat. The James–Lange theory fails to account for why the bear is seen as frightening in the first place. (We shall return to this issue below.)

### Cannon's critique of the James–Lange theory

According to Cannon, there are four major faults with the James–Lange theory:

- The theory assumes that for each subjectively distinct emotion there is a corresponding set of physiological changes enabling us to label the emotion that we are experiencing.
- Even if this assumption were true, physiological arousal would still not be sufficient.
- Physiological arousal may not even be necessary.
- The speed with which we often experience emotions seems to exceed the speed of response of the viscera, so how could the physiological changes be the source of sudden emotion?

Cannon argued that ‘the same visceral changes occur in very different emotional states and in non-emotional states’. In other words, the James–Lange theory was built on the assumption that different emotional stimuli induce different patterns of ANS activity, and that perception of these different patterns results in different emotional experiences.

According to the Cannon–Bard theory, the ANS responds in the same way to all emotional stimuli: the sympathetic branch prepares the organism for flight or fight, through increased heart rate and blood pressure, pupil dilation, increased blood flow to the muscles, increased respiration and increased release of adrenaline and noradrenaline from the adrenal medulla. This means that there must be more to our emotional experience than simply physiological arousal, otherwise we would not be able to tell one emotional state from another.

### Evidence for physiological specificity

According to LeDoux, this represents ‘one of the most pesky problems in emotion research’. He points out that the emphasis of research has been on ANS activity, and this emphasis is due partly to Cannon’s criticism of the James–Lange theory.

The methods of Ax (Box 12.3) would be ethically unacceptable today, but his findings have been confirmed by others (e.g. Frankenheuser). Schachter confirmed Ax’s original findings that fear is influenced largely by adrenaline; but he also found that anger produces a mixed adrenaline–noradrenaline response and that pain produces a noradrenaline-like pattern. Schachter and Singer concluded:
Whether or not there are physiological distinctions among the various emotional states must be considered an open question. Any differences which do exist are at best rather subtle and the variety of emotion, mood and feeling states do not appear to be matched by an equal variety of visceral patterns.23

This conclusion is consistent with Schachter’s cognitive labelling theory, which sees physiological arousal as necessary for emotional experience,24 but the nature of the arousal is irrelevant (see below).

Less extreme and controversial methods than Ax’s include:

• the directed facial action method, in which participants are instructed to make the facial expressions characteristic of various emotions while ANS activity is recorded;
• the relived emotion method, in which participants are asked to think about previous emotional experiences while these measures are being made.

Levenson carried out a series of experiments using both methods. He maintains that it is a ‘myth’ that every emotion is autonomically different (Box 12.4). It seems far more likely that reliable differences will be found only between emotions for which there are different associated typical behaviours, and even among this smaller set it is quite unlikely that they will not share some features.

Even if there were identifiable patterns of physiological response associated with different subjective emotions, Cannon argued that such physiological changes themselves do not necessarily produce emotional states. In other words, physiological arousal is not sufficient. This was demonstrated by Maraño (Box 12.5).26 However, the study by Hohmann suggests that, although physiological changes are not sufficient for the experience of ‘full-blooded’ emotions, they may still be necessary (Box 12.6).27

Levenson et al. compared anger, disgust, fear and sadness (negative emotions), and happiness (positive emotion) and surprise.28 They identified a small number of fairly reliable differences in patterns of autonomic nervous system (ANS) activity, both between the negative emotions, and between the negative emotions as a group and happiness.

For example, anger, fear and sadness all produce larger increases in heart rate than disgust does, while anger produces a larger increase in finger temperature than fear does.

These differences have been found consistently across populations differing in occupation, age (from young people to 71- to 90-year-olds), culture (Americans and Minangkabau males living in western Sumatra, Indonesia) and gender, and across the directed facial action and relived emotion methods.

Levenson believes that positive emotions might not be associated with any particular pattern of behaviour, or, if they are, it would be characterized by low activity, making little metabolic demand on the ANS:

Instead of having distinctive autonomic signatures ... positive emotions might be associated with a state of physiological quiescence ... their primary function might be to ‘undo’ the autonomic activation produced by negative emotions ... to restore the organism to its pre-arousal state in a more efficient and rapid manner than would be the case if the negative emotions were allowed to run their natural course.25

This implies that, at least in our present state of knowledge, we cannot draw general conclusions about the specificity of the body’s response to emotional stimuli – it depends partly on which emotion (positive or negative) we are talking about.

### Box 12.3 Be afraid: the Ax man’s coming

In a famous, but ethically highly dubious, experiment, Ax measured various aspects of electrodigital (skin conductance), electromyographic (muscle action potential), cardiovascular and respiratory activity in participants who were deliberately frightened and made angry.20

The participants were told that they were participating in a study of hypertension and were asked to lie quietly on a couch while physiological measures were taken.

As the electrodes were attached, it was casually mentioned that the technician who usually operated the technical equipment in an adjacent room was sick, and a man who had recently been fired for incompetence and arrogance was filling in for him. A few minutes later, after baseline measures had been recorded, either the ‘anger condition’ followed by the ‘fear condition’ occurred, or vice versa.

In the fear condition, a continuous mild shock was administered to one finger, without any warning or explanation. The intensity increased gradually, until the participant complained. Then sparks were made to jump.

In the anger condition, the technician (an actor) entered the room and spent 5 minutes checking the wiring. During this time, he jostled the participant, criticised the attending nurse, and blamed the participant for causing a fault in the equipment.

Of 14 different measures taken, Ax found that seven were significantly different between the two conditions. For example, fear was associated with increased heart rate, skin conduction level, muscle action potential frequency and breathing rate (reflecting the effects of adrenaline). Anger was accompanied by increased diastolic blood pressure, frequency of spontaneous skin conduction responses and action potential size (reflecting the greater influence of noradrenaline).

### Box 12.4 The physiology of positive and negative emotions

Levenson et al. compared anger, disgust, fear and sadness (negative emotions), and happiness (positive emotion) and surprise. They identified a small number of fairly reliable differences in patterns of autonomic nervous system (ANS) activity, both between the negative emotions, and between the negative emotions as a group and happiness.

For example, anger, fear and sadness all produce larger increases in heart rate than disgust does, while anger produces a larger increase in finger temperature than fear does.

These differences have been found consistently across populations differing in occupation, age (from young people to 71- to 90-year-olds), culture (Americans and Minangkabau males living in western Sumatra, Indonesia) and gender, and across the directed facial action and relived emotion methods.

Levenson believes that positive emotions might not be associated with any particular pattern of behaviour, or, if they are, it would be characterized by low activity, making little metabolic demand on the ANS:

Instead of having distinctive autonomic signatures ... positive emotions might be associated with a state of physiological quiescence ... their primary function might be to ‘undo’ the autonomic activation produced by negative emotions ... to restore the organism to its pre-arousal state in a more efficient and rapid manner than would be the case if the negative emotions were allowed to run their natural course.

This implies that, at least in our present state of knowledge, we cannot draw general conclusions about the specificity of the body’s response to emotional stimuli – it depends partly on which emotion (positive or negative) we are talking about.
According to Schachter, what Marañon’s and Hohmann’s participants reported is precisely what would be expected from his cognitive labelling theory, which sees emotional experience as a joint function of cognitive and physiological factors (see below).24

**The Cannon–Bard theory**

Cannon removed the sympathetic nervous system in cats, and Sherrington severed the spinal cord and vagus nerve in dogs. In both cases, feedback from the viscera to the brain was prevented, but the animals showed apparently normal emotional reactions. Cannon took these findings to mean that physiological changes may not even be necessary for emotional experience. In addition, Dana studied a patient with a spinal-cord lesion: despite having no sympathetic functioning and only extremely limited muscular movement, the patient showed a range of emotions, including grief, joy, displeasure and affection. Similarly, Chwalisz et al. found that people with spinal-cord injuries experience emotion as intensely as before the injury, as intensely as ‘normal’ people, and as intensely as people with spinal-cord injuries that do not block bodily sensations. These findings seem to support Cannon’s view.

As Figure 12.4 shows, the subjective emotion is quite independent of the physiological changes involved. The emotion-producing stimulus is processed by the thalamus. This sends impulses to the cortex, where the emotion is consciously experienced, and to the hypothalamus, which sets in motion certain autonomic physiological changes.

**An evaluation of the Cannon–Bard theory**

Cannon also questioned how, because we often feel emotions quite rapidly and yet the viscera are quite slow to react, the physiological changes could be the source of such sudden emotion (as required by the James–Lange theory). However, although the viscera are not sensitive to certain kinds of stimulation (e.g. burning, cutting), they provide much better feedback than Cannon suspected. Many visceral changes can occur sufficiently quickly that they could be the causes of feelings of emotion.

Pinel advocates a position falling between the extreme views represented by the Cannon–Bard and James–Lange theories. On the one hand, the Cannon–Bard view that the ANS responds in the same way to all emotional stimuli is clearly incorrect: several differences have been well documented. On the other hand, there is insufficient evidence to make a strong case for the James–Lange view that each emotion is characterized by a different pattern of ANS activity.

**Schachter’s cognitive labelling theory**

According to Schachter, Cannon was wrong in thinking that bodily changes and the experience of emotion are independent, and the James–Lange theory was mistaken in claiming that physiological changes cause the feeling of emotion. Although sharing the James–Lange belief that physiological changes precede the experience of emotion,
Schachter argues that we have to decide which particular emotion we are feeling. The label we attach to our arousal depends on what we attribute that arousal to (Figure 12.5).

Schachter is saying that physiological arousal (factor 1) is necessary for the experience of emotion, but the nature of arousal is immaterial: what is important is how we interpret that arousal (factor 2). Hence, the theory is also known as the **two-factor theory of emotion**. The classic experiment that demonstrates this cognitive theory of emotion is Schachter and Singer’s ‘adrenaline experiment’ (Box 12.7).

Schachter and Singer were testing three interrelated hypotheses regarding the interaction between physiological and cognitive factors in the experience of emotion:

- If we experience a state of physiological arousal for which we have no immediate explanation, we will label this state and describe it in terms of the cognitions available. So, precisely the same state of arousal could receive different labels (e.g. ‘euphoria’/‘anger’ – groups B and C). (Physiological arousal and cognitive labelling are necessary.)
- If we experience a state of physiological arousal for which we have a completely appropriate explanation (e.g. ‘I’ve just been given an injection of adrenaline’), we will label this state accordingly (group A).
- Given the same circumstances, we will react emotionally or describe our feelings as emotions only to the extent

---

**Box 12.7 Schachter and Singer’s adrenaline experiment**

Participants were given an injection of adrenaline but told that they were given a vitamin injection in order to see its effect on vision. The participants were then tested under one of four conditions:

- **Group A** participants were given accurate information about the side effects of the injection (palpitations, tightness in the throat, tremor, sweating).
- **Group B** participants were given false information about the side effects (itching, headache).
- **Group C** participants were given no information about the side effects.
- **Group D** (control group) participants were given a saline injection but otherwise treated like group C participants.

Before being given a ‘vision test’, each participant (one at a time) sat in a waiting room with another ‘participant’ (a stooge of the experimenters). For half the participants in each condition, the stooge acted either in a happy, frivolous way (making paper aeroplanes, laughing out loud, playing with a hula-hoop: euphoria condition), or very angrily (eventually tearing up the questionnaire that he and every participant was asked to complete: anger condition). (The group B condition was run only with a euphoric stooge.)

Participants’ emotional experience was assessed in two ways:

- Observers’ ratings of the degree to which they joined in with the stooge’s behaviour.
- Self-report scales.

As predicted:

- participants in groups A and D were much less likely to join in with the stooge or to report feeling euphoric or angry;
- participants in groups B and C were much more likely to assume the stooge’s behaviour and emotional state.

---

**Figure 12.5 Schachter’s cognitive labelling (or two-factor) theory. (ANS: autonomic nervous system).**
that we experience a state of physiological arousal (groups A–C). (Physiological arousal is necessary.)

**An evaluation of cognitive labelling theory**

- Schachter and Wheeler confirmed these results by injecting participants with either adrenaline or chlorpromazine (which inhibits arousal); controls were injected with a placebo. While watching a slapstick comedy, the adrenaline participants laughed more, and the chlorpromazine participants less, than the controls.

- Dutton and Aron’s study (Box 12.8) confirms Schachter’s claim that the autonomic arousal that accompanies all emotions is similar and that it is our interpretation of that arousal that matters – even though sometimes this results in our misidentifying our emotions. Dutton and Aron’s suspension-bridge participants seemed to be mislabelling their fear as sexual attraction to the interviewer.

- The focus of Schachter’s model is an atypical state of affairs, where the participant is unsure about the cause of arousal (groups B and C). But Schachter admitted that usually we are aware of a precipitating situation before the onset of arousal (which usually takes 1–2 seconds to reach consciousness). Therefore, it is normally perfectly obvious to us what aspects of the situation have provoked the emotion. However, even here the meaning of the emotion-inducing circumstances requires some cognitive analysis before the emotion can be labelled.

- Schachter claims that the *quantitative* aspect of emotion can arise without cognitive mediation (‘Am I in a state of emotional arousal?’ – as in Valins’ study). But the *qualitative* aspect requires prior cognition (‘What emotion is it that I am experiencing?’ – as in Laird’s study). Mandler has called Schachter’s theory the ‘jukebox theory’ – arousal is like the coin that gets the machine going, and cognition is the button we push to select the emotional tune.

- According to Parkinson, the view that affect (emotion) is post-cognitive is now probably the most popular attitude among emotion theorists. But even if we accept the important role of cognitive factors, is our emotional experience really as labile or malleable as Schachter claims? Are environmental cues really as easily accepted as the basis for inferences about our own feelings?

- Using the original Schachter and Singer paradigm, several studies have concluded that when we try to explain a state of arousal, we do not merely use others’ behaviour as a guide to what we are feeling. We call on many other sources of information as well, particularly our own past history: we search for previous occasions on which we felt this arousal state to explain why it is occurring now. Although other people’s behaviour might suggest – or even dictate (through conformity) – how we should behave in that situation, it does not tell us how we’re feeling. At the very least, others’ behaviour must in some way be appropriate.

- These later studies also found that people who do not have a ready-made explanation for their adrenaline-produced arousal are more likely to attach a negative emotional label to it, such as unease or nervousness, similar to ‘free-floating anxiety’. This suggests that emotional lability is not as great as Schachter maintains: unexplained arousal has a negative, unpleasant quality about it.

---

**Box 12.8 Falling in love on a suspension bridge**

The study participants were unsuspecting males, aged 18–35 years, visiting the Capilano Canyon in British Columbia, Canada.

An attractive female interviewer approached the men and asked them questions as part of a survey on the effects of scenery on creativity. One of the things the men were asked to do was invent a short story about an ambiguous picture of a woman (a picture from the Thematic Apperception Test (TAT); see Chapter 15). This was later scored for sexual content, taken to reflect the men’s sexual attraction towards the interviewer.

Some men were interviewed on an extremely unstable suspension bridge, less than 2 metres wide and 150 metres long, composed of wooden boards attached to wire cables, running from one side of the canyon to the other. This bridge, about 75 metres above the canyon, tends to sway, tilt and wobble, giving the impression that one is about to fall over the side. There are only very low handrails of wire cable for support (high arousal condition).

Other men were interviewed on a solid wooden bridge upstream, about 3 metres above a shallow rivulet, with high handrails and without any swaying or tilting (low arousal condition).

As predicted, the stories of the men in the high arousal condition contained significantly more sexual imagery.

The interviewer also invited the men to contact her if they wanted more information about the research. Again in line with predictions, four times as many men from the high arousal condition contacted the researcher compared with men in the low arousal condition.

To show that arousal was the independent variable, Dutton and Aron also arranged for another group of men to be interviewed at least 10 minutes after crossing the suspension bridge. By this time, the symptoms of their physical arousal should have been declining. These non-aroused men did not show the signs of sexual arousal shown by those in the high arousal condition.
The role of attribution

According to Schachter, group A participants in the adrenaline experiment could attribute their arousal to the injection (they had a ready-made explanation and so did not need an emotional explanation). For those in groups B and C, however, no such ready-made explanation was available, and so the stooge’s behaviour was used as a cue for explaining their own state of arousal (as either euphoria or anger).

Taking one of James’s original examples (running away from the bear), the original cause of the bodily reactions (the bear) is irrelevant. This is because our emotional experience is based on feedback from our bodily reactions (running away). But for Schachter, it is what we attribute our arousal to that determines the label we give to it. In the adrenaline experiment, the initially unexplained arousal is attributed to the (rather extreme) behaviour of the confederate and so is labelled euphoria or anger accordingly.

Similarly, the men in Dutton and Aron’s experiment who were tested on the swaying suspension bridge were unaware of the ‘real’ cause of their arousal. They attributed it instead to the female interviewer. We know that arousal was the independent variable, and it is highly likely that, if the attractive interviewer had not approached the men, they would have labelled their arousal ‘fear’, because it would have been attributed to a frightening stimulus (the bridge).

What all these examples show is that the cognitive labelling theory is essentially based on attributional principles (see Gross9). This represents a major form of influence that Schachter’s theory has had on cognitive theories of emotion in general.

According to Weiner, certain kinds of attribution produce specific emotions.41,42 For example, success produces a very general positive feeling (e.g. happiness), while failure produces a very general negative feeling (e.g. sadness). But if the outcome (either success or failure) either is very different from what is expected or has very important consequences, then we try to figure out the reasons for or causes of the outcome. These reasons will take the form of internal or external attributions, which in turn can be broken down into controllable or uncontrollable. It is the combination of internal/external and controllable/uncontrollable that will determine specific emotional responses (Figure 12.6).

The misattribution effect

The adrenaline and suspension-bridge experiments show that people can make mistakes in how they attribute their arousal. This mislabelling of our feelings, and drawing mistaken conclusions about the causes of those feelings, is called the misattribution effect.43

As part of their suspension-bridge experiment, and in a later experiment, Dutton and Aron invited male students to participate in a learning experiment.35,44 After meeting an attractive female partner, half the students were frightened with the news that they would be suffering some ‘quite painful’ electric shocks. Before the experiment was due to begin, they were given a short questionnaire ‘to get some information on your present feelings and reactions, since these often influence people on the learning task’. Asked how much they would like to date and kiss their partner, the aroused (frightened) men expressed more intense attraction than the non-frightened men.

By definition, the female partner was sexually attractive, and so it was far easier for the men to transfer their arousal to her and to mislabel their arousal as sexual. In this way, the female partner represented a salient or credible source of arousal.45 (She also represents a clear, unambiguous source of arousal.) Similarly, if female participants are

shown slides of attractive nude males, it may be easy to alter their preferences among the pictures based on false heart-rate feedback, whereas this would be very difficult to achieve if the nude males were replaced by slides of naked hippos. (This is a deliberately modified version of an example given by Taylor et al.46)

Cognitive appraisal or affective primacy?
When evaluating the James–Lange theory earlier, we noted that it fails to account for why a bear, say, should make us run away. In other words, it fails to take into account our appraisal of the emotional ‘stimulus’ (Box 12.9). Appraisal is the thinking that leads to emotion,9 and appraisal theory is a development of Schachter’s cognitive labelling theory.

According to Lazarus, some degree of cognitive processing is an essential prerequisite for an affective reaction to a stimulus to occur and is an integral feature of all emotional states. For Lazarus, ‘... emotion results from evaluative perception of a relationship (actual, imagined or anticipated) between a person (or animal) and the environment’.47

Lazarus proposes that cognitive appraisal invariably precedes any affective reaction, although it does not have to involve any conscious processing. Zajonc argues that there is generally little direct evidence of either the existence or nature of such preconscious cognitive processing49 (although the study of subliminal perception suggests otherwise; see Gross50). Zajonc argues that cognition and affect operate as independent systems, and an emotional response may precede cognitive processes under certain circumstances. For example, we may meet someone very briefly and form a positive or negative impression, despite not being able to remember any detailed information about them later, such as hair or eye colour.51

Parrott asks how it is possible to describe certain emotions as ‘irrational’ if emotions do not intrinsically entail beliefs.9 Also, most emotions are ‘about’ something – and this is cognitive. The most important problem for Zajonc is that how we think about a situation influences how we feel (e.g. why we think someone behaved as they did determines whether we feel angry or sympathetic; see Figure 12.6).

Zajonc seems to overestimate the amount of cognitive processing that Lazarus and other cognitive appraisal theorists are claiming. For example, Lazarus simply argues that some minimal cognitive analysis at some level always precedes emotional experience. But this can be quite automatic, and so ‘cognitive appraisal’ is quite consistent with the sense of ‘immediacy’ that so much emotional experience has (and which Frijda sees as a characteristic of emotion53).

What is ‘an emotion’?
Clore defines emotions as mental states.53 Neither physiological arousal nor feeling states provide the best way of trying to capture the nature of an emotion. Emotions are special kinds of feeling, namely those that we judge to have an emotional cause. This is why feelings that are generated artificially by electrical stimulation or hormone injection (or some other non-cognitive means) are not emotions (see Box 12.5). For Clore, emotion terms seem to refer to something beyond feelings, to psychological states of which feelings are perhaps a necessary but not a sufficient condition.

Many of the examples Zajonc gives of emotion without cognition (affective primacy or ‘preferences need no inferences’) do not seem to describe emotional states at all. For example, when someone leaps out in front of you and shouts ‘Boo’, your physiological and bodily response (including your facial expression) would be described more accurately as a startle reflex than as fear.

According to Scherer, the classic debate between Lazarus and Zajonc, which had a major impact on the psychology of emotion during the 1980s, was concerned mostly with the level of processing involved – and not with whether any processing took place.54 This, in turn, revolved around the definition of ‘cognition’.

What is cognition?
If ‘cognition’ means or includes basic sensory processing, then most, if not all, emotions will have some cognitive component. However, LeDoux19 and Panksepp,55 both biologists, suggest that the brain circuitry underlying emotion and cognition is different. Cognition is seen as depending on the neocortex and hippocampus. If ‘cognition’ is restricted to processes involving these brain areas, then emotion can occur without cognition, since non-humans with extensive lesions in these structures still display emotional responses.

---

**Box 12.9 Subcision in the Arunta**48

Participants were shown a film (Subcision in the Arunta) that depicts aboriginal boys undergoing circumcision as part of a puberty rite. The boys are shown having their penis cut with a jagged flint knife. This usually causes high levels of stress in viewers of the film (and probably in the boys too). The soundtrack was manipulated, so that:

- the pain, jaggedness of the knife and so on were emphasized (trauma);
- the boys’ anticipation of entering manhood was stressed (denial);
- the emotional elements were ignored and the traditions of the aboriginal people were emphasized (intellectualization);
- there was no commentary (silent control).

As predicted, arousal (measured by galvanic skin response (GSR) and heart rate) was highest in the trauma condition, next highest in the control condition, and lowest in the other two conditions.

What we tell ourselves about external situations (cognitive appraisal) influences our level of arousal.
CONCLUSIONS

According to Davidson and Ekman, most theorists now acknowledge that emotion can be elicited in the absence of conscious cognitive mediation. If a broad view of cognition is taken, then most would also agree that some cognitive processing is required for most emotion. Dalgleish maintains that the view that cognition is an integral part of emotion is predominant within the psychology of emotion. The challenge is to specify more precisely the types of cognitive processing that may be critical to the emotion generation process, and to identify the neural circuitries that underlie emotion and cognition respectively. We also need to study the interactions between emotion and cognition.

KEY POINTS

- Ekman and Friesen identify six primary universal emotions, which are probably innate. Plutchik’s emotion wheel also incorporates primary emotions, but distinguishes these from complex emotions.
- An evolutionary approach to understanding primary or basic emotions includes considering their current function. But ‘basic’ emotions differ between cultures and over time within the same culture. They may be psychologically or culturally basic – rather than biologically basic.
- According to social constructionism, emotions are culturally and historically relative. They exist within a system of beliefs and values, which differ between cultures and change over time.
- For each distinct emotion, there is the subjective experience, physiological changes, associated behaviour and cognitive appraisal of the emotion-producing stimulus/situation.
- The James–Lange theory turns the common-sense theory of emotion on its head, by claiming that our emotional experience is the result of perceived bodily changes, in particular skeletal changes.
- Studies by Valins (using the false feedback paradigm) and Laird (testing the facial feedback hypothesis) support the James–Lange theory, although they fail to take into account any visceral changes that may be taking place. They both suggest that physiological arousal is not sufficient to account for emotional experience.
- Cannon criticized the James–Lange theory for assuming that different emotional states are associated with different patterns of ANS activity. The Cannon–Bard theory claims that the ANS responds in the same way to all emotional stimuli.
- Using the directed facial action and the relived emotion methods, Levenson reports physiological differences between anger, disgust, fear and sadness. Both the James–Lange and the Cannon–Bard theories take too extreme a view regarding physiological specificity, and the truth lies somewhere in between.
- Marimon’s and Hohmann’s studies support Cannon’s claim that physiological arousal is not sufficient for emotional experience, although they indicate that it is necessary. However, Cannon’s own study of cats, plus those of Sherrington and Dana, suggest that it might not even be necessary.

REFERENCES

According to Titchener, a student of Wundt: ‘The doctrine of attention is the nerve of the whole psychological system’. However, the Gestalt psychologists (see Box 9.1 in Chapter 9) believed that the concept of attention was unnecessary (a stimulus array’s properties were sufficient to predict the perceptual response to it: see Chapter 16). The behaviourists argued that, since ‘attention’ was unobservable, it was not worthy of experimental study (see Chapters 10 and 14).

Interest in the study of attention re-emerged following the publication of Broadbent’s *Perception and Communication*, which also had a great impact on the development of cognitive psychology overall. Broadbent argued that the world is composed of many more sensations than can be handled by the perceptual and cognitive capabilities of the human observer. To cope with the flood of available information, humans must selectively attend to only some information and somehow ‘tune out’ the rest. Attention, therefore, is the result of a limited-capacity information-processing system. Solso calls this a ‘pipeline’ theory. To understand our ability to selectively attend to things, researchers study focused (or selective) attention.

Central to the information-processing approach is the computer analogy. This is arguably most evident in explanations of memory (see Chapter 17) and attention. Concepts such as buffer store and limited-capacity processor are drawn from information technology (IT) and built into the models of attention that we discuss in this chapter.

Almost all the early models of attention assumed *serial processing*, a step-by-step process in which each operation is carried out in turn. The first of these was Broadbent’s *filter model*, followed by Treisman’s *attenuation model* and the *pertinence model*. These are all single-channel models of selective attention. But early attempts to explain *divided attention*, such as Kahneman’s *central capacity theory*, also assumed serial processing. In *parallel processing*, two or more operations are carried out at the same time. This is the view taken in Allport’s *multi-channel theory* of divided attention (doing more than one thing at a time).

Assumptions about serial and parallel processing reflect changes in the underlying computer analogy, which in turn reflect developments in computer technology. For much of the 1950s and 1960s, computers were capable only of serial processing. During the 1980s and 1990s, machines capable of massive parallel processing were built, and theorists have returned to an earlier belief that cognitive theories should be based more closely on the brain’s neural networks. The human brain is the parallel processing machine par excellence.

**WHAT IS ATTENTION?**

One famous definition of attention is that of William James, according to whom:

> It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others.

Although we cannot necessarily equate attention with consciousness (see below), James’s definition underlines the selective nature of attention. This is echoed in Solso’s definition: ‘... the concentration of mental effort on sensory or mental events’. However, this is only one of two major ways in which attention has been defined and investigated. A crucial distinction is made between the following:

- The mechanisms by which certain information is registered and other information is rejected, whether or not the latter enters conscious awareness (*selective* or *focused attention*).
- Some upper limit to the amount of processing that can be performed on incoming information at any one time (*capacity* or *divided attention*).

As we saw in Chapter 10, the term ‘attention’ has also been used to refer to arousal level, vigilance, and the ability to stay alert and concentrate.
METHODS OF STUDYING ATTENTION

Selective attention

People are presented with two or more simultaneous ‘messages’ and are instructed to process and respond to only one of them. The most popular way of doing this is to use shadowing, in which one message is fed into the left ear and a different message into the right ear (through headphones). Participants have to repeat one of these messages aloud as they hear it.

The shadowing technique is a particular form of dichotic listening. This is the simultaneous reception of two different stimulus inputs, one to each ear. Shadowing was first used by Cherry, who wanted to study the cocktail party phenomenon, in which we manage to select one or two voices to listen to from the hubbub of conversations taking place at the same time and in the same room. The participant is asked to select, which can tell us something about the selection process and what happens to unattended stimuli. Most studies have looked at auditory attention.

Divided attention

In the dual-task technique, people are asked to attend and respond to both or all of the messages. Whereas shadowing focuses attention on a particular message, the dual-task method deliberately divides the participant’s attention. This provides useful information about a person’s processing limitations, attention mechanisms and their capacity.

SELECTIVE (OR FOCUSED) AUDITORY ATTENTION

Cherry’s dichotic listening and shadowing research

In his initial experiments, Cherry’s participants wore headphones through which pairs of spoken prose messages were presented to both ears simultaneously (binaural listening). Cherry found that various physical differences affected a person’s ability to select one of the messages to attend to, in particular voice intensity, the speaker’s location and the speaker’s gender. Cherry also found that, when these differences were controlled for in the two messages (so that each message was, say, spoken in an equally intense female voice), their meaning was extremely difficult to separate. In later experiments, Cherry used dichotic listening and shadowing. Although participants were able to shadow the specified message, little of the non-shadowed message was remembered. Box 13.1 lists other research findings from shadowing.

Box 13.1 Other research findings using shadowing

- Little of the non-shadowed message was remembered, even when the same word was presented 35 times to the non-shadowed ear.
- Participants did not notice whether the message was spoken in a foreign language or changed from English to a different language.
- Although speech played backwards was reported as having ‘something queer about it’, most participants believed it to be normal speech.
- A pure tone of 400 cycles/s was nearly always noticed, as was a change of voice from male to female or from female to male.

These data suggested that, although the physical properties of the message in the non-shadowed ear were ‘heard’, semantic content (its meaning) was completely lost.

Researchers quickly moved on from Cherry’s original question about how we can attend to one conversation, and began asking why so little seemed to be remembered about the other conversations.

Broadbent’s split-span studies

Broadbent reported the results of a series of studies using the split-span procedure. In this study, three digits (e.g. 8, 2, 1) are presented via headphones to one ear at the rate of one digit every half-second. Simultaneously, three different digits (e.g. 7, 3, 4) are presented to the other ear. The task is to listen to the two sets of numbers and then write down as much as can be remembered.

The digits can be recalled either:

- according to the ear of presentation – ear-by-ear recall: the numbers above could be recalled as either 8, 2, 1, 7, 3, 4 or 7, 3, 4, 8, 2, 1; or
- according to their chronological order of presentation – pair-by-pair recall. Since the digits have been presented in pairs, this would involve recalling the first pair (8, 7 or 7, 8), followed by the second pair (2, 3 or 3, 2) and finally the third pair (1, 4 or 4, 1).

When subjects are simply given a list of six digits at a rate of one every half-second, serial recall is typically 95 per cent accurate. However, Broadbent found that the split-span procedure produced accurate recall only 65 per cent of the time. Moreover, pair-by-pair recall was considerably poorer than ear-by-ear recall. If given a choice, people preferred ear-by-ear recall.

SINGLE-CHANNEL THEORIES OF FOCUSED AUDITORY ATTENTION

Single-channel theories propose that somewhere in information processing is a ‘bottleneck’ or filter that allows some
information to be passed on for further analysis, while the other information is either discarded or processed to only a limited degree. The three theories that have been proposed differ mainly over whether the filtering takes place early or late in information-processing. This means that they differ in terms of the nature and extent of processing of the non-attended material.

**Broadbent’s early-selection filter theory**

Broadbent’s theory was the first systematic attempt to explain both Cherry’s findings and the findings of split-span experiments. Broadbent assumes that our ability to process information is capacity-limited. Information from the senses passes ‘in parallel’ to a short-term store. This is a temporary ‘buffer system’, which holds information until it can be processed further and, effectively, extends the duration of a stimulus (see Chapter 17). The various types of information (e.g. two or more voices) are preserved in their original form and then passed to a selective filter. This operates on the basis of the information’s physical characteristics, selecting one source for further analysis and rejecting all others.

Information allowed through the filter reaches a limited-capacity channel (the filter is necessary precisely because the channel is capacity-limited). This corresponds to the ‘span of consciousness’, or what we experience as happening now. The information allowed through the filter is analysed in that it is recognized, possibly rehearsed and then transferred to the motor effectors (muscles), producing an appropriate response (Figure 13.1).

Broadbent considered the short-term store to be capable of holding information for a period of time before it decayed. So, two simultaneous stimuli can be processed, provided that the processor can get back to the store before the information in it has disappeared. Consequently, attending to one thing does not necessarily mean that everything else is lost. However, Broadbent maintained that processing two different pieces of information from two channels would always take longer, and be less efficient, than processing the same information from one channel. This is because switching attention between channels takes a substantial period of time.

**Tests of Broadbent’s theory**

According to the filter theory, (i) the non-shadowed message is not allowed to pass through the filter and (ii) the input to the relevant ear is the physical property on which the information is selected.

However, the theory assumes that, because the non-shadowed message is filtered out according to its physical characteristics, its meaning should not be subject to any sort of higher-level analysis. But when we are at a party, our attention sometimes switches from the person with whom we are conversing to another part of the room (e.g. if we hear our name mentioned). This was demonstrated experimentally by Moray, who found that when the participant’s name was presented to the non-attended (non-shadowed) ear, attention switched to that ear about one-third of the time.

**An evaluation of Broadbent’s theory**

- Treisman found that if meaningful material presented to the attended ear was switched in mid-sentence to the non-attended ear, participants would occasionally change the focus of their attention to the non-attended ear and then shadow that material before changing back to the attended ear.
- Treisman discovered that if a French translation of the shadowed material was presented as non-shadowed material, some bilingual participants realized that the shadowed and non-shadowed material had the same meaning.
- Corteen and Wood conditioned participants to produce a galvanic skin response (GSR) whenever they heard a particular target word. A small electric shock was delivered immediately after the target word was heard.
The target word produced a GSR when presented to the non-attended ear, as did synonyms. However, GSRs did not occur every time the conditioned words were presented.

- Mackay presented the word ‘bank’ in a sentence, and participants subsequently had to recognize the sentence they had heard. Recognition was influenced by whether the word ‘river’ or ‘money’ had been presented to the non-attended ear.\(^{18}\)

These studies, and that of Gray and Wedderburn (Box 13.2),\(^ {19}\) suggest that the meaning of the input to the non-attended ear is processed at least some of the time. Further, Underwood found that participants trained at shadowing can detect two-thirds of the material presented to the non-attended ear.\(^ {20}\) This throws doubt on Broadbent’s claim that the non-shadowed message is always rejected at an early stage of processing. Also, when the material used is sufficiently different (such as one being auditory and the other visual), then memory for the non-shadowed message is good. This indicates that the material must have been processed at a higher level than that proposed by Broadbent.\(^ {21}\)

**Treisman’s attenuation (or stimulus-analysis system) model**

According to Treisman,\(^ {4,16}\) competing information is analysed for things other than its physical properties, including sounds, syllable patterns, grammatical structure and the information’s meaning.\(^ {15}\) Treisman suggested that the non-shadowed message is not filtered out early on, but that the selective filter *attenuates* it (Figure 13.2). So, a

---

**Box 13.2 Why use one ear when two will do?\(^ {19}\)**

Gray and Wedderburn presented, to each ear alternately, the syllables composing a word, plus random digits. Thus, when one ear ‘heard’ a syllable, the other ‘heard’ a digit. For example, in one experiment, participants heard the following:

- **Left ear:** OB 2 TIVE
- **Right ear:** 6 JEC 9

In other experiments, phrases were used in place of words, such as ‘Dear Aunt Jane’, ‘Mice eat cheese’ and ‘What the hell’. According to Broadbent, participants should have reported ‘ob-two-tive’, or ‘six-jec-nine’. This, of course, is nonsense. But the filter model maintains that it is the physical nature of the auditory signal (which ear receives which input), and not meaning, that determines what is attended to and, hence, what is recalled.

What participants actually reported was ‘objective’ or ‘Dear Aunt Jane’, etc. In other words, they acted ‘intelligently’. The ears do not always function as different information channels, and switching between channels is fairly easy to do.

---

message that is not selected on the basis of its physical properties would not be rejected completely, but its ‘volume’ would be ‘turned down’.

Both non-attenuated and attenuated information undergoes these further analyses. This may result in an attenuated message being attended to, depending on its features. Treisman suggested that biologically relevant and emotionally important stimuli may be ‘pre-sets’ to which attention is switched, irrespective of the content of the attenuated message. This accounts for our ability to switch attention to a different conversation when our name is mentioned. Since it is the features of a stimulus that determine whether or not the stimulus is attended to, the concept of *probabilistic filtering* is perhaps a better way of appreciating Treisman’s theory than that of attenuation.\(^ {22}\)

**The Deutsch–Norman late-selection filter model**

Deutsch and Deutsch\(^ {5}\) and Norman\(^ {23,24}\) completely rejected Broadbent’s claim that information is filtered out early on. According to the Deutsch–Norman model, filtering or selection occurs only after all inputs have been analysed at a high level, for example after each word has been recognized by the memory system and analysed for meaning (Figure 13.3).

The filter is placed nearer the response end of the processing system; hence, it is a ‘late’ selection filter. Because processing will have already been undertaken on the infor-
information that has been presented, some information will have been established as pertinent (most relevant) and will have activated particular memory representations; this is why the model is sometimes called the pertinence model. When one memory representation is selected for further processing, attention becomes selective. The model implies that we perceive everything we encounter but are consciously aware of only some of it.

Tests of the Treisman and Deutsch–Norman models

Both the Treisman and the Deutsch–Norman model can account for the processing of non-shadowed material (whereas Broadbent’s theory cannot). If the Deutsch–Norman model is correct, then participants should be able to identify as many target words in the non-shadowed message as in the shadowed message, since both are allegedly completely analysed for meaning. Treisman and Geffen, however, found that target words were much better detected in the shadowed message (87%) than in the non-shadowed message (8%). This is consistent with Treisman’s view that the non-shadowed message is attenuated.

However, Treisman and Geffen’s findings assume that the shadowed and non-shadowed messages are equally important. Deutsch and Deutsch argued that this assumption wasn’t met, because participants had to indicate when they heard a target word by tapping. In other words, participants had to shadow and tap in one message, but only tap in the other. This made the target words in the shadowed message more important than those in the non-shadowed message. Treisman and Riley overcame this problem by requiring participants to stop shadowing and to tap as soon as they detected a target word in either ear. Under such conditions, performance was still better for the shadowed message (76%) than for the non-shadowed message (33%).

This finding is consistent with Treisman’s model, but inconsistent with the Deutsch–Norman claim that performance should not differ (since the targets were equally pertinent, irrespective of the ear to which they were presented). However, the detection rate for the non-attended ear in Treisman and Riley’s study (33%) was much higher than that in Treisman and Geffen’s study (8%). This provides some support for the Deutsch–Norman model.

The Deutsch–Norman model predicts that participants asked immediately afterwards should be able to repeat back the words presented to the non-shadowed ear. However, the non-shadowed message gets into short-term memory for only a brief period and is then forgotten very quickly. Norman found that participants could remember the last couple of words presented to the non-attended ear if tested immediately, but not after a short continuation of the shadowing task. This finding was replicated by Glucksberg and Cowan.

An evaluation of single-channel models

- Despite some support for the Deutsch–Norman model, Wilding believes that less is known about non-attended messages than the model claims. However, more is known than can be explained by either Broadbent’s or Treisman’s models.
- The major criticism of single-channel theories is their lack of flexibility, and several more ‘flexible’ theories have been advanced. According to Johnston and Heinz, attentional selectivity can occur at several different stages of processing, depending on the demands made by the experimental task. In order to minimize demands on capacity, selection is made as early as possible.
- Johnston and Heinz and Johnston and Wilson presented findings consistent with their view that processing is more flexible than predicted by single-channel theories. For example, Johnston and Wilson showed that participants processed words presented to both ears, but only when they did not know to which ear particular target words would be presented. These data suggest that non-target words are processed only to the extent necessary to perform a task.
- Many researchers question whether any single, general-purpose, limited-capacity central processor can, in principle, account for the complexities of selective attention. Much of the relevant evidence comes from dual-task studies, which are concerned more directly with processing capacity – that is, divided attention (see below).
FOCUSED VISUAL ATTENTION

According to Driver:

The cluttered scenes of everyday life present more objects than we can respond towards simultaneously, and often more than we can perceive fully at any one time. Accordingly, mechanisms of attention are required to select objects of interest for further processing. In the case of vision, one such mechanism is provided by eye movements, which allow us to fixate particular regions so that they benefit from the greater acuity of the fovea.35

The fovea provides maximum acuity for visual stimuli. So, when we fixate on an object, maximum visual processing is carried out on the object whose image is projected on to the fovea. The resources given to the other parts of the visual field are ‘attenuated’36

Posner and colleagues found that when individuals are told to fixate on one part of the visual field, it is still possible to attend to stimuli about 7 degrees either side of the fixation point.37,38 Also, attention can be shifted more quickly when a stimulus is presented in an expected rather than an unexpected location. Thus, visual attention is not confined to the part of the visual field that is processed by the fovea but can be shifted without corresponding changes in eye movements. Indeed, such shifts in attention frequently precede the corresponding eye movement.39 Posner calls this ‘covert attention’.39

The internal mental spotlight and the zoom lens

Posner likened covert attention to an internal mental spotlight that ‘illuminates’ any stimulus in the attended region, so that it is perceived in greater detail. It essentially duplicates the functions of eye movements internally, by allowing a particular region of space to be perceptually enhanced.35

LaBerge required participants to judge whether the middle letter of five letters (e.g. L A C I E) came from the beginning or end of the alphabet (directed attention condition).40 But on some occasions, a stimulus such as – 7 – – – was presented, and the task was to determine whether the 7 was one of two letters (T or Z). LaBerge found that the speed of judgement was a function of the distance from the centre of attention. Thus, reaction times were fastest for items at the centre of the stimulus and slower for those at its periphery, even though all items were within the fovea’s region.

LaBerge concluded that visual attention is most concentrated at the centre of the internal spotlight and least at its periphery. When information beyond its centre needs to be processed, the spotlight must be shifted to ensure maximal processing. Because this takes time, participants in Posner and colleagues’ experiments took longer to judge a stimulus when it appeared in an unexpected location.41

LaBerge also found that when participants were required to attend to the whole five-letter word string (global attention condition), the ‘width’ of the spotlight’s ‘beam’ increased (based on the similarity of reaction times for items at the centre and periphery). These findings led Eriksen to propose the zoom-lens model of visual attention.42 This accepts the existence of an internal mental spotlight but suggests that it has a beam that may be very narrow (in the case of LaBerge’s letter task) or broad (in the case of LaBerge’s word task). It is simply a variable-beam spotlight.43

An evaluation of the spotlight model

Despite evidence that little or no processing occurs beyond the spotlight,44 both the spotlight and zoom-lens models have been contradicted in several studies (Box 13.3).
The fate of unattended visual stimuli

For Johnston and Dark, stimuli beyond the focus of visual attention are subject to no, or virtually no, semantic processing. Any such processing is limited to mainly simple physical features. However, Driver disagrees. For example, when a picture is shown as the unattended stimulus on one trial, it slows the processing of an attended word with an identical or similar meaning on the next trial (negative priming). The fact that processing of the attended stimulus is reduced suggests that the meaning of the unattended stimulus must have been subject to some sort of processing.

Treisman’s feature-integration theory

Treisman’s theory was developed on the basis of findings using the visual search procedure. Participants are presented with an array of visual material (Figure 13.5) in which a target item is embedded on some trials but absent on others, and the ‘distractor’ items can be varied so that they are similar to or different from the target letter. The participant’s task is to decide whether the target is present or absent.

![Visual search array](image)

Figure 13.5 Visual search array. The task is to find the number 5 among the letters

Treisman argued that when people perform a visual search task, they process many items simultaneously, without being fully aware of the exact nature of the distractor items. Visual information-processing might occur pre-attentively, depending on the nature of the stimuli (such as whether they have angular or curved features when the task is to detect a particular letter).

However, Treisman argues that attention must be focused on a stimulus before its features can be synthesized into a pattern. In one of Treisman and Gelade’s experiments, participants were required to detect the presence of the letter T among an array of Is and Ys. Because the horizontal bar at the top of a T distinguishes it from an I and a Y, this could be done fairly easily just by looking for the horizontal bar. Participants took around 800 ms to detect the T, and the detection time was not affected by the size of the array (i.e. the number of Is and Ys). In another experiment, the T was embedded in an array of Is and Zs. Here, looking for a horizontal bar on its own does not aid detection, since the letter Z also has a horizontal bar at the top. To detect a T, participants needed to look for the conjunction of a horizontal and vertical line. This took around 1200 ms. Moreover, detection time was longer when the size of the array was increased. On the basis of these (and other) findings, Treisman proposed her feature-integration theory (Box 13.4).

An evaluation of Treisman’s theory

- Treisman has claimed evidence for the occurrence of illusory conjunctions in her visual search experiments. Treisman and Schmidt, for example, required participants to identify two black digits flashed in one part of the visual field. In another part, letters in various colours were presented (e.g. a blue T or a red S). After reporting the digits, participants were asked what letters they had seen and their colour. Most participants reported seeing illusory conjunctions (e.g. a blue S) almost as frequently as correct conjunctions. This supports the view that accurate perception occurs only when attention is focused on an object. When it is not, the features of objects are processed but not always combined accurately.
- However, results from experiments in which moving items are intermingled with static items challenge Treisman’s theory (Box 13.5).

Visual attention and brain damage

Many researchers are interested in the brain regions involved in attention (e.g. Driver, Halligan). People who have had a right-hemisphere stroke involving the parietal
lobe may completely ignore stimuli occurring on the left side; for example, they may fail to eat food from the left side of their plate and be unaware of their body on that side (Figure 13.7). The fascinating thing about this unilateral visual neglect is that these effects occur even though the pathways from the receptors to the central nervous system (CNS) for the neglected information remain intact.

According to Posner and Petersen, the parietal lobe is responsible for disengaging attention from its present focus, and patients with damage to the pulvinar nucleus (part of the thalami) have difficulty in shifting attention to a new target.

Interestingly, among 4- to 10-year-old children, those who took less time to switch attention in a specially devised computer game were more likely to show awareness of traffic as they approached a busy road.

---

**Box 13.5 The moving target experiment**

Participants were asked to search for the presence or absence of a single moving X among static Xs and moving Os (Figure 13.6). The target is defined only by its specific conjunction of form and movement, since its shape is shared with the static X and its movement with the Os.

Treisman’s theory would predict that serial attention was necessary for each item when searching for the target, so that decision times would increase with an increasing number of distractors.

In fact, the target was found easily, regardless of the display’s size. This implies a parallel process, and in other experiments McLeod et al. showed that the parallel search arose because attention could be restricted to just the group of items with common motion to the exclusion of the static items. Because the target has a unique shape, it can be detected in parallel.

---

**DIVIDED ATTENTION**

**Some demonstrations of dual-task performance**

Allport et al. showed that skilled pianists were able to read music successfully while shadowing speech. Later, Shaffer reported the case of an expert typist who could type accurately from sight while shadowing speech. Perhaps the most striking example of dual-task performance comes from Spelke et al., who had two students spend 5 hours a week training at performing two tasks simultaneously. Initially, the students were required to read short stories while writing down dictated words. At first they found this difficult, and both their comprehension and writing suffered. But after 6 weeks of training, the students could read as quickly, and comprehend as much of what they read, when reading with dictation as when reading without it. Interestingly, though, they could remember very little of what they had written down, even though thousands of words had been dictated to them over the course of the experiment.

At this point, the task was altered and the students had to write down the category to which a word belonged (requiring more processing of the words), while simultaneously...
reading the short stories. Although again the task was difficult initially, they eventually performed it without any reduction in their comprehension of the stories.

Factors affecting dual-task performance

According to Hampson, factors that make one task easier also tend to make the other easier because ‘Anything which minimises interference between processes or keeps them “further apart” will allow them to be dealt with more readily either selectively or together’.58

Eysenck and Keane identify three factors that affect our ability to perform two tasks at once: difficulty, practice and similarity (Box 13.6).9

Theories of divided attention

As we noted earlier, models of selective attention assume the existence of a limited-capacity filter capable of dealing with one information channel at a time. As Hampson and Morris have observed, these theories imply a series of stages of processing, starting with superficial, physical analysis, and working ‘upwards’ towards the ‘higher’ cognitive analyses for meaning.15

In Hampson and Morris’s view, these processes are better thought of as an integrated mechanism, with the high and low levels interacting and combining in the recognition of stimuli. Accordingly, it is better to look at the system’s overall processing.

Limited-capacity theories

Kahneman’s theory

According to Kahneman, humans have a limited amount of processing capacity, and whether or not tasks can be performed successfully depends on how much demand they make on the limited-capacity processor.7 Some tasks require little processing capacity, leaving plenty available for performing another task simultaneously. Others require much more, leaving little ‘spare’.

The process of determining how much capacity is available (‘effort’) is related to the allocation of that capacity. How much capacity a task requires depends on things such as its difficulty and a person’s experience of it. How capacity is allocated depends on enduring dispositions, momentary intentions and the evaluation of the attentional demands (Figure 13.8). The central processor is responsible for the allocation policy and constantly evaluates the level of demand. When demand is too high, the central processor must decide how available attention should be allocated.

Kahneman sees arousal as playing an important part in determining how much capacity is available. Generally,

<table>
<thead>
<tr>
<th>Box 13.6 Effects of difficulty, practice and similarity on dual-task performance</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Difficulty</strong>: generally, the more difficult the task, the less successful is dual-task performance. However, it is hard to define task difficulty objectively, since a task that is difficult for one person might not be difficult for another (this relates to practice: see below). Also, the demands made by two tasks individually are not necessarily the same as when the tasks are performed concurrently. Thus, performing two tasks together may introduce fresh demands and the risk of interference.</td>
</tr>
<tr>
<td><strong>Practice</strong>: as we have seen, practice improves dual-task performance. This could be because people develop new strategies for performing each task, minimizing interference between them. Another possibility is that practice reduces a task’s attentional demands. Finally, practice may produce a more economical way of functioning that uses fewer resources.</td>
</tr>
<tr>
<td><strong>Similarity</strong>: Allport et al. showed that when people are required to shadow one message and learn pictorial information, both tasks can be performed successfully.21 This is, presumably, because they do not involve the same stimulus modality. Two tasks also disrupt performance when both rely on related memory codes (e.g. visual memory), make use of the same stages of processing (e.g. the input stage) or require similar responses to be made.</td>
</tr>
</tbody>
</table>

Based on Eysenck and Kane.9

![Figure 13.8](https://example.com/kahneman_theory.png)
more attentional resources are available when we are aroused and alert than when we are tired and lethargic. Attention can be divided between tasks, provided that the total available capacity is not exceeded. This explains the findings of the dichotic listening tasks discussed earlier: shadowing requires almost all of the capacity available, leaving the non-shadowed message insufficient capacity. Kahneman’s theory also predicts that, as skill at carrying out a task increases, so less capacity is needed for it and more becomes available for other tasks. Thus, when people are trained at shadowing, they become able to shadow and to attend to the non-shadowed message.20

Evaluation of Kahneman’s theory
Kahneman’s theory portrays attention as a much more flexible and dynamic system than do the models of focused attention. However, it does not address the issue of how decisions to channel attention are made. The difficulty in defining the general limits of capacity has led some researchers to suggest that the concept of limited capacity should be abandoned.15

Norman and Bobrow’s theory
Following on from Kahneman, Norman and Bobrow have offered a central capacity interference account of attentional phenomena (Box 13.7).33

Evaluation of Norman and Bobrow’s theory
This distinction between resource- and data-limited processes can explain findings from both focused and divided attention research. For example, Treisman and Geffen found that participants shadowing words in one ear had difficulty recognizing target words presented simultaneously to the other ear.25 Lawson, however, found that under similar conditions, participants could detect target tones presented in the non-attended ear.59 This finding can be explained by proposing that the tone-detection process becomes data-limited much sooner than the word-recognition process.

However, the theory’s biggest weakness is its inability to predict beforehand the results that an experiment is likely to produce. Because it allows for differential allocation of resources to tasks, an experimenter can never know the level of resources allocated to a particular task. Any results can therefore be interpreted in a way consistent with the theory, and no results can ever be taken as negative evidence.

Multi-channel theories
Supporters of limited-capacity models defend their approach by pointing out that the attentional system breaks down as more and more is demanded of it. Also, if data from divided-attention studies are considered carefully, it is not true that two tasks can be performed together with no disruption at all.66 Nevertheless, several researchers have rejected the concept of a general-purpose, limited-capacity processor completely. For Allport, the concept of attention is often used synonymously with ‘consciousness’, with no specification of how it operates.8,61,62 This has done little to increase our understanding of the very problems that it is meant to explain.

Modules and multiple resources
According to Allport, it is difficult to see how the neurology of the brain could produce a system of processing capacity that was completely open to any of the tasks that might be presented to it.15 It is much more profitable to view the data in terms of tasks competing for the same specialized processing mechanisms or modules, each of which has a limited capacity but none of which is uniquely ‘central’.

When two tasks are highly similar, they compete for the same modules, and this leads to performance impairments. However, because dissimilar tasks use different modules, both can be performed simultaneously. A virtually identical theoretical account has been proposed by Navon and Gopher63 and Wickens64 in their multiple-resource theory. Certainly, the findings of dual-task studies (e.g. Allport et al.21) are consistent with the idea of different processing mechanisms handling the requirements of different tasks.

However, this approach is also non-falsifiable, since any pattern of data can be explained by proposing the existence of a particular pattern of modules.65 If multiple resources do operate in parallel, then they must do so in a highly integrated way, since our behaviour is typically coherent.9

Attempts at synthesizing capacity and module accounts
According to Eysenck66–68 and Baddeley,69 a much better way of accommodating the data from divided-attention studies is to see capacity and module accounts as being complementary rather than competitive. Synthesis models propose the existence of a modality-free central capacity processor, which is involved in the coordination and control of behaviour, and specific processing systems. In Baddeley’s working memory model, for example, there are two independently operating and specific systems – an articulatory/phonological loop and a visuospatial scratch-

---

**Box 13.7 Norman and Bobrow’s central capacity interference theory**

This theory’s central feature is its distinction between resource-limited and data-limited processes. On a complex task, performance is related to the amount of resources devoted to it. As more resources are allocated, so task performance improves up to some point. Performance is thus resource-limited.

But on some tasks, applying more resources does not lead to improved performance because of external influences (e.g. when participants are required to identify a quiet tone among loud, masking ‘white’ noise). This sort of task is data-limited, because performance can be improved only by altering the stimuli (e.g. by making the tone louder or the masking noise quieter).
These systems can explain why overt repetition of an overlearned sequence of digits does not interfere with verbal reasoning, since the former uses an articulatory loop and the latter a central processor (see Chapter 17).

**Automatic v. controlled processing**

As we have seen, both laboratory evidence and everyday experience indicate that we can learn to perform two tasks simultaneously and highly efficiently. For some researchers, this is because many processes become automatic; that is, they make no attentional demands if they are used or practised often enough. Two important theoretical contributions are those of Schneider and Shiffrin and Norman and Shallice.

**Schneider and Shiffrin's automaticity model**

Schneider and Shiffrin distinguish between controlled and automatic attentional processing:

- **Controlled processing** makes heavy demands on attentional resources, is slow, is capacity-limited and involves consciously directed attention towards a task.
- **Automatic processing** makes no demands on attentional resources, is fast, is unaffected by capacity limitations, is unavoidable and difficult to modify (it always occurs in the presence of an appropriate stimulus), and is not subject to conscious awareness.

The results of several studies (e.g. Schneider and Fisk) are consistent with Schneider and Shiffrin’s view. If people are given practice at a task, then they can perform it quickly and accurately, but their performance is resistant to change. An example of apparent automaticity in real life occurs when we learn to drive a car. At first, focused attention is required for each component of driving, and any distraction can disrupt performance. Once we have learned to drive, and as we become more experienced, our ability to attend simultaneously to other things increases.

Logan suggests that automaticity develops through practice, because automatic responses involve an almost effortless retrieval of an appropriate and well-learned response from memory. This does not involve conscious memory, because no thought processes intervene between the presentation of a stimulus and the production of an appropriate response. In Logan’s view, then, automaticity occurs when stored information about the sequence of responses necessary to perform a task can be accessed and retrieved rapidly.

**An evaluation of Schneider and Shiffrin’s model**

Despite its intuitive appeal, it is unclear whether automaticity results from a speeding up of the processes involved in a task or from a change in the nature of the processes themselves. Also, the view that automatic processing makes no demands on attention has been challenged by findings indicating that allegedly automatic tasks do influence the performance of simultaneously performed tasks (e.g. Hampson). Additional problems occur with the Stroop effect (Box 13.8).

---

**Box 13.8 The Stroop effect**

Stroop showed that if a colour word (e.g. ‘blue’) is written in a conflicting colour (e.g. the word ‘blue’ written in red ink), then participants find it difficult to name the colour in which the word is written.

Because reading is such a well-learned, unavoidable and automatic activity, the word interferes with the requirement to name the colour.

An analogue of the Stroop effect can be tried here. Say as quickly as you can the number of characters in each of the rows below.

```
5 5 5
1 1 1
2
3 3 3 3
4 4
5 5 5
4 4 4 4 4
5 5 5 5
3
4 4 4
2 2 2 2
3 3
4 4 4
2 2 2
1 1 1 1
3
2 2 2
```

Flowers et al. found that people have difficulty resisting saying the numbers that make up each row rather than counting the numbers, because number recognition is much more automatic compared with number counting. But automatic responses are not always unavoidable.

**Norman and Shallice’s supervisory attentional system model**

To overcome what Eysenck calls the ‘unavoidability criterion’, Norman and Shallice proposed that processing involves two separate control systems: contention scheduling and the supervisory attentional system (SAS). Some behaviours involve fully automatic processing, which occurs with little conscious awareness of the processes involved and is controlled by schemas (organized plans for behaviour; see below and Chapter 17).

However, such processes are capable of disrupting behaviour, and so contention scheduling occurs as a way of resolving conflicts among schemas. This produces partially automatic processing, which generally involves more conscious awareness than fully automatic processing but does not require deliberate direction or conscious control. Deliberate control involves the SAS and occurs in decision-making and trouble-shooting, allowing flexible responding.
to occur in novel situations. Baddeley claims that SAS is like the operation of free will, while content scheduling leaves no place for free will.77

**An evaluation of Norman and Shallice’s model**

According to Eysenck and Keane, Norman and Shallice’s model is superior to Schneider and Shiffrin’s because it ‘… provides a more natural explanation for the fact that some processes are fully automatic whereas others are only partially automatic’.9

Their SAS model is not worked out in the same degree of detail, or empirically tested as extensively, as Schneider and Shiffrin’s automaticity model. However, it does provide a very useful basis for conceptualizing the central executive of Baddeley and Hitch’s78 working-memory model (Box 13.9; see also Chapter 17).77

---

### Box 13.9 Is working memory’s central executive just an attentional system?

As we have noted, Baddeley and Hitch identified the central executive with Norman and Shallice’s supervisory attentional system (SAS), agreeing that the SAS was often disrupted in patients with frontal lobe damage. Such patients sometimes show paradoxical behaviour, such as perseveration (becoming locked into a specific activity) or its opposite (being unable to resist the temptation to respond inappropriately to features in the immediate environment). An example of the latter is utilization behaviour, in which the patient responds automatically to surrounding objects (e.g. drinking someone else’s coffee, or, on one occasion, seizing a hypodermic needle and injecting the examining doctor).79

According to Baddeley, there has been an explosion of research into how behaviour is controlled, with an emphasis on how the frontal lobes are related to the ability to focus, divide and switch attention. Although the first two appear to be separable functions of the central executive, switching seems to be more complex. Baddeley’s own research has pointed to the important role of the phonological loop in controlling behaviour via sub-vocal speech.

If the central executive is a purely attentional system, which could not itself store information, how did the phonological loop and the visuospatial sketchpad (the other ‘slave’ system) work together in the absence of a common code or language? And how could the whole system interface with long-term memory (LTM)?

Baddeley’s solution to these critical problems is to propose a fourth slave (or sub-) system, namely the episodic buffer. This sits between the central executive and LTM, accepting information from any part of the system and holding it in a multidimensional code. It is taken to be of limited capacity (about four episodes or chunks; see Chapter 17) and accessible through conscious awareness. It is an essentially passive store – a television screen rather than a stage: the hard work goes on elsewhere but depends on the episodic buffer for its display.79

---

### Action slips

Action slips have been defined as the performance of unintended actions, or actions that deviate from the actor’s intentions, and have been researched extensively by Reason.80,81 Reason originally asked 36 participants to keep a diary record of the action slips they made over a 4-week period. The participants recorded 433 action slips between them. Reason was able to place 94 per cent of these action slips into one of five categories (Box 13.10).

**Explaining action slips**

**Closed- and open-loop control**

Paradoxically, action slips seem to occur with highly practised and overlearned actions, which should, therefore, be least subject to errors. Reason81 proposes that, when we first learn to perform a behaviour, our actions are subject to closed-loop control.81 In this, a central processor or attentional system guides and controls a behaviour from start to finish. When we are skilled at a behaviour, it is under open-loop control, controlled by motor programmes or other automatic processes.

Closed-loop control is slow and effortful, whereas open-loop control is fast and allows attentional resources to be given over to other activities. However, closed-loop control is less prone to error and responds more flexibly to environmental demands compared with open-loop control. As a result, action slips occur because of an overreliance on

---

### Box 13.10 Reason’s five categories of action slips

- **Storage failures** (40%): repeating an action that has already been completed; for example, pouring a second kettle of boiling water into a teapot of freshly made tea without any recognition of having made the tea already.
- **Test failures** (20%): forgetting the goal of a particular sequence of actions and switching to a different goal; for example, intending to turn on the radio but walking past it and picking up the telephone instead. These slips occur, presumably, because a planned sequence of actions is not monitored sufficiently at some crucial point in the sequence.
- **Sub-routine failures** (18%): either omitting or reordering the stages in a sequence of behaviour; for example, making a pot of ‘tea’ but failing to put any tea in it.
- **Discrimination failures** (11%): failing to discriminate between two objects involved in different actions; for example, mistaking toothpaste for shaving cream.
- **Programme assembly failures** (5%): incorrectly combining actions; for example, unwrapping a sweet, putting the paper in your mouth and throwing the sweet in the bin.

Based on Eysenck82 and Reason.81
open-loop control when closed-loop control (selectively attending to the task) should be occurring.

As shown in studies of focused attention, material not attended to is typically poorly remembered because it is not stored in long-term memory (LTM). So, the most common type of action slip, storage failures, can be explained in terms of open-loop induced attentional failures leading to a failure to store (and hence recall) previous actions. As a result, an action may be repeated. Other slips also seem amenable to explanation in terms of open-loop control.82

**Schema theory**
An alternative theoretical account has been advanced by Norman84 and elaborated by Sellen and Norman (Box 13.11).85 Their theory is based on the concept of the schema, first proposed by Bartlett (see Chapter 17).86 Briefly, a schema is an organized mental representation of everything we understand by a given object, concept or event, based on past experience.

<table>
<thead>
<tr>
<th>Box 13.11 Sellen and Norman’s schema theory of action slips85</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Parent schemas</strong> are the highest-level schemas, corresponding to an overall intention or goal (e.g. going to a football match). At a lower level are <strong>child schemas</strong>, which correspond to the actions involved in accomplishing the overall intention or goal (e.g. driving the car to the football ground and buying a ticket).</td>
</tr>
<tr>
<td>Each schema has a particular activation level, and a behaviour occurs when the activation level is reached (which depends on the current situation and current intentions) and when appropriate ‘triggering’ conditions exist. An action slip occurs if:</td>
</tr>
<tr>
<td>- there is an error in the formation of an intention; or</td>
</tr>
<tr>
<td>- an incorrect schema is activated; or</td>
</tr>
<tr>
<td>- activation of the correct schema is lost; or</td>
</tr>
<tr>
<td>- there is faulty triggering of an active schema.</td>
</tr>
</tbody>
</table>

Reason and Mycielska believe that a thorough understanding of the nature of action slips is necessary in order to avoid potential disaster occurring in the real world.87 Eysenck maintains that action slips would be eliminated if we were to use closed-loop control for all behaviours, but this would be a waste of valuable attentional resources.88 The frequency of action slips reported by Reason’s participants (an average of about one action slip per day) suggests that people alternate between closed-loop and open-loop control as circumstances dictate.89 For Eysenck:

*The very occasional action slip is a price which is generally worth paying in order to free the attentional system from the task of constant monitoring of our habitual actions.*88

Action slips represent the minor errors of an action system that typically functions very well indeed.82

Similarly, ‘Absent-minded errors demonstrate misapplied competence rather than incompetence’.89

Each type of action slip might require its own explanation. Although the mechanisms underlying them may appear similar, they might actually be very different.9 Consider Box 13.12.

<table>
<thead>
<tr>
<th>Box 13.12 Reason’s ‘oak–yolk effect’ experiment81</th>
</tr>
</thead>
<tbody>
<tr>
<td>Answer the following series of questions as quickly as possible:</td>
</tr>
<tr>
<td>- Q: What do we call the tree that grows from acorns?</td>
</tr>
<tr>
<td>A: Oak</td>
</tr>
<tr>
<td>- Q: What do we call a funny story?</td>
</tr>
<tr>
<td>A: Joke</td>
</tr>
<tr>
<td>- Q: What sound does a frog make?</td>
</tr>
<tr>
<td>A: Croak</td>
</tr>
<tr>
<td>- Q: What is Pepsi’s major competitor?</td>
</tr>
<tr>
<td>A: Coke</td>
</tr>
<tr>
<td>- Q: What’s another word for cape?</td>
</tr>
<tr>
<td>A: Cloak</td>
</tr>
<tr>
<td>- Q: What do you call the white of an egg?</td>
</tr>
<tr>
<td>A: Yolk</td>
</tr>
</tbody>
</table>

‘Yolk’ is, in fact, the *wrong* answer (correct answer = albumen). Reason found that 85 per cent of his participants made this error, compared with only 5 per cent of a control group given just the final question. However, are such trick-induced action slips comparable to those that occur spontaneously in everyday life? According to Sellen and Norman, the laboratory environment is the least likely place to see truly spontaneous absent-minded errors.85 In Eysenck & Keane’s words:

*The number of occurrences of any particular kind of action slip is meaningful only when we know the number of occasions on which the slip might have occurred but did not. Thus, the small number of discrimination failures [reported by Reason] may reflect either good discrimination or a relative lack of situations requiring anything approaching a fine discrimination.*9

**CONCLUSIONS**

It is possible sometimes to divide attention between two different tasks, although how this is achieved has not been explained satisfactorily. Two broad types of explanation are those that propose a general-purpose limited-capacity processor, and those that identify modules, each with a limited capacity but none of which is central. The idea that
many processes become automatic and make no demands on attention has some support and helps to explain why we sometimes perform behaviours that we did not intend. Action slips involve behaviours that are highly practised and are the price we pay for not having to monitor our actions continuously.

**KEY POINTS**

- According to Broadbent, who was trying to account for Cherry’s cocktail party phenomenon, humans must selectively attend to some information and tune out the rest.
- Using binaural listening, Cherry identified several physical differences affecting selective attention to one of two messages. He also used dichotic listening, in which participants had to shadow one of the messages. They could do this, but they remembered little, if anything, of the non-shadowed message, whose meaning was lost completely.
- Three single-channel models share the belief in a ‘bottleneck’ or filter that allows some information to be passed on for further processing, either discarding the rest or processing it to only a limited degree. The models differ mainly in terms of how early or late the filtering takes place.
- Broadbent’s early-selection filter theory accounts for Cherry’s findings and his own split-span data. But people’s ability to switch attention to the non-attended ear when their name is spoken, together with other research findings relating to the processing of meaning, are inconsistent with Broadbent’s theory.
- According to Treisman’s attention model, competing information is analysed for its physical properties, and for sounds, syllable patterns, grammatical structures and meaning. The selective filter ‘turns down’ the non-shadowed message. If this includes biological ‘pre-sets’, our attention will switch to the non-shadowed message.
- The Deutsch–Norman late-selection filter theory/pertinence model sees selection as occurring only after all inputs have been analysed at a high level. The filter is nearer the response end of the processing system.
- Mechanisms involved in focused visual attention include eye movements that allow us to fixate specific regions of the visual field. But visual attention is not confined to the part of the visual field processed by the fovea, as demonstrated by covert attention. This is like an internal mental spotlight.
- According to Eriksen’s zoom-lens model, the internal spotlight has a beam that may be very narrow or very broad.
- According to Treisman’s feature-integration theory, focusing attention on their location allows unitary features to be formed into their various objects. Illusory conjunctions can arise in the absence of relevant stored knowledge or focused attention.
- Researchers interested in divided attention typically measure dual-task performance. Three factors affecting dual-task performance are task difficulty, practice and similarity.
- According to Kahneman, humans have only a limited processing capacity. Different tasks require different amounts of processing capacity, leaving more or less available for performing other tasks.

INTRODUCTION

As we note in Chapter 9, psychology comprises a number of different theoretical perspectives or approaches. Each approach makes different assumptions about the particular aspects of a person that are worthy of study, which helps to determine an underlying model or image of what people are like. In turn, this model or image determines a view of the nature of development, the preferred methods of study, the nature of psychological normality, the major cause(s) of abnormality, and the preferred methods and goals of treatment.

Learning theory is associated with the behaviourist approach, which dominated American psychology in particular for much of the first half of the twentieth century. Given the central role of learning in philosophical behaviourism, it is hardly surprising that the topic of learning itself should be central within psychology as a whole.

WHAT DO WE MEAN BY ‘LEARNING’?

The concept of learning is a good example of the discrepancy between the everyday, common-sense use of a term and its technical, scientific use (see Chapter 9). In everyday conversation, the emphasis is usually on what is learned (the end product), such as learning to drive a car, use the Internet or speak French. But when psychologists use the term, their focus is on how the learning takes place (the learning process).

Learning is a hypothetical construct: it cannot be observed directly; instead, it can only be inferred from observable behaviour. So, for example, if a person’s performance on a task at time 1 differs from performance on the task at time 2, then we might infer that learning has taken place. But if that change is observed just once, then we may be much more hesitant about making such an inference. Learning, therefore, normally implies a fairly permanent change in a person’s behavioural performance. Again, temporary fluctuations in behaviour can occur as a result of fatigue, drugs, temperature changes and so on, and this is another reason for taking permanence as a minimum requirement for saying that learning has taken place.

However, permanent changes in behaviour can also result from things that have nothing to do with learning, such as the effects of brain damage on behaviour, and the changes associated with puberty and other maturational processes. So, if a change in behaviour is to be counted as learning, then the change must be linked to some kind of past experience (regardless of whether there was any attempt to bring about that change). For these reasons, psychologists usually define learning as ‘... a relatively permanent change in behaviour due to past experience’ or ‘... the process by which relatively permanent changes occur in behavioural potential as a result of experience’.

Learning versus performance

The second definition has one major advantage over the first; namely, it implies a distinction between learning (behavioural potential) and performance (actual behaviour).

If you can swim, you are almost certainly not doing so as you read this chapter – but you could readily do so if faced with a pool full of water. So what you could do (potential behaviour based on learning) and what you are actually doing (current performance) are two different things. Ultimately, of course, the only proof of learning is a particular kind of performance (e.g. exams). Performance can fluctuate due to fatigue, use of drugs and emotional factors, and so it is much more variable than learning, which is more permanent. (Exams come to mind again – many students have left an exam knowing what they could not demonstrate during the exam itself.)

Some basic questions about learning

Although it is generally agreed by psychologists that learning is relatively permanent and due to past experience, there is much less agreement about exactly what changes when learning takes place and what kinds of past experience are involved. Put another way, how do the changes occur? And what mechanisms are involved? One important issue that divides psychologists is the extent to which they focus on the overt, behavioural changes as opposed to the covert, cognitive changes.
THE BEHAVIOURIST APPROACH

Basic principles and assumptions

According to Skinner:

The first explicit behaviourist was John B. Watson, who in 1913 issued a kind of manifesto called *Psychology as the Behaviourist Views It*. As the title shows, he was not proposing a new science but arguing that psychology should be redefined as the study of behaviour... Most of the psychologists at the time believed they were studying mental processes in a mental world of consciousness, and they were naturally not inclined to agree with Watson. Early behaviourists wasted a good deal of time, and confused an important issue, by attacking the introspective study of mental life.7

Watson claimed that only by modelling itself on the natural sciences could psychology legitimately call itself a science (see Chapter 9). He argued for a certain type of behaviourism, namely *methodological behaviourism*: only events/phenomena that can be verified intersubjectively (i.e. agreed upon by two or more people) are suitable for scientific investigation. Cognition, thinking, believing, feeling, pain and so on are private events, and so they are not accessible to anyone else. Therefore, they should be excluded from a science of psychology.

In this sense, what was revolutionary about Watson’s behaviourist manifesto has become almost taken-for-granted, ‘orthodox’ psychology. It could be argued that all psychologists are methodological behaviourists. Belief in the importance of empirical methods, especially the experiment, as a way of collecting data about humans (and non-humans), which can be quantified and statistically analysed, is a major feature of mainstream psychology.

**Skinner’s radical behaviourism**

Skinner, generally regarded as the arch-behaviourist, rejected Watson’s insistence on ‘truth by agreement’. According to his radical behaviourism, cognitions are covert behaviours (‘within the skin’) that should be studied by psychologists along with overt behaviours (capable of being observed by two or more people). He was not ‘against cognitions’, but he said that ‘so-called mental activities are metaphors or explanatory fictions and ... behaviour attributed to them can be more effectively explained in other ways’.

For Skinner, these more effective explanations of behaviour come in the form of the principles of reinforcement derived from his experimental work with rats and pigeons (see below). What is ‘radical’ about Skinner’s radical behaviourism is the claim that feelings, sensations and other private events cannot be used to explain behaviour but are to be explained in an analysis of behaviour (behaviour analysis). Since private events cannot be manipulated, they cannot serve as independent variables; but they can serve as dependent variables. Some recent studies of consciousness seem to support Skinner’s claim that our common-sense belief that we will our actions is an illusion (see Chapter 10 and Gross4).

Although methodological behaviourism proposes to ignore such inner states (they are inaccessible), Skinner ignores them only as variables used for explaining behaviour (they are irrelevant) and argues that they can be translated into the language of reinforcement theory. According to Nye, Skinner’s ideas are also radical because he applied the same type of analysis to both covert and overt behaviour.8

Skinner stressed the importance of identifying functional relations between environmental conditions and behaviours. According to Leslie:

... the psychology of an individual consists primarily of an account of those functionally defined behavioural characteristics that occur in the environments typically encountered by that individual. A person, if you like, is primarily to be understood as ‘what he or she does’ and that account of their behaviour cannot ... be described without also describing the location or occasion of those behaviours and the important consequences of those behaviours ...9

From the perspective of behaviour analysis, the key process of psychological change is operant conditioning:

... whereby those behaviours that are functionally effective for the individual become more frequent (in the corresponding environment) while other behaviours decline in frequency ...9

The behaviour is not caused by either the individual or the environment. Rather:

... it is the history of interaction between the behavioural repertoire of the individual (that is, the whole range of behaviours shown by the person) and the environment that selects, and in a sense causes, the behaviour ...9

Skinner also saw his brand of behaviourism as a thoroughgoing, ‘deep’ behaviourism.10 According to Skinner, radical behaviourism is not a scientific law or set of empirical findings. It is meta-scientific; that is, it attempts to define what a science of behaviour should look like. The questions that Skinner asks are essentially philosophical. According to O’Donohue and Ferguson:

... radical behaviourism is a philosophy of science, or more exactly, a philosophy of psychology. Skinner calls the science based on this philosophy the experimental analysis of behaviour or behaviour analysis.10

Given this important distinction between methodological and radical behaviourism, we need to consider some principles and assumptions that apply to behaviourism in general (Box 14.1).

Skinner made the crucial distinction between *respondents* (or respondent behaviour), which are triggered automatically by particular environmental stimuli, and *operants* (or operant behaviour), which are essentially voluntary (Figure 14.1). A related distinction is that between classical or
respondent (Pavlovian) conditioning and operant or instrumental (Skinnerian) conditioning.

**Classical conditioning: why do dogs drool over bells?**

Ivan Pavlov was a physiologist interested in the process of digestion in dogs. He was awarded the Nobel Prize in 1904 (the year Skinner was born). He developed a surgical technique for collecting a dog’s salivary secretions. A tube was attached to the outside of its cheek, so the drops of saliva could be measured easily (Figure 14.2).

Pavlov noticed that the dogs would often start salivating before they were given any food, such as when they looked at the food or saw the feeding bucket, or even when they heard the footsteps of the laboratory assistant who was coming to feed them. These observations led to the study of what is now called classical (or Pavlovian) conditioning: a stimulus (e.g. a bell) that would not normally produce a particular response (e.g. salivation) eventually comes to do...
so by being paired with another stimulus (e.g. food) that does normally produce the response (Figure 14.3).

Before conditioning, the taste of food will naturally and automatically make the dog salivate, but the sound of a bell will not. The food is thus referred to as an unconditioned stimulus (UCS), and the salivation is an unconditioned response (UCR): an automatic, reflex, biologically built-in response. The dog does not have to learn to salivate in response to food, because it does so naturally.

During conditioning, the bell is paired with the food. Because the bell does not naturally produce salivation, it is called a conditioned stimulus (CS): it produces salivation only on the condition that it is paired with the UCS. It is also neutral with regard to salivation before conditioning.

If the bell and food are paired often enough, the dog starts to salivate as soon as it hears the bell and before the food is presented. When this occurs, conditioning has taken place. The salivation is now referred to as a conditioned response (CR), because it is produced by a conditioned stimulus (CS) – the bell.

This basic procedure can be used with a variety of conditioned stimuli, such as buzzers, metronomes, lights and geometric figures. The exact relationship between the CS and the UCS can also be varied to give different kinds of conditioning. What is described above involves delayed/forward conditioning (Table 14.1).

### Higher-order conditioning

Pavlov demonstrated that a strong CS could be used instead of food to produce salivation in response to a new stimulus that had never been paired with food. For example, a buzzer (previously paired with food) is paired with a black square. After ten pairings (using delayed conditioning), the dog will salivate a small but significant amount at the sight of the black square before the buzzer is sounded. The black square has never been associated with food directly, but only indirectly through association with the buzzer. It is as if the CS were functioning as a UCS.

The buzzer–food combination is referred to as first-order conditioning, and the black square–buzzer pairing as

---

### Table 14.1 Four types of classical conditioning based on different conditioned stimulus (CS)–unconditioned stimulus (UCS) relationships

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Delayed or forward</strong></td>
<td>The CS is presented before the UCS, and remains ‘on’ while the UCS is presented and until the unconditioned response (UCR) appears. Conditioning has occurred when the conditioned response (CR) appears before the UCS is presented. A half-second interval produces the strongest learning. As the interval increases, learning becomes poorer. This type of conditioning is typically used in the laboratory, especially with non-humans.</td>
</tr>
<tr>
<td><strong>Backward</strong></td>
<td>The CS is presented after the UCS. Generally this produces very little, if any, learning in laboratory animals. However, much advertising uses backward conditioning (e.g. the idyllic tropical scene is set, and then the coconut bar is introduced).</td>
</tr>
<tr>
<td><strong>Simultaneous</strong></td>
<td>The CS and UCS are presented together. Conditioning has occurred when the CS on its own produces the CR. This type of conditioning often occurs in real-life situations (e.g. the sound of the dentist’s drill accompanies the contact of the drill with your tooth).</td>
</tr>
<tr>
<td><strong>Trace</strong></td>
<td>The CS is presented and removed before the UCS is presented, so that only a ‘memory trace’ of the CS remains to be conditioned. The CR is usually weaker than in delayed or simultaneous conditioning.</td>
</tr>
</tbody>
</table>
second-order conditioning. Pavlov found with dogs that learning could not go beyond third- or fourth-order conditioning. Even so, conditioning is beginning to look at a rather more complex process.

**Generalization and discrimination**

In *generalization*, the CR transfers spontaneously to stimuli similar to, but different from, the original CS. For example, if a dog is trained using a bell of a particular pitch and is then presented with a bell a little higher or lower in pitch, the dog will still salivate, although only one bell (the original CS) was actually paired with food. However, if the dog is presented with bells that are increasingly different from the original, the CR will gradually weaken and eventually stop altogether – the dog is showing discrimination (Figure 14.4).

Pavlov also trained dogs to discriminate in the original conditioning procedure. For example, if a high-pitched bell is paired with food but a low-pitched bell is not, the dog will start salivating in response to the former but not to the latter (discrimination training). An interesting phenomenon related to discrimination is what Pavlov called experimental neurosis (Box 14.2).

**Extinction and spontaneous recovery**

If dogs have been conditioned to salivate to a bell, and the bell is repeatedly presented without food, the CR of salivation gradually becomes weaker and eventually stops altogether (extinction). However, if a dog that has undergone extinction is removed from the experimental situation and then put back a couple of hours or so later, it will start salivating again. Although no further pairing of the bell and food has occurred, the CR of salivation reappears in response to the bell (spontaneous recovery). This shows that extinction involves not an ‘erasing’ of the original learning but rather a learning to inhibit or suppress the CR when the CS is continually presented without a UCS.

**Classical conditioning and human behaviour**

There have been many laboratory demonstrations involving human participants. It is relatively easy to classically condition and extinguish CRs, such as the eye-blink and galvanic skin response (GSR). But what relevance does this have for understanding human learning and memory, let alone thinking, reasoning or problem-solving?

In normal adults, the conditioning process can apparently be overridden by instructions: simply telling participants that the UCS will not occur causes instant loss of the CR, which would otherwise extinguish only slowly. Most participants in a conditioning experiment are aware of the experimenter’s contingencies (the relationship between stimuli and responses) and, in the absence of such awareness, often fail to show evidence of conditioning.

There are also important differences between very young children, and those with severe learning difficulties, and older children and adults, regarding their behaviour in a variety of operant conditioning and discrimination learning experiments. These seem largely attributable to language development (see below).

All this suggests that people have rather more efficient, language- (or rule-) based forms of learning at their disposal than the laborious formation of associations between a CS and UCS. Even behaviour therapy, one of the apparently more successful applications of conditioning principles to human behaviour, has given way to cognitive-behaviour therapy (see Chapter 66).

**Classical conditioning and phobias**

Watson was the first psychologist to apply the principles of classical conditioning to human behaviour. He did this in what is considered to be one of the most ethically dubious psychology experiments ever conducted (Box 14.3).

It is unclear whether Watson and Rayner intended to remove Little Albert’s phobia. What is certain is that Albert’s mother removed him from the hospital before this could happen. They might have attempted to remove the phobia through the method of *direct unconditioning* as used by Jones (Box 14.4). This is an early example of what Wolpe called *systematic desensitization* (see Chapter 67).

Behaviour therapists, such as Eysenck, regard the Little Albert experiment as demonstrating how all phobias are acquired in everyday life. A fear of the dentist, for example, could be learned in the following way:

---

**Box 14.2 Experimental neurosis: how to drive a dog mad**

Pavlov trained dogs to salivate to a circle but not to an ellipse, and then gradually changed the shape of the ellipse until it became almost circular. As this happened, the dogs started behaving in ‘neurotic’ ways – whining, trembling, urinating and defecating, refusing to eat and so on. It was as if the dogs did not know how to respond: was the stimulus a circle (in which case, through generalization, they ‘ought’ to salivate), or was it an ellipse (in which case, through discrimination, they ‘should not’ salivate)?
Drill hitting a nerve (UCS) → pain/fear (UCR).

Sound of drill (CS) + drill hitting nerve (UCS) → pain/fear (UCR).

Sound of drill (CS) → fear (CR).

If you are looking at the dentist peering into your mouth, you may become afraid of upside-down faces. If the dentist is wearing a mask, you may acquire a fear of masks too. Also, through generalization, you can come to fear all drill-like noises or all white coats worn by medical personnel and laboratory technicians.

Human phobias may be perpetuated through avoiding the object of our fears. In other words, we do not give the fear a chance to undergo extinction (see Chapter 67). This occurs in conjunction with operant conditioning, whereby the avoidance behaviour becomes strengthened through negative reinforcement.

**Operant conditioning: why do rats press levers?**

When Skinner drew the distinction between respondent and operant behaviour, he was not rejecting the discoveries of Pavlov and Watson. Rather, he was arguing that most animal and human behaviour is not triggered or elicited by specific stimuli. He was interested in how animals operate on their environment, and how this operant behaviour is instrumental in bringing about certain consequences, which then determine the probability of that behaviour being repeated. Skinner saw the learner as much more active than Pavlov or Watson did (Box 14.5).

Just as Watson’s ideas were based on the earlier work of Pavlov, so Skinner’s study of operant conditioning grew out of the earlier work of another American, Edward Thorndike.

**Thorndike’s law of effect**

Thorndike built puzzle-boxes for use with cats, whose task was to operate a latch that would automatically cause the door to spring open (Figure 14.5). Each time they managed to escape, there was a piece of fish, visible from inside the puzzle-box, waiting for them. The cats were deprived of food for a considerable time before the experiments began and so were highly motivated. After eating the fish, the cats

---

**Box 14.3 The case of Little Albert**

Albert B’s mother was a wet-nurse in a children’s hospital. Albert was described as ‘healthy form birth’, and ‘on the whole stolid and unemotional’. When he was about 9 months old, his reactions to various stimuli were tested – a white rat, a rabbit, a dog, a monkey, masks with and without hair, cotton-wool, burning newspapers, and a hammer striking a steel 4-foot steel bar just behind his head. Only the last of these frightened him, so this was designated the unconditioned stimulus (UCS; the fear was the unconditioned response, UCR). The other stimuli were neutral because they did not produce fear.

When Albert was just over 11 months old, the rat and the UCS were presented together: as Albert reached out to stroke the animal, Watson crept up behind the baby and brought the hammer crashing down on the steel bar.

This occurred seven times in total over the next 7 weeks. By this time, the rat (the conditioned stimulus, CS) on its own frightened Albert, and the fear was now a conditioned response (CR). Watson and Rayner had succeeded in deliberately producing in a baby a phobia of rats.

The CR transferred spontaneously to the rabbit, the dog, a seal-skin fur coat, cotton-wool, Watson’s hair and a Santa Claus mask. But it did not generalize to Albert’s building blocks or to the hair of two observers (so Albert was showing discrimination).

Five days after conditioning, the CR produced by the rat persisted. After 10 days it was ‘much less marked’, but it was still evident a month later.

**Box 14.4 The case of Little Peter**

Peter was a 2-year-old living in a charitable institution. Jones was interested mainly in those children who cried and trembled when shown an animal (e.g. a frog, rat or rabbit). Peter showed an extreme fear of rats, rabbits, feathers, cotton-wool, fur coats, frogs and fish, although in other respects he was regarded as well adjusted. It was not known how these phobias had arisen.

Jones, supervised by Watson, put a rabbit in a wire cage in front of Peter while the child ate his lunch. After 40 such sessions, Peter ate his lunch with one hand and stroked the rabbit (now on his lap) with the other hand.

In a series of 17 steps, the rabbit (still in the cage) had been brought a little closer each day, and then let free in the room. Eventually the rabbit sat on Peter’s lunch tray.
were put straight back in the box, and the whole process was repeated.

At first the cats struggled to get out, behaving in a purely random way, and it was only by chance that the first escape was made. But every time the cats were returned to the puzzle-box, it took them less time to operate the latch and escape again. For instance, with one of the boxes, the average time for the first escape was 5 min, but after 10–20 trials this was reduced to about 5 s.

Thorndike accounted for this by claiming that the learning was essentially random or trial-and-error. There was no sudden flash of insight into how the releasing mechanism worked, but rather there was a gradual reduction in the number of errors made and hence the escape time. What was being learned was a connection between the stimulus (the manipulative components of the box) and the response (the behaviour that allowed the cat to escape). Further, the stimulus–response (S–R) connection is ‘stamped in when pleasure results from the act, and stamped out when it doesn’t’ (law of effect). This is crucially important as a way of distinguishing classical and operant conditioning, which Skinner did 40 years later.

**Skinner’s ‘analysis of behaviour’**

Skinner used a form of puzzle-box known as a ‘Skinner box’. This was designed for a rat or pigeon to do things in, rather than escape from. The box has either a lever (in the case of rats) or illuminated discs (in the case of pigeons), under which is a food tray. The experimenter decides exactly what the relationship shall be between pressing the lever and the delivery of a food pellet, providing total control of the animal’s environment. But it is the animal that has to do the work.

Skinner used the term ‘strengthen’ in place of Thorndike’s ‘stamping in’, and ‘weaken’ in place of ‘stamping out’. He regarded Thorndike’s terms as too mentalistic, and his own as more objective and descriptive (Box 14.6).

---

**Box 14.5 Major similarities and differences between classical and operant conditioning**

**SIMILARITIES**

- They are both types of associative learning.
- Generalization, discrimination, extinction and spontaneous recovery occur in both.

**DIFFERENCES**

- In classical conditioning, the unconditioned response (UCR) or conditioned response (CR) is elicited (triggered automatically) by the unconditioned stimulus (UCS) or conditioned stimulus (CS) (it is essentially a reflex, involuntary response). In operant conditioning, behaviour is emitted by the organism and is essentially voluntary.
- In classical conditioning, the stimulus is guaranteed to produce the response, while the likelihood of a particular operant response being emitted is a function of the past consequences of such behaviour (it is more or less probable, but never certain).
- In classical conditioning, the UCS works in basically the same way regardless of whether it is pleasurable (e.g. food) or aversive (e.g. electric shock). In operant conditioning, responses that result in pleasurable outcomes are likely to be repeated, while those that result in aversive outcomes are not.
- In classical conditioning, completely new stimulus–response (S–R) connections are formed; operant conditioning, however, involves the strengthening or weakening of response tendencies already present in the animal’s behavioural repertoire.
- In classical conditioning, the reinforcer (UCS) is presented regardless of what the animal does, and is presented before the response. In operant conditioning, the reinforcer is presented only if the animal emits some specified, preselected behaviour and is presented after the behaviour.
- In classical conditioning, the strength of conditioning is typically measured in terms of response magnitude (e.g. how many drops of saliva) and/or latency (how quickly a response is produced by a stimulus). In operant, strength is measured mainly as response rate (Table 14.2).

---

**Box 14.6 Skinner’s analysis of behaviour (or the ABC of operant conditioning)**

The analysis of behaviour requires an accurate but neutral representation of the relationship (or contingencies) between the following:

- **Antecedents**: the stimulus conditions, e.g. the lever, the click of the food dispenser, a light that may go on when the lever is pressed
- **Behaviours or operants**: e.g. pressing the lever
- **Consequences**: what happens as a result of the operant behaviour – i.e. reinforcement or punishment.
According to Skinner’s version of the law of effect, ‘behaviour is shaped and maintained by its consequences’. The consequences of operants can be positive reinforcement, negative reinforcement or punishment (Figure 14.6).

Although both positive and negative reinforcement strengthen behaviour (making it more probable), each works in a different way. Positive reinforcement involves presenting something pleasurable (e.g. food), while negative reinforcement involves the removal or avoidance of some ‘aversive’ (literally ‘painful’) state of affairs (e.g. electric shock). Punishment weakens behaviour (making it less probable), through the presentation of an aversive stimulus (Figure 14.7).

### Reinforcers and reinforcement

Food is a reinforcer, and electric shock a punisher. The process whereby food is presented as a result of, say, lever-pressing is (positive) reinforcement; when electric shock is presented, it is called punishment. Skinner argues that deciding whether something is a reinforcer or a punisher can be done only after it has been made contingent on a specific behaviour on a number of occasions. Thus, if the behaviour is strengthened when followed by food, then the food is a reinforcer; if the shock weakens the behaviour, then the shock is a punisher. Reinforcers and punishers cannot be defined independently of the effects they have on behaviour.

Skinner’s definition could be accused of circularity (‘a...
reinforcer is whatever strengthens behaviour’ and ‘whatever strengthens behaviour is a reinforcer’). In practice, animals are starved for several hours before the experiments begin, in order to ensure that they will be motivated and find food reinforcing.

Skinner argues that his approach is more scientific, since the intended effect may not always coincide with the actual effect. For example, if a child who feels deprived of his or her parents’ attention is smacked and shouted at when misbehaving, the child is more likely to carry on being naughty. For a child who feels ignored, any attention is better than no attention at all. So, what is ‘punishment’ as far as the parents are concerned may be a positive reinforcement for the child. Similarly, a positive reinforcement can be called a reward only loosely, since the term ‘reward’ implies that the rewarder expects to strengthen some behaviour, whereas ‘positive reinforcement’ refers to what has been shown to strengthen it.

**Primary and secondary reinforcers**

Primary reinforcers (e.g. food, water, sex) are natural reinforcers (reinforcing in themselves). Secondary reinforcers acquire their reinforcing properties through association with primary reinforcers; that is, we have to learn (through classical conditioning) to find them reinforcing. Examples of human secondary (or conditioned) reinforcers are money, trading stamps, cheques and tokens (see Chapter 67).

In a Skinner box, if a click accompanies the presentation of each pellet of food, then the rat will eventually come to find the click on its own reinforcing. The click can then be used as a reinforcer for getting the rat to learn some new response. (Clickers are used in dog training, at first in conjunction with a primary reinforcer, such as a food treat, and then on their own). Secondary reinforcers are important because they bridge the gap between the response and the primary reinforcer, which may not be presented immediately.

**Schedules of reinforcement**

Another important aspect of Skinner’s work is concerned with the effects on behaviour of how frequently and how regularly (or predictably) reinforcements are presented. Ferster and Skinner identified five major schedules, each of which is associated with a characteristic pattern of responding.20 This part of Skinner’s research is largely counter-intuitive.21 Rats and pigeons (and probably most mammals and birds) typically ‘work harder’ (press the lever/peck the disc at a faster rate) for scant reward: when reinforcements are relatively infrequent and irregular or unpredictable, they
Learning theory will go on working long after the reinforcement has been withdrawn. So, each schedule can be analysed in terms of pattern and rate of response and resistance to extinction (see Table 14.2).

The rate of response can be represented by plotting responses cumulatively as steps along a vertical axis, against the time when they are made along the horizontal axis (Figure 14.8). Skinner called this a ‘cumulative record’.

![Typical cumulative records for a response (e.g. ever pressing) reinforced using five schedules of reinforcement. CRF, continuous reinforcement; FR, fixed ratio; FI, fixed interval; VI, variable interval; VR, variable ratio.](image)

A continuous schedule is usually used only when some new response is being learned. Once it has been emitted regularly and reliably, it can be maintained by using one of the four partial or intermittent schedules, but this change must be gradual. If the animal is switched from a continuous schedule to, say, a reinforcement given on average every 50 responses (VR 50), it will soon stop responding. Skinner originally used an interval schedule, because a reinforcer is guaranteed, sooner or later, so long as one response is made during the interval.

**Shaping: the reinforcement of successive approximations**

Reinforcement can be used to build up relatively complex behaviour (not part of the animal’s natural repertoire) by reinforcing closer and closer approximations to the desired behaviour (shaping). First, the behaviour must be broken down into a number of small steps, each of which is reinforced in sequence. Gradually, what the animal can do is much more like what the experimenter is trying to teach it. This is what animal trainers have been doing for hundreds of years, and it is the method of reinforcement that Skinner used to teach pigeons to play ping-pong or to turn a full anticlockwise circle. Most human skills are learned in this step-by-step manner.

Shaping also provides an important foundation for behaviour modification. This is used to teach children and adults with learning difficulties to use the toilet, feed and dress themselves, and other social skills. It has also been used to develop speech in children with autism and adults with schizophrenia (see Chapter 67).

**Negative reinforcement: escape and avoidance learning**

Escape and avoidance learning are the two major ways in which negative reinforcement has been studied in the laboratory. Escape learning is relatively simple. For example, rats can learn to press a lever in order to turn off electric shock. Avoidance learning is more complex and more relevant to certain aspects of human behaviour (Box 14.7).

Miller trained rats to run out of a white room, through a small door, into a black room by giving them shocks in the white room. After pretraining, the door was closed and could be opened only by the rat turning a wheel. Even though no further shocks were given, the residual ‘aversiveness’ of the white room (acquired through classical conditioning) was sufficient to motivate the rats to learn quickly to turn the wheel. This allowed them to run through into the ‘safe’ room, thus relieving their anxiety (negative reinforcement).

This illustrates an important difference between positive and negative reinforcement in relation to extinction. If we try to teach a rat a new response in order to get it into a black box that used to contain food, the rat will soon stop responding (it soon ‘discovers’ that the food is no longer available).

**Box 14.7 Avoidance learning through negative reinforcement**

Most laboratory studies use a shuttle box, a box divided into two compartments, sometimes with a barrier or door between them. Electric shocks can be delivered through the floor of either compartment independently of the other. Neither side is permanently safe, but only one is electrified at any one time.

The animal’s task is to find which is the safe side on any one occasion. A warning signal (a light or buzzer) is given whenever the electrified side is to be changed, so the animal can always avoid being shocked if it switches sides when it hears or sees the signal.

According to the two-factor theory\(^{23}\) or the two-process theory\(^{23}\), the animal first learns to be afraid (the warning signal elicits an anticipatory emotional response of fear/anxiety through classical conditioning). It then learns a response to reduce the fear (jumping the barrier is negatively reinforced by avoiding the shock before it is switched on).
available). But if a rat successfully escapes from a white room that used to be dangerous, the rat may go on escaping indefinitely (it does not stay around long enough to ‘discover’ that the shock is no longer happening).

So, responses motivated by conditioned fear/anxiety should take longer to extinguish than those motivated by positive incentives. Avoidance learning prevents the learner from testing reality, and this has been found in dogs and humans.30 This can explain both the persistence of human phobias and the use of methods to remove them based on the principle of forced reality testing (see Chapter 67).

Punishment

Skinner maintained that, with both humans and non-humans, positive (and, to a lesser extent, negative) reinforcement is a much more potent influence on behaviour than is punishment. This is largely because punishment can only make certain responses less likely: you cannot teach anything new by punishment alone.

However, Campbell and Church argue that punishments are, if anything, a stronger influence on behaviour than the incentive effects of reinforcements (at least as far as laboratory animals are concerned).27 But punishment produces unpleasant side effects, such as stress, anxiety, withdrawal and aggression.

Estes concluded that punishment merely suppresses lever-pressing in the short term but does not weaken it.28 Other experiments have shown that the strength and duration of the suppression effect depend on the intensity of the punishment and the degree of deprivation. However, the response is still suppressed rather than unlearned.

When alternative ways of obtaining reinforcers are available, punishment has a more powerful suppressive effect on the punished behaviour.29 For example, Azrin and Holz combined punishment and reinforcement, so that response A was punished while response B (incompatible with A) was positively reinforced.30 Skinner advocates this with human beings.

The antecedents of behaviour: stimulus control

In operant conditioning, the stimulus indicates the likely consequence of emitting a particular response: the operant behaviour is more likely to occur in the presence of some stimuli than others. If a rat has been reinforced for pressing the lever, then it is more likely to go on emitting that response as the lever becomes associated with both reinforcement and the action of pressing (probably through classical conditioning). Technically, lever-pressing has now come under the stimulus control of the lever. But there is still no inevitability about pressing it, only an increased probability. (This is why the term ‘S–R psychology’ strictly applies only to classical conditioning.)

Similarly, drivers’ behaviour is brought under the stimulus control of traffic signals, road signs, other vehicles, pedestrians and so on. Much of our everyday behaviour can be seen in this way. Sitting on a chair, answering the telephone, turning on the television and so on are all operants that are more likely to occur in the presence of those stimuli because of the past consequences of doing so.

A special case of stimulus control is a discriminative stimulus. If a rat in the Skinner box is reinforced for lever-pressing only when a light is on, then the light soon becomes a discriminative stimulus (the rat presses the lever only when the light is on).

Does conditioning work in the same way for all species?

The fact that many experiments involving a variety of species can all be described as classical conditioning does not in itself mean that there is only one mechanism involved, or only one explanation that applies equally to all species and all cases.31 Although conditionability seems to be an almost universal property of nervous systems (including those of sea snails, flatworms and fruit flies), many psychologists have argued that there can be no general laws of learning.

If such laws do exist, then one of them is likely to be the law of contiguity: events (or stimuli) that occur close together in time and space are likely to become associated with each other. Most of the examples of conditioning that we have considered so far would appear to ‘obey’ the law of contiguity. Box 14.8 describes some very important exceptions to this law.

Although rats can also be conditioned to novel smells, auditory, visual and tactile stimuli are not associated so readily with internal illness. As for pigeons, it is impossible to deter them from water and, for other species, taste aver- sions are very difficult to establish, even if the animal is made very ill. In almost all species, aver-sions to new
flavours are learned more easily than aversions to familiar flavours (saccharine solution is a novel taste for the rat).

**Biological constraints on conditioning**

It seems, then, that there are definite biological limitations on the ability of animals to develop a conditioned aversion. Similarly, rats typically learn very quickly to avoid shock in a shuttle box and to press a lever for food. However, they do not learn very readily to press a lever in order to avoid shock. Pigeons can be trained quickly to fly from one perch to another in order to avoid shock, but it is almost impossible to train them to peck a disc in order to avoid shock.

Findings such as these have led Bolles and others to conclude that we cannot regard the basic principles of learning as applying equally to all species in all situations. We must take into account the evolutionary history of the species, as well as the individual organism’s learning history. An important idea in this context is Seligman’s concept of preparedness. Animals are biologically prepared to learn actions that are related closely to the survival of their species (e.g. learned water or food aversions), and these prepared behaviours are learned with very little training. Equally, contra-prepared behaviours are contrary to an animal’s natural tendencies and so are learned with great difficulty, if at all. Seligman believes that most of the behaviour studied in the laboratory falls somewhere in between these two extremes.

As far as human behaviour is concerned, much of the relevant data relate to how easily certain conditioned fear responses can be induced in the laboratory or how common certain naturally occurring phobias are compared with others. For example, Ohman et al. paired slides of snakes and spiders with a strong electric shock and quickly established conditioned emotional responses to these slides – but not to slides of flowers, houses or berries. Seligman observed that human phobias tend to fall into certain narrow categories – mostly animals and dangerous places. Most common of all were fears of snakes, spiders, the dark, high places and closed-in places; often there is no previous evidence for the fear actually having been conditioned (see Chapter 40). Also, classically conditioned responses extinguish faster in humans than animals. This is because the CRs are modulated by more complex human memories.

**Classical conditioning**

Pavlov described the CS as a ‘signal’ for the UCS, the relationship between CS and the UCS as one of ‘stimulus substitution’, and the CR as an ‘anticipatory’ response (or ‘psychic secretions’), suggesting that his dogs were expecting the food to follow the bell. Consistent with this interpretation, Rescorla presented two groups of animals with the same number of CS–UCS pairings, but the second group also received additional presentations of the UCS on its own without the CS. The first group showed much stronger conditioning than the second group, indicating that the most important factor (at least in classical conditioning) is how predictably the UCS follows the CS, rather than how often the CS and UCS are paired.

**Blocking** also supports a more cognitive interpretation. For example, if an animal is shown a light, quickly followed by an electric shock, then the light soon comes to elicit fear as a CR. If a noise is then added (noise + light + shock), then the noise should also soon become a CS, because it too is being paired with shock. However, this is not what happens. If the noise is later presented alone, it fails to produce a CR. It seems that the noise has somehow been ‘blocked’ from becoming a CS because of the previous conditioning to the light. In cognitive terms, since the light already predicts shock, the noise is irrelevant. It provides no additional information – the animal already ‘knows’ that shock will follow the light.

**Operant conditioning**

Seligman’s study of learned helplessness is described in Box 14.9. According to Seligman, the dogs learned that no behaviour on their part had any effect on the occurrence (or non-occurrence) of a particular event (the shock). This has

---

**Box 14.9 Learned helplessness**

Dogs were strapped into a harness and given a series of shocks from which they could not escape. The dogs were later required to jump a barrier in a shuttle box within 10 s of a warning signal, or suffer 50 s of painful shock.

Control dogs (which had not been subjected to the inescapable shocks) learned the avoidance response very quickly, but about two-thirds of the experimental dogs seemed unable to do so. The experimental dogs seemed passively resigned to suffering the shock. Even if they did successfully avoid the shock on one trial, they were unlikely to do so on the next trial. Some dogs had to be pushed over the barrier 200 times or more before this learned helplessness wore off.
been demonstrated by Miller and Norman using human participants.43 Maier and Seligman have tried to explain depression in humans in terms of learned helplessness (see Chapter 39).44

Skinner’s claim that reinforcements and punishments automatically strengthen and weaken behaviour has been challenged by Bandura: ‘Reinforcements serve principally as an informative and motivational operation rather than as a mechanical response strengthener.’45,46

Reinforcement provides the learner with information about the likely consequences of certain behaviour under certain conditions; that is, it improves our prediction of whether a given action will lead to pleasant (reinforcement) or unpleasant (punishment) outcomes in the future. It also motivates us by causing us to anticipate future outcomes. Our present behaviours are governed largely by the outcomes that we expect them to have, and we are more likely to learn behaviour if we value its consequences.

Social learning theory
This cognitive reinterpretation of reinforcement forms part of Bandura’s social learning theory (SLT),45,46 which has been applied to a variety of behaviours, including aggression, moral and gender development, and personality (see Gross47 and Chapter 19). SLT represents an attempt to reinterpret certain aspects of Freud’s psychoanalytical theory in terms of classical and operant conditioning.

As well as focusing on human social behaviour, Bandura and other social learning theorists believe that there are important cognitive mediating variables between stimulus and response without which we cannot explain human behaviour adequately. Some of the most important cognitive variables include self-concept, self-monitoring (or self-regulation) and self-efficacy (our belief that we can act effectively and exercise control over events that influence our lives).55,48 Self-efficacy is crucially important for motivation: how we judge our own capabilities is likely to affect our expectations about future behaviour (see Chapter 15). The central importance of cognitive factors is reflected in Bandura’s renaming of SLT as social cognitive theory.48,49

Social learning theorists also emphasize the role of observational learning (or modelling); that is, learning through the behaviour of others – models. This occurs spontaneously, with no deliberate effort by the learner, or any intention by the model to teach anything. Observational learning takes place without any reinforcement: mere exposure to the model is sufficient for learning to occur.50

Tolman’s cognitive behaviourism
Although working within the behaviourist tradition in the 1920s, 1930s and 1940s, Tolman would be regarded today as a cognitive psychologist. He explained the learning of rats in terms of inferred cognitive processes, in particular cognitive or mental maps.

In Box 14.10, clearly the rats in group 3 had been learning their way through the maze during the first 10 days, but the learning was latent (hidden or ‘behaviourally silent’). In other words, the learning did not show up in their actual behaviour until they received the incentive of the reinforcement on day 11. Tolman and Honzik concluded that reinforcement may be important in relation to performance of learned behaviour, but that it is not necessary for the learning itself.51

---

**Box 14.10 Latent learning: who needs reinforcement?**

- **Group 1** rats were reinforced every time they found their way through a maze to the food box.
- **Group 2** rats were never reinforced.
- **Group 3** rats received no reinforcement for the first 10 days of the experiment, but did so from day 11.

Not surprisingly, the rats in group 1 learned the maze quickly and made fewer and fewer mistakes, while the rats in group 2 never reduced the time it took to find the food, and moved around aimlessly much of the time.

The rats in group 3 made no apparent progress during the first 10 days, but they then showed a sudden decrease in the time it took to reach the goal box on day 11, when they received their first reinforcement. They caught up almost immediately with the rats in group 1 (Figure 14.9).

**Figure 14.9** Results of Tolman and Honzik’s study of latent learning in rats
Tolman’s *place learning* (or *sign learning*) theory maintains that rats learn expectations as to which part of the maze will be followed by which other part of the maze. Tolman called these expectations *cognitive maps*, a primitive kind of perceptual map of the maze, an understanding of its spatial relationships (much like the mental map you have of familiar streets leading to places you know well).

Although a cognitive map can only be inferred from actual behaviour, it is difficult to know how else to explain the findings that rats will take shortcuts to the food box if the old path is blocked. Similarly, if the maze were rotated, the rats could find the usual food location from several different starting points. Restle flooded a maze immediately after a group of rats had learned to run it, and they were able to swim to the goal box with no more errors than when they had walked. This clearly supports Tolman’s interpretation.

**Practical applications of learning theory**

As we have seen, methodological behaviourism’s emphasis on experimentation, operational definitions and the measurement of observable events has had a major influence on the practice of scientific psychology in general, quite unrelated to any views about the nature and role of mental events. Other, more tangible, contributions include the following:

- **Behaviour therapy** and **behaviour modification** (based on classical and operant conditioning, respectively) are major approaches to the treatment of abnormal behaviour (see Chapter 67) and one of the main tools in the clinical psychologist’s kit bag (see Chapter 9). Specific examples of behaviour modification in particular have been given above.

- **Behavioural neuroscience** is an interdisciplinary field of study, using behavioural techniques to understand brain function and neuroscientific techniques to elucidate behavioural processes. Although many researchers believe that behaviour can be reduced to, or explained by, brain processes, the evidence shows that each is dependent on the other.

- **Behavioural pharmacology** involves the use of schedules of reinforcement to assess the behavioural effects of new drugs that modify brain activity. Most importantly, the research has illustrated how many behavioural effects of drugs are determined as much by the current behaviour and reinforcement contingencies as by the effects of the drug on the brain.

- **Environmental enrichment studies** have produced evidence for neuronal plasticity; that is, the brain’s capacity for change and adapting to changing environmental conditions. These findings have exciting implications for the treatment of strokes and other conditions involving brain damage.

According to Leslie:

> The life-long interaction between the behaviour of the individual and the environment produces changes in the brain. This in turn changes behaviour, and so the interaction goes on. Any attempt to deal with a human behavioural problem can involve changes to the nervous system, behaviour or the environment.

**Learning theory and addiction**

**Classical conditioning**

According to Claridge and Davis, the common reward pathway in the brain is also involved in *associative learning*; that is, in establishing the conditioned reinforcement of environmental cues that signal the approach or onset of the natural reward state. They are referring to *classical conditioning*.

As applied to addiction, classical conditioning might be able to explain how a stimulus associated with a drug (e.g. drug paraphernalia) can come to produce a similar response to the response produced by the drug itself (as well as a similar reaction in the brain), but it cannot explain how or why the drug is taken in the first place. Unless the drug is forced upon the individual in some way, we need to account for how addiction is initiated, and classical conditioning (on its own) cannot do this because it can account only for involuntary behaviour.

Because of the powerful nature of the response produced by most drugs, classical conditioning can better explain the maintenance of addictive behaviours (e.g. through the process of *stimulus generalization*). However, what about addictive activities that do not involve such powerful, biologically determined UCRs? For example, by definition, gamblers win only some of the time (they usually lose more often than they win); so why does gambling not stop through extinction? The answer seems to rely on operant conditioning (see below).

As we have seen, when experimental animals are presented with the CS without the UCS, the CR gradually weakens and eventually stops altogether (*experimental extinction*); this is equivalent to the addict being denied access to the substance or activity of their addiction and abstaining. However, when the UCS is later reintroduced, experimental animals will display the CS again (through *spontaneous recovery*). This corresponds to the addict’s relapse and shows that in extinction the CS is merely suppressed rather than destroyed.

From an evolutionary perspective, the ability of environmental cues to signal the approach or onset of the natural reward state is clearly a very adaptive function: the organism will fare much better if it can discriminate between stimuli that predict when a rewarding event is likely to happen, and those that do not. A relatively large body of research supports the role of the amygdala in this process, because it maintains a representation of the affective (emotional) value...
of the CS (see Claridge and Davis). This is a good example of how the function of brain structures complements, and is correlated with, psychological processes (here, acquiring conditioned responses through classical conditioning).

The strength of conditioned reinforcement is greatly enhanced when the CS is paired with certain kinds of UCS (in particular, pharmacological rewards, e.g. cocaine) than others (e.g. food). This demonstrates that classical conditioning is a more complex learning process than it might at first appear: its effects are mediated by which particular UCS is used (which suggests the role of biological factors). Other research has demonstrated the role of biological factors (see above).

**Operant (instrumental or Skinnerian) conditioning**

One of the best-known explanations of gambling behaviour is that it illustrates very well the process of operant conditioning, specifically, a variable ratio reinforcement schedule (see Table 14.2). As in all cases of operant conditioning, the organism must perform some specified action in order to receive a particular positive reinforcement.

In general terms, applying this framework to drug dependence is straightforward if we define dependence operationally as an excessive tendency to engage in drug-taking behaviour. According to Powell:

...This implies that the rewards to the addict are so salient, and sufficiently reliable, that he or she has become motivated to take the drug progressively more often in order to achieve these effects, eventually reaching a point where the desire overwhelms all else...56

If a gambler is used to winning only on a certain proportion of occasions, then not winning on any particular occasion will come as no surprise and will not cause the behaviour to extinguish (as might happen if the gambler wins every time). Tied to this irregularity of success is the unpredictability (the gambler does not know when the next success will come): not winning will not ‘throw’ the gambler. However, wins and losses average out over a large number of bets. (Of course, if the gambler never won again, the behaviour would, eventually, cease).

This account relates to maintenance of behaviour: the gambling will persist in the absence of reinforcement because the gambler is used to receiving only intermittent, irregular reinforcements. However, as with classical conditioning, its ability to explain initiation is very limited. Unlike classical conditioning, a VR schedule describes a situation where the reinforcer is presented a specific proportion of times the response is made. As we have seen, the behaviour persists for much longer than it would if the reinforcement occurred every time (i.e. abstinence is more difficult to achieve); relapse (which occurs only after a period of abstinence) is, therefore, less likely to occur in the first place, but if it does occur, it can be also be explained in terms of spontaneous recovery.

However, just because gambling is commonly given as the classic example of human behaviour controlled by a VR schedule does not mean that other addictive behaviours can necessarily be explained in similar terms. The equivalent for the drug addict would be that only sometimes does snorting cocaine produce a high; although some highs may be higher than others, this is hardly equivalent to winning or not winning on, say, a fruit machine. Also, different classes of drug exert very different pharmacological effects, so that the rewards that have contributed to the development of the addiction will vary from drug to drug.56

As well as accounting for maintenance/persistence of certain addictive behaviours, operant conditioning also offers an explanation of how difficult it might be for someone to break their habit. For example, the decision to try to break a habit can be seen as reflecting the strength of its punishing outcomes: since most habits produce mixed effects, some pleasant and others aversive, addicts may find themselves in an approach-avoidance conflict, where motivation fluctuates between wanting to use and wanting to stop.56

In the context of gambling, Sharpe (cited in Bennett) claims that, although VR schedules undoubtedly contribute to high levels of social gambling, they do not fully explain pathological gambling, where consistent and significant losses do not cause the individual to stop gambling. Sharpe suggests that large payouts and, in particular, a ‘big win’ early in a gambling career establish and sustain pathological gambling. These presumably distort expectations of the outcomes of gambling and support losses in the expectation of future ‘big wins’.

**Social learning theory**

As we saw above, neither classical nor operant conditioning can easily explain how addictive behaviours occur in the first place. But SLT, through its emphasis on observational learning/modelling, together with its claim that mere exposure to the model is sufficient for learning to take place, can quite easily explain why someone would begin engaging in behaviour that leads to addiction. Although reinforcement of some kind might be necessary for the learned behaviour to actually show, this may only require the model to be rewarded.50 So, for example, observing a model win at a fruit machine might be enough for a child to begin developing the habit.

---

**KEY POINTS**

- Learning has played a major part in the development of psychology as a scientific discipline and is central to the behaviourist approach. Psychologists are interested in learning as a process.
- It is generally agreed that learning involves a relatively permanent change in behaviour due to past experience.
Watson’s methodological behaviourism focuses on what can be observed and quantified by different observers. Skinner’s radical behaviourism regards mental processes as both inaccessible and irrelevant to explaining behaviour.

The distinction between respondent and operant behaviour corresponds to classical (respondent or Pavlovian) and operant (instrumental or Skinnerian) conditioning, respectively.

In classical conditioning, the pairing of a conditioned and an unconditioned stimulus results in the former eliciting a response that formerly was produced only by the latter.

Delayed/forward, backward, simultaneous and trace conditioning differ according to the relationships between the conditioned and the unconditioned stimuli.

Generalization, discrimination, extinction and spontaneous recovery represent conditioning phenomena that make it more complex and versatile. Spontaneous recovery demonstrates that extinction involves a learning to inhibit/suppress the conditioned response.

Watson applied classical conditioning to human behaviour for the first time by inducing fear of a rat in Little Albert. Jones removed animal phobias from Little Peter using an early form of systematic desensitization.

Compared with classical conditioning, operant conditioning considers learning to be a much more active process. Skinner was interested in how animals operate on their environment, and how their activity is instrumental in producing certain consequences.

Skinner’s work was based on Thorndike’s law of effect. He designed a form of puzzle-box (a Skinner box), and called the consequences of behaviour positive reinforcement, negative reinforcement and punishment.

Reinforcement (both positive and negative) strengthens behaviour, while punishment weakens it.

Primary reinforcers are naturally reinforcing, while secondary/conditioned reinforcers come to be reinforcing through association with primary reinforcers.

Different schedules of reinforcement can be analysed in terms of pattern/rate of response and resistance to extinction. Variable schedules involve high, steady rates of response and high resistance to extinction, compared with fixed and continuous schedules.

Shaping involves the reinforcement of successive approximations to the desired behaviour.

Escape and avoidance learning are two forms of negative reinforcement. They have been explained by the two-factor theory, according to which both classical and operant conditioning are involved. The persistence of human phobias can be understood in terms of avoidance learning.

Punishment seems to involve a suppression of behaviour and is most effective when combined with the reinforcement of an incompatible response.

Taste-aversion experiments contribute to the view that the basic principles of conditioning do not apply equally to all species in all situations.

Preparedness helps to explain experimental findings showing that different species acquire certain conditioned responses more or less easily, and why certain human phobias are more common than others.

Classical conditioning involves learning about relations between environmental events, rather than a simple strengthening of S–R associations. Seligman’s concept of learned helplessness illustrates the complexity of operant conditioning and has been used to explain human depression.

Tolman’s studies of latent learning show that learning can take place in the absence of reinforcement. Rats learn a cognitive map of the maze rather than the individual movements of walking or running that take them to the food box.

Methodological behaviourism has influenced the practice of scientific psychology in general. Other applications of learning theory include behaviour therapy and modification, behavioural neuroscience and pharmacology, and environmental-enrichment studies.

Although classical and operant conditioning can both explain the maintenance of various addictions, only social learning theory can account for their initiation.

Motivation

Richard Gross

INTRODUCTION

Trying to define motivation is a little like trying to define psychology itself. Taking as a starting point the layperson’s view of psychology as the study of ‘what makes people tick’, motivation is concerned with why people act and think the way they do. ‘Why’ questions – and related ‘how’ questions – usually imply causes and underlying mechanisms or processes.

Each of the major theoretical approaches within psychology (behaviourist, psychodynamic, humanistic, neurobiological/biogenic, cognitive, evolutionary, social constructionist: see Gross1) tries to identify the key processes and mechanisms. This is also true of the neurobiological/biogenic approach. At the heart of each approach lies an image of human beings that, in essence, is a theory of the causes of human behaviour.

Motivated behaviour is goal-directed, purposeful behaviour. It is difficult to think of any behaviour, human or non-human, that is not motivated in this sense. However, just how the underlying motives are conceptualized and investigated depends very much on the persuasion of the psychologist. For example:

● A psychodynamic psychologist will try to discover internal, unconscious drives and motives (see Chapter 19 for a discussion of Freud’s psychoanalytical theory).

● A behaviourist psychologist will look for environmental schedules of reinforcement, which can explain the behaviour of rats and pigeons as effectively as that of human beings (see Chapter 14). As a radical behaviourist, Skinner rejects the claim that mental or other internal events or processes – conscious or unconscious – can influence behaviour in any way. For him, ‘motivation’ and other mentalistic terms are ‘explanatory fictions’.

● A humanistic psychologist, such as Maslow, will try to understand a person’s behaviour in terms of a hierarchy of motives, with self-actualization at the top of the hierarchy.

● For a biopsychologist, what is crucial are bodily events and processes taking place in the central nervous system (CNS), the autonomic nervous system (ANS) and the endocrine system, or interactions between these different systems. These events and processes are related to the biological survival of the person or animal.

Although we shall consider a range of different motives, this chapter has a very ‘biological’ flavour. Maslow’s hierarchy of needs is useful as a general framework for examining other approaches. Homeostatic drive theories try to explain hunger and thirst. But even in the case of such basic biological motives as these, cognitive and other individual factors, as well as social, cultural and other environmental factors, play a crucial role.

We shall also consider non-homeostatic needs and drives, including electrical self-stimulation of the brain (ES-SB), competence and cognitive motives, and some important social motives.

WHAT IS MOTIVATION?

According to Rubin and McNeil, motives are a special kind of cause that ‘… energize, direct and sustain a person’s behaviour (including hunger, thirst, sex and curiosity)’.2 Similarly, ‘Motivation refers, in a general sense, to processes involved in the initiation, direction, and energization of individual behaviour …’3

The word ‘motive’ comes from the Latin movere (= move), and this is captured in Miller’s definition:

The study of motivation is the study of all those pushes and prods – biological, social and psychological – that defeat our laziness and move us, either eagerly or reluctantly, to action.4

As we noted in the introduction to this chapter, different schools of thought within psychology look for the causes of behaviour in very different places. These differences indicate that motives may vary with regard to a number of features or dimensions, including:

● internal or external;
● innate or learned;
● mechanistic or cognitive;
● conscious or unconscious.

Several attempts have been made to classify different kinds of motive. For example, Rubin and McNeil classify
motives into (i) survival or physiological motives and (ii) competence or cognitive motives. Social motives represent a third category. Clearly, humans share survival motives with all other species, as well as certain competence motives (see below). But other motives are peculiarly and uniquely human, notably self-actualization, which lies at the peak of a ‘hierarchy of needs’ in Maslow’s humanistic theory.

**Maslow’s hierarchy of needs**

Although Maslow’s theory is commonly discussed in relation to personality (see Chapter 19), its focus on needs makes it equally relevant to motivation (Figure 15.1). (The book in which Maslow first proposed his hierarchy was called *Motivation and Personality*.) According to Maslow, we are subject to two quite different sets of motivational states or forces:

- those that ensure survival by satisfying basic physical and psychological needs (physiological, safety, love and belongingness, esteem); and
- those that promote the person’s self-actualization; that is, realizing one’s full potential, ‘becoming everything that one is capable of becoming’, especially in the intellectual and creative domains.

As Maslow states, ‘We share the need for food with all living things, the need for love with (perhaps) the higher apes, [and] the need for Self-Actualization with [no other species].’

Behaviours that relate to survival or deficiency needs (deficiency or D-motives) are engaged in because they satisfy those needs (a means to an end). But behaviours that relate to self-actualization are engaged in for their own sake, because they are intrinsically satisfying (growth, being or B-motives). The latter include the fulfilment of ambitions; the acquisition of admired skills; the steady increase of understanding about people, the universe and oneself; the development of creativeness in whatever field; and, most importantly, simply the ambition to be a good human being. It is simply inaccurate to speak in such instances of tension reduction, which implies the overcoming of an
annoying state, for these states are not annoying.7 (Another term for ‘tension reduction’ is ‘drive reduction’, which is discussed below). Maslow’s argument is that to reduce the full range of human motives to drives that must be satisfied or removed is simply mistaken.

The hierarchical nature of Maslow’s theory is intended to highlight the following points:

- Needs lower down in the hierarchy must be satisfied before we can attend to needs higher up. For example, if you are reading this while your stomach is trying to tell you that it is lunchtime, you probably won’t absorb much about Maslow (pun intended!). Similarly if you are tired or in pain. Yet you can probably think of exceptions, such as the starving artist who finds inspiration despite hunger, or the mountain climber who risks his or her life for the sake of adventure (what Maslow would call a ‘peak’ experience – an unintended pun!).

- Higher-level needs are a later evolutionary development: in the development of the human species (phylogensis), self-actualization is a fairly recent need. This applies equally to the development of individuals (ontogenesis): babies are concerned much more with their bellies than with their brains. But it is always a case of one need predominating at any one time rather than excluding all other needs.

- The higher up the hierarchy we go, the more the need becomes linked to life experience and the less ‘biological’ it becomes. Individuals achieve self-actualization in different ways, through different activities and by different routes. This is related to experience, not biology: ‘A musician must make music, an artist must paint, a poet must write, if he is to be ultimately at peace with himself. What a man can be, he must be.’7 This quote from Maslow captures nicely the idiographic nature of Maslow’s theory – that is, the view that every individual is unique (see Chapter 19).

- The higher up the hierarchy we go, the more difficult it becomes to achieve the need. Many human goals are remote and long-term and can be achieved only in a series of steps. This pursuit of aims and goals that lie very much in the future is unique to human beings, although individuals differ in their ability to set and realize such goals.

THE EARLY STUDY OF MOTIVATION

As with many other aspects of psychology, the study of motivation has its roots in philosophy (see Chapter 9 and Gross8). Rationalists saw human beings as free to choose between different courses of action. This makes the concept of motivation almost unnecessary: it is our reason that determines our behaviour. This idea of freedom and responsibility is a basic premise of both humanistic and cognitive approaches (but see Chapter 10).

The seventeenth-century British philosopher Hobbes proposed the theory of hedonism. This maintains that all behaviour is determined by the seeking of pleasure and the avoidance of pain. These are the ‘real’ motives (whatever we may believe, and this idea is central to Freud’s psychoanalytical theory, captured in the concept of the pleasure principle. Similarly, the basic principles of positive and negative reinforcement can be seen as corresponding to the seeking of pleasure and the avoidance of pain, respectively, and these are central to Skinner’s operant conditioning (see Chapter 14).

During the 1920s, the concept of instinct (Box 15.1) was largely replaced by the concept of drive. The term ‘drive’ was first used by Woodworth, who compared human behaviour with the operation of a machine: the mechanism of a machine is relatively passive and drive is the power applied to make it ‘go’. The concept of drive has taken two major forms: homeostatic drive theory,12 which is a physiological theory, and drive-reduction theory,13 which is primarily a theory of learning.

Box 15.1 Motives as instincts

The concept of instinct played a major role in early psychological approaches to motivation. Many psychologists, inspired by Darwin’s theory of evolution, which argued that humans and animals differ only quantitatively,9 identified human instincts that would explain human behaviour.

For example, McDougall originally proposed 12, and by 1924 over 800, separate instincts.10 But to explain behaviour by labelling it explains nothing (e.g. ‘We behave aggressively because of our aggressive instinct’ is a circular statement). This, combined with the sheer proliferation of instincts, seriously undermined the whole approach.

However, the concept of instinct – with certain important modifications – remains a central feature of the ethological approach to behaviour, in particular non-human animal behaviour (see Gross et al.11).

HOMEOSTATIC DRIVE THEORY

The term ‘homeostasis’ is derived from the Greek homos (= same), and stasis (= stoppage). The term was coined by Cannon to refer to the process by which an organism maintains a fairly constant internal (bodily) environment; that is, how body temperature, blood sugar level, salt concentration in the blood, and so on are kept in a state of relative balance or equilibrium.12

The basic idea is that when a state of imbalance arises (e.g. through a substantial rise in body temperature), some-
thing must happen to correct the imbalance and restore equilibrium (sweating). In this case, the animal does not have to ‘do’ anything, because sweating is completely automatic and purely physiological. However, if the imbalance is caused by the body’s need for food or drink (tissue need), then the hungry or thirsty animal has to do something in order to obtain food or water. This is where the concept of a homeostatic drive becomes important. Tissue need leads to internal imbalance, which leads to homeostatic drive, which leads to appropriate behaviour, which leads to restoration of internal balance, which leads to drive reduction.

The internal environment requires a regular supply of raw materials from the external world. Although oxygen intake, for example, is involuntary and continuous, eating and drinking are voluntary and discontinuous (or spaced). We talk about a hunger and thirst drive, but we do not talk about an oxygen drive. Because of the voluntary nature of eating and drinking, hunger and thirst are the homeostatic drives that biopsychologists have been most interested in.

**Hunger and eating**

**Does hunger cause eating?**

If there is a common-sense theory of eating, it is that we eat because – and when – we are hungry. What could be simpler? If asked why we get hungry, most people would probably say that ‘our bodies get hungry’; that is, certain events take place in our bodies when we have not eaten for a certain period of time, and these events act as the signal to eat. We experience that signal as hunger.

This fits neatly with the hunger drive outlined above. If we place the experience of hunger in between internal imbalance and homeostatic drive, we get a blend of the common-sense and drive-reduction theories, with hunger towards the end of a chain of causation that results in eating.

But is hunger either a necessary or sufficient condition for eating to occur? Can eating occur in the absence of hunger, and is it possible that we might not eat despite being hungry? We have all been tempted by the look or the smell of food when not feeling hungry, and we are not usually still hungry by the time the dessert trolley comes along. In other words, we often eat simply because we like it. This suggests that hunger is not necessary for eating. Conversely, people who go on weight-loss diets or hunger strike choose to not eat (or to eat less than they might otherwise do) despite being very hungry, suggesting that hunger is not sufficient.

So, there seems to be no biological inevitability about the hunger–eating relationship. However, as Blundell and Hill point out, under many circumstances there is a close relationship between the pattern of food intake and the rhythmic fluctuation of hunger. For example, many experimental studies confirm a strong link between the intensity of experienced hunger sensations and the amount of food eaten. This fairly consistent finding has been interpreted as showing that there is a causal connection between hunger and the size of a following meal. But in reality, certain physiological mechanisms are probably producing both the sensations of hunger and the eating behaviour.

Blundell and Hill propose an *appetite-control system*, in which hunger, eating and physiological mechanisms are coupled together, but the coupling is not perfect. There will be circumstances where uncoupling can occur, as in the hunger strike example and in cases of eating disorders (e.g. obesity, anorexia nervosa; see Chapter 42). So, what might some of these physiological mechanisms be? Assuming that, normally, these are coupled (or correlated) with hunger, what happens when the ‘body gets hungry’?

**What prompts us to eat?**

Carlson points out that the physiological signals that cause eating to begin are not necessarily the same signals that cause it to end. There is considerable delay between the act of eating (the *correctional mechanism*) and a change in the state of the body. So, although we may start eating because the level of nutrients has fallen below a certain point, we certainly do not stop because that level has been restored to normal. In fact, we usually stop eating long before this, since digestion takes several hours to complete. Therefore, the signals for hunger and for satiety (the state of no longer being hungry) are sure to be different. Probably the earliest formal theory of hunger was proposed by Cannon (Box 15.2).

**An evaluation of Cannon’s ‘hunger pangs’ theory**

Sometimes patients have their stomach removed because of disease and the oesophagus is ‘hooked up’ directly to the duodenum or small intestine. The patients continue to report feeling hungry and satiated. Even though their stomachs are bypassed, they maintain normal body weight by eating more frequent, smaller meals. Similarly, cutting the neural connections between the gastrointestinal tract (comprising mainly the stomach and intestine) and the brain (i.e. cutting the vagus nerve) has little effect on food intake either in experimental animals or in human patients.

These findings suggest that Cannon exaggerated the importance of stomach contractions in causing hunger. But this does not mean that the stomach and the gastrointestinal tract play no part in hunger and satiety. If the vagus nerve is cut, then signals arising from the gut can still be communicated to the brain via the circulatory system. These signals convey information about the components of the food that has been absorbed. Some of the nutrients whose depletion acts as a signal to start eating are fats (lipids), carbohydrates (including glucose), vitamins/mineral salts and proteins/amino acids. Fats and carbohydrates are burned up in cellular reactions and provide the energy to fuel metabolic processes.

Also, the presence of food in the stomach (stomach load-
Box 15.2 ‘Swallow a balloon if you’re hungry’

Cannon originally believed that the hunger drive is caused by stomach contractions (‘hunger pangs’) and that food reduces the drive by stopping the contractions.

Washburn swallowed an empty balloon tied to the end of a thin tube. Then Cannon pumped some air into the balloon and connected the end of the tube to a water-filled glass U-tube, so that Washburn’s stomach contractions would cause an increase in the level of water at the other end of the U-tube (Figure 15.2). He reported a ‘ pang’ of hunger each time a large stomach contraction was recorded.

Figure 15.2 System developed by Cannon and Washburn in 1912 for measuring stomach contractions

These results were soon confirmed by a case study (cited in Carlson16) of a patient with a tube implanted through his stomach wall, just above the navel. He had accidentally swallowed some acid, which caused the walls of his oesophagus to fuse shut. The tube allowed him to feed himself and provided a means of observing his stomach activities.

When there was food in his stomach, small rhythmic contractions (subsequently named peristaltic contractions/peristalsis) mixed the food and moved it along the digestive tract. When it was empty, the contractions were large and associated with the patient’s reports of hunger.

Glucostatic theory

According to the glucostatic theory (GT), the primary stimulus for hunger is a decrease in the level of blood glucose below a certain set-point. Glucose is the body’s (especially the brain’s) primary fuel. The ‘glucostat’ was assumed to be a neuron (probably in the hypothalamus) that detects the level of blood glucose in much the same way as a thermostat measures temperature.

According to Pinel, Mayer’s version of GT was particularly influential, because it dealt with a serious problem associated with earlier versions. He proposed that it was glucose utilization (the rate at which glucose is used), rather than absolute blood glucose level, that was regulated by feeding. Although these are usually highly correlated, Mayer’s version could account for those few occasions where high levels are associated with hyperphagia (overeating). For example, people with diabetes mellitus overeat despite having high blood glucose levels. This is because, in diabetes mellitus, the pancreas fails to produce sufficient quantities of insulin (needed for glucose to enter most body cells and to be utilized by them).

Mayer’s hypothesis was supported by experiments with mice, which appeared to identify the location of the glucoreceptors in the ventromedial hypothalamus (VMH). Mayer and Marshall concluded that the VMH is a satiety centre. However, although a fall in blood glucose may be the most important physiological signal for hunger, it is not the only one. If animals eat a meal that is low in carbohydrate but high in fats or proteins, they still manage to eat a relatively constant amount of calories, even though their blood glucose is reduced slightly. If eating were controlled exclusively by blood glucose, we would expect the animals to overeat and become fat.

Lipostatic theory

According to Green, the lipostatic theory (LT) focuses on the end product of glucose metabolism, namely the storage of fats (lipids) in adipocytes. When there is food in the stomach, small rhythmic contractions mixed the food and moved it along the digestive tract. When it was empty, the contractions were large and associated with the patient’s reports of hunger.

ing) is important in the regulation of feeding: if the exit from the stomach to the duodenum is blocked, rats will still eat normal-sized meals. It seems that information about the stretching of the stomach wall caused by the presence of food is passed to the brain (via the vagus nerve), allowing the brain’s feeding centres to control meal size.

When we engage in vigorous physical activity, the muscles are fuelled by fats and carbohydrates, which are stored as energy reserves. The cells that store our fat reserves are called adipocytes, which clump together as adipose tissue (or simply ‘fat’). Carbohydrates are stored as glycogen. Two major accounts of why we start eating are the glucostatic and the lipostatic theories.
hunger purely in terms of lowered levels of glucose and fat, we would still need to identify other influences on eating. According to Pinel:

The modern era of feeding research has been characterized by an increasing awareness of the major role played by learning in determining when we eat, what we eat, how much we eat, and even how the food that we eat is digested and metabolised. The concept of the feeding system has changed from that of an immutable system that maintains glucose and fat levels at predetermined set points, to that of a flexible system that operates within certain general guidelines but is ‘fine-tuned’ by experience...  

Eating for pleasure

Both humans and other animals are drawn to eat (rather than driven to eat) by food’s incentive properties – that is, its anticipated pleasure-producing effects (or palatability). According to incentive theories, both internal and external factors influence eating in the same way, namely by changing the incentive value of available foods. Signals from the taste receptors seem to produce an immediate decline in the incentive value of similar-tasting food, and signals associated with increased energy supply from a meal produce a general decrease in the incentive properties of all foods.

Support for this view comes from the discovery of lateral hypothalamus neurons that respond to the incentive properties of food rather than to food itself. When monkeys were repeatedly allowed to eat one palatable food, the response of lateral hypothalamus neurons to the food declined (a form of habituation?), but the response to other palatable foods did not decline. Neurons that responded to the animal’s sight of food would begin to respond to a neutral stimulus that reliably predicted the presentation of food. These findings explain very neatly the common experience of the mouth watering (salivating) at the mere mention of, or even seeing a picture of, a favourite food (Box 15.4).

---

**Box 15.3 Lowering body weight before the lesion**

Keesey and Powley deprived rats of food so that the rats’ body weight was substantially lowered. When lesions were then made in the lateral hypothalamus, the rats started eating more rather than less food.

In normal rats, the lesion lowers the body-weight set-point, and the resulting failure to eat occurs because the animal is trying to adjust to this lower target weight.

However, if the weight is reduced before the lesion is made to below the lesion-produced target, the rat increases feeding (following the lesion) in order to reach the new (higher) set-point.

---

**Box 15.4 Learning to salivate**

The smell of food, and the dinner bell, are food-predicting cues (or classically conditioned stimuli). They trigger digestive and metabolic events such as salivation, insulin secretion and gastric secretions (classically conditioned responses). These digestive/metabolic events are also called cephalic phase responses.

Pavlov was the first to demonstrate that a cephalic phase response can be conditioned: the sight or smell of milk produced abundant salivation in puppies raised on a milk diet, but not in those raised on a solid diet.

Feeling hungry at the times of the day when we usually eat (whether or not we are experiencing an energy deficit) is another example of a classically conditioned response (see Chapter 14).
Knowing what to eat

If learning is involved in the way that humans and other animals respond to foods that are already palatable, could learning be involved in what is found palatable in the first place?

We have innate preferences for tastes that are associated in nature with vital nutrients. For example, sweetness detectors on the tongue are probably there because they helped our ancestors identify food that is safe to eat. Even when we are not particularly hungry, we tend to find a sweet taste pleasant, and eating something sweet tends to increase our appetite.16

Both humans and other animals also have the ability to learn the relationship between taste and the post-ingestion consequences of eating certain food. In taste-aversion studies, rats learn to avoid novel tastes that are followed by illness (see Chapter 14).16 Rats are also able to learn to prefer tastes that are followed by the infusion of nutrients and flavours that they smell on the breath of other rats.

Rats and human beings have in common a metabolism that requires them to eat a variety of different foods: no single food provides all essential nutrients. We generally find a meal that consists of moderate amounts of several different foods more interesting than a huge plate of only one food, however palatable that food might be. If we have access to only one particular food, we soon become tired of it (sensory-specific satiety). This encourages the consumption of a varied diet.

Cultural evolution helps the selection of balanced diets. For example, Mexicans increased the calcium in their diet by mixing small amounts of mineral lime into their tortillas. But in the industrialized societies of Europe and North America, we seem to prefer diets that are fundamentally detrimental to our health. Manufacturers tend to sell foods that are highly palatable and energy-dense but that often have little nutritional value. This encourages us to overeat and, as a result, to increase fat deposits and body weight. Blundell and Hill maintain that in evolutionary terms, overeating makes good sense:

... For human beings it can be supposed that during most of the tens of thousands of years of human evolution the biggest problem facing human-kind was the scarcity of food ... the existence of an abundance of food, highly palatable and easily available, is a very recent development in evolutionary terms. Accordingly, it is unlikely that evolutionary pressure has ever led to the development of mechanisms to prevent overconsumption ... 15

What stops a meal?

According to Blundell and Hill (1995), satiety (feeling ‘full up’ or satisfied) is, by definition, not instantaneous but something that occurs over a considerable period of time.15 It is useful, therefore, to distinguish different phases of satiety associated with different mechanisms, which, together, comprise the satiety cascade. Most important for understanding the suppression and subsequent control of hunger are:

- post-ingestive effects, including gastric distension, the rate of gastric emptying, the release of hormones (e.g. cholecystokinin (CCK); Box 15.5), and the stimulation of certain receptors along the gastrointestinal tract;
- post-absorptive effects – that is, mechanisms arising from the action of glucose, fats, amino acids and other metabolites after absorption across the intestine into the bloodstream.

<table>

<tr>
<th>Box 15.5 Cholecystokinin</th>
</tr>
</thead>
<tbody>
<tr>
<td>After food reaches the stomach, the protein is broken down into its constituent amino acids. As digestion proceeds, food gradually passes into the duodenum (small intestine). This controls the rate of stomach emptying by secreting a peptide hormone (short chains of amino acids) called cholecystokinin (CCK). CCK is secreted in response to the presence of fats, detected by receptors in the walls of the duodenum.</td>
</tr>
<tr>
<td>Many studies have found that injecting CCK into hungry rats causes them to eat smaller meals. Wolkowitz et al. gave people injections of a drug that blocks CCK receptors in the peripheral nervous system (but not in the brain): they reported feeling more hungry and less full after a meal than controls given a placebo.</td>
</tr>
</tbody>
</table>

Based on Carlson.16

There is currently considerable research interest in whether protein, fat and carbohydrate differ in their satiating efficiency and their capacity to reduce hunger. One clear finding is that carbohydrates are efficient appetite suppressants. Also, the fat content of food influences its texture and palatability, but it has a disproportionately weak effect on satiety.15

Although the stomach may not be very important in causing hunger (see Box 15.2), it does seem to be important in satiety. For example, we noted that stomach-loading and stretching of the stomach wall play a part in reducing hunger. The gastric branch of the vagus nerve carries emergency signals from the stretch receptors in the stomach wall, preventing us from overeating and damaging the stomach.

The brain’s control of eating

It has been known since the early 1800s that tumours of the hypothalamus can cause hyperphagia (excessive overeating) and obesity in humans.18 But not until the advent of stereotaxic surgery in the late 1930s were experimenters able to assess the effects of damage to particular areas of the hypothalamus on the eating behaviour of experimental animals (Box 15.6).

Ventricomedial hypothalamus syndrome

Paradoxically, ventromedial hypothalamus (VMH)-lesioned rats are not ‘hell-bent’ on eating – they will not simply eat anything and everything. The taste of food seems to be
especially important in hyperphagic rats. Most animals will eat even bad-tasting food (‘you’ll eat anything if you’re hungry enough’), but hyperphagic rats are very fussy and will refuse their regular food if quinine is added, even if this means that they become underweight.  

What about people?

One possible explanation for the finicky eating of VMH-lesioned rats is that they become less sensitive to internal cues of satiation (e.g. blood glucose level, body fat content) and more responsive to external cues (e.g. taste). Schachter claims that this may also apply to overweight people. Schachter et al. found that normal-weight people responded to the internal cue of stomach distension (‘feeling bloated’) by refusing any more food, but obese people tended to go on eating. The obese people seemed to be responding to the availability of food, although they are less willing than normal-weight people to make an effort to find food; normal-weight people will search for food, but only if they are genuinely hungry.  

Overweight people tend to report that they feel hungry at prescribed eating times, even if they have eaten only a short time before. Normal-weight people tend to eat only when they feel hungry, and this is relatively independent of clock time. However, this increased sensitivity to external cues is not necessarily what causes some people to become obese – it could just as easily be an effect of obesity.  

Although people with hypothalamic tumours tend towards obesity, there is no evidence that the hypothalamus does not function properly in overweight people generally.  

Differences in basal metabolic rate largely determine our body weight and are probably hereditary. There is very little evidence to suggest that lack of impulse control, poor ability to delay gratification and eating too quickly contribute to overweight. However, the role of complex psychological variables has been studied much more extensively in relation to anorexia nervosa and bulimia nervosa (see Chapter 42).  

Box 15.6 Hyperphagia in rats

Hetherington and Ranson found that large bilateral lesions in the lower central portion of the hypothalamus (the ventromedial nucleus, VMN) cause hyperphagia: the rat will carry on eating until it becomes grotesquely fat, doubling or even trebling its normal body weight.

Although several structures were damaged by such lesions, it was generally assumed that the ventromedial hypothalamic (VMH) was the crucial structure.

The resulting hyperphagia was taken to indicate that the normal function of the VMH is to inhibit feeding when the animal is ‘full’. Hence, the VMH became known as the satiety centre. The centre has been found in rats, cats, dogs, chickens and monkeys.  

Lateral hypothalamus syndrome

If the VMH has traditionally been regarded as a ‘brake’ on eating, then the lateral hypothalamus has been seen as the ‘accelerator’. Bilateral lesions to the lateral hypothalamus cause aphagia, a refusal to eat, even to the point of death from starvation. Even rats made hyperphagic by VMH lesions will become aphagic by the addition of lateral hypothalamic lesions. These findings suggest very strongly that the lateral hypothalamus is a feeding centre.

However, the lateral hypothalamus syndrome also includes adipsia (complete cessation of drinking). Both aphagia and adipsia are, in turn, part of a more general lack of responsiveness to sensory input. The lateral hypothalamus itself is a relatively large, complex and ill-defined area, with many nuclei and several major nerve tracts running through it. Although electrical stimulation of the lateral hypothalamus produces eating, it also triggers drinking, gnawing, temperature changes and sexual activity. Conversely, eating can also be elicited by stimulation of other areas of the hypothalamus, the amygdala, hippocampus, thalamus and frontal cortex. For all these reasons, Pinel believes that to call the lateral hypothalamus a ‘hunger centre’ is a misnomer.  

THIRST AND DRINKING

What starts us drinking?

It was thought until recently that drinking is motivated by a deficit in the body’s water resources – that is, by deviation from set-points, as part of a homeostatic drive mechanism. However, most drinking (like most eating) occurs in the absence of deficits. This suggests that the motivation to drink comes from anticipating its pleasurable effects (positive incentive properties). We tend to prefer drinks that have a pleasant taste (e.g. fruit juice) or pleasant pharmacological effects (e.g. alcoholic drinks, coffee, tea).  

Positive incentive theory

Water deprivation increases the positive incentive value of almost all salt-free drinks. After 24 h without a drink, people report that even plain water has a pleasant taste. If you add a little saccharine to the water of non-deprived rats, their water intake rockets. Like people, rats with unlimited access to water or other palatable fluids drink far more than they actually need.

As with food, sensory-specific satiety has a major effect on drinking. As fond as rats are of saccharine, if saccharine solution is available constantly (‘on tap’), they begin to prefer it less than when it is available only periodically.  

Dry-mouth theory

A dry mouth and throat are obvious cues to thirst (the counterpart of the stomach contraction cues to hunger; see
Box 15.2). Although a dry mouth is one consequence of water deficiency, it is not the primary factor in thirst. For example, producing a chronic dry mouth by removal of the salivary glands does not substantially increase water intake, unless rats are fed dry food or kept in a very hot environment. Conversely, blocking the sensation of a dry mouth fails to decrease water intake.

The most convincing evidence against the dry-mouth theory comes from sham drinking, in which water flows down the oesophagus and then out through a fistula before it can be absorbed. Despite the lack of a dry mouth, animals sham-drink continuously.18

What makes us stop drinking?

According to set-point theories, drinking brings about a return to an internal water resource set-point. When this has been achieved, drinking stops. But, like hunger, thirst and drinking seem to stop long before enough time has elapsed for the body to have absorbed the water from the stomach, and for the water–salt balance in the blood to have been restored.

Stomach distension probably contributes to satiety. Cold water is more thirst-quenching because it moves out of the stomach much more slowly and so provides a clearer stomach-distension signal to the brain. The mouth-metering mechanism also plays a part; this gauges the amount of water being ingested and compares the amount needed to restore the water balance.

If set-point theories were correct, we would expect that delivering water directly to where it is needed would eliminate thirst and deprivation-induced drinking. However, if water is injected directly into a rat’s stomach or bloodstream, drinking is reduced by only 30 per cent of the amount injected. Even total replenishment of an animal’s water resources has only a modest inhibitory effect on deprivation-induced drinking (about 30 per cent). These findings pose difficulties for any set-point theory.18

**HULL’S DRIVE-REDUCTION THEORY**

As we noted earlier, Hull’s motivational theory must be considered in the context of his theory of learning. The drive-reduction theory was intended to explain the fundamental principle of reinforcement, both positive (reduction of a drive by the presentation of a stimulus) and negative (reduction of a drive by the removal or avoidance of a stimulus).

Hull was interested in the primary (physiological) homeostatic needs and drives of hunger, thirst, air, avoiding injury, maintaining an optimum temperature, defecation and urination, rest, sleep, activity and propagation (reproduction). He believed that all behaviour (human and animal) originates in the satisfaction of these drives (Figure 15.3).

**Needs versus drives**

Although the terms ‘need’ and ‘drive’ are often used interchangeably, they are fundamentally different:

- **Needs** are physiological and can be defined objectively, such as in terms of hours without food or blood sugar level.
- **Drives** are psychological (behavioural) and are hypothetical constructs – that is, abstract concepts that refer to processes/events believed to be taking place inside the person/animal but that cannot be directly observed or measured.

However, Hull operationalized drives as hours of deprivation. He proposed a number of equations, which were meant to be testable in laboratory experiments.36 Perhaps the most important of these was:

$$sEr = D \times V \times K \times sHr$$

where $sEr$ is the intensity or likelihood of any learned behaviour, which can be calculated if four other factors are known, namely:

- $D$: the drive or motivation, measured by some indicator of physical need, such as hours of deprivation;
- $V$: the intensity of the signal for the behaviour;
- $K$: the degree of incentive, measured by the size of the reward or some other measure of its desirability;
- $sHr$: the habit strength, measured as the amount of practice given, usually in terms of the number of reinforcements.

**Evaluation of drive-reduction theory**

Hull’s basic premise is that animals (and, by implication, people) *always* learn through primary drive reduction. But the relationship between primary drives and needs is very unclear, as we saw earlier when discussing the eating behaviour of obese people.

At its simplest, needs can arise without specific drives, as in learning what and how much to eat (see above). For example, we need vitamin C, but we would not normally talk of a ‘vitamin C drive’ in the same way that we talk about a general hunger drive.
Conversely, drives can occur in the absence of any obvious physiological need. An important example of a non-homeostatic drive in rats is electrical (self)-stimulation of the brain (ES-SB) (Box 15.7).

Box 15.7 What a rat wouldn’t do for a shock

Olds and Milner implanted an electrode near a rat’s septum (part of the limbic system), so that every time the rat pressed a lever it received an electric shock (Figure 15.4).

Figure 15.4 Olds implanted electrodes in the hypothalamus of rats. The rats could trigger an electrical stimulus by depressing a lever. The region where the electrode was implanted constitutes some kind of pleasure centre.

Rats made between 3000 and 7500 lever-pressing responses in a 12-h period. Olds reported that one rat stimulated itself more than 2000 times/h for 24 consecutive hours.

Olds reported that rats that normally press a lever 25 times/h for food reward will press 100 times/min for a reward of electrical (self)-stimulation of the brain (ES-SB).

Brain stimulation is such a powerful reinforcer that a male rat with an electrode in its lateral hypothalamus will self-stimulate in preference to eating if hungry, drinking when thirsty or having access to a sexually receptive female. This effect has been found in rats, cats, monkeys and pigeons (and humans, occasionally). The main reward site for ES-SB is the median forebrain bundle (MFB), a fibre tract that runs from the brainstem up to the forebrain through the lateral hypothalamus. The effect seems to depend on the presence of dopamine and noradrenaline. These reward centres are generally thought of as the neural substrate of ‘pleasure’, so that any behaviour defined as pleasurable involves their activation. ES-SB is seen as a shortcut to pleasure, eliminating the need for natural drives and reinforcers (Box 15.8).

Tolman’s cognitive behaviourism challenged Skinner’s theory of operant conditioning, because it showed that learning could take place in the absence of reinforcement (latent learning; see Chapter 14). By implication, Tolman showed that learning could take place in the absence of drive reduction.

Hull’s theory emphasized primary (homeostatic) drives to the exclusion of secondary (non-homeostatic) drives. Primary drives are based on primary (innate) needs, but much human (and, to a lesser extent, non-human) behaviour can be understood only in terms of secondary (acquired) drives. Several behaviourist psychologists, notably Miller, Mowrer and Dollard and Miller, modified Hull’s theory to include acquired drives (in particular, anxiety), which led to a great deal of research on avoidance learning in the 1950s (see Chapter 14).

In Maslow’s terms, drive-reduction theory deals only with survival needs, completely ignoring the self-actualization (or ‘growth’) needs that make human motivation distinctively different from that of non-humans.

Box 15.8 The ‘addicted brain’

Neurobiologists have known for a long time that drugs have their effects because they ultimately boost the activity of the brain’s reward system: a complex circuit of neurons that evolved to make us feel flush after eating or having sex. At least initially, stimulating this system makes us feel good, which encourages us to repeat whatever induced the pleasure (the feeling is a powerful reinforcer). But research has indicated that chronic drug use can actually produce structural and functional changes in the system’s neurons that can last for weeks, months or years after the fix.

A key part of the circuit is the pathway extending from dopamine-producing neurons of the ventral tegmental area (VTA) to dopamine-sensitive neurons in the nucleus accumbens (NA), situated deep beneath the frontal cortex. Changes to these neurons contribute significantly to the tolerance, dependence and craving that fuel repeated drug use and lead to relapses, even after long periods of abstinence.

There are also pathways linking the NA and VTA with other brain regions that can help make addicted people highly sensitive to reminders of past highs – such as drug paraphernalia (the equipment used in drug-taking) and places where they have scored – vulnerable to relapse when stressed, and unable to control the urge to seek drugs.

Functional magnetic resonance imaging (fMRI) and positron-emission tomography (PET) scans have revealed that the NA in the brains of people addicted to cocaine ‘lights up’ when they are offered a snort or when shown a video of someone using cocaine or even a photograph of white lines on a mirror. The amygdala and NA influence both the cocaine-induced rush and the craving for more of the drug, which becomes stronger as the euphoria wears off (see Chapter 70).
NON-HOMEOSTATIC NEEDS AND DRIVES

Just as ES-SB cannot be accommodated by drive reduction when considering only non-human motivation, so non-humans seem to have other non-homeostatic drives that they share, to some degree, with humans.

Competence motives: motives without specific primary needs

According to White, the ‘master reinforcer’ that keeps most of us motivated over long periods of time is the need to confirm our sense of personal competence: our capacity to deal effectively with the environment. It is intrinsically rewarding and satisfying to feel that we are capable human beings, to be able to understand, predict and control our world.

Unlike hunger, which comes and goes, competence seems to be a continuous, ongoing motive. We cannot satisfy it and then do without it until it next appears, because it is not rooted in any specific physiological need. This is why it is not very helpful to think of the competence motive as a drive that pushes us into seeking its reduction. While homeostatic drives involve an attempt to reduce something (tissue need), competence motives often involve the search for stimulation.

Seeking stimulation

If rats are allowed to become thoroughly familiar with a maze, and then the maze is changed in some way, they spend more time exploring the altered maze. This occurs even in the absence of any obvious extrinsic reward, such as food. The rats are displaying a curiosity drive. Butler and Harlow et al. gave monkeys mechanical puzzles to solve, such as undoing a chain, lifting a hook and opening a clasp. The monkeys did these puzzles over and over again, for hours at a time, with no other reward: they were displaying their manipulative drive.

Play and motivation

Much of the behaviour normally described as play can be thought of in terms of the drives for curiosity, exploration and manipulation. The purpose of play from the child’s point of view is simple enjoyment. The child does not consciously play in order to find out how things work, or to exercise the imagination; instead, the child plays simply because playing is fun and intrinsically satisfying. Any learning that does result is quite incidental. However, for the young child, there is no real distinction between ‘work’ and ‘play’ in an adult sense.

Piaget distinguishes between play, which is performed for its own sake, and intellectual activity or learning, which has an external aim or purpose. This distinction is meant to apply to all three major types of play that he describes: mastery, symbolic/make-believe and play with rules (see Chapter 8). Nor is play confined to humans. The young of many species engage in activities that seem to have little to do with homeostatic or survival needs. However, the higher up the evolutionary scale the species is, the more apparent and purposeful the play becomes, and the more the nature of play changes as the young animal develops.

Motivation and adaptation

Piaget saw play as essentially an adaptive activity. Throughout development, play helps to consolidate recently acquired abilities and to aid the development of additional cognitive and social skills. In the same way, the competence motives of curiosity, exploration and manipulation undoubtedly have adaptive significance for an individual and, ultimately, for the species. Investigating and exploring the environment equips an animal with ‘knowledge’ that can be used in times of stress or danger.

Optimum-level (or arousal) theories

According to Berlyne, investigation and exploration are based on an inbuilt tendency to seek a certain ‘optimum’ level of stimulation or activity. Exploring the unfamiliar increases arousal, but if it is very different from what we are used to, arousal will be too high (we feel anxious and tense). If it is not different enough, then arousal is too low (we soon become bored).

Optimum-level theories are supported by sensory-deprivation experiments. In classic experiments carried out by Hebb and colleagues at McGill University in the 1950s, participants were almost completely cut off from their normal sensory stimulation by wearing blindfolds, earmuffs, cardboard tubes on their arms and legs, and so on (Figure 15.5). They soon began to experience extreme psychological discomfort, reported hallucinations (Figure 15.6), and could not tolerate their confinement for usually more than 3 days.

Cohen and Taylor studied the psychological effects of long-term imprisonment. They found that sensory deprivation and monotony are experiences that prisoners share with explorers, space travellers and round-the-world sailors. Conversely, excessive stimulation (‘sensory overload’) is also debilitating and may be responsible for some kinds of psychological disorders in highly urbanized societies (see Chapter 11).

The need for control

Another major kind of competence motive is the need to be in control of our own destiny and not at the mercy of external forces. This is linked closely to the need to be free from the controls and restrictions of others, to dictate our own actions and not to be dictated to. According to Brehm, when our freedom is threatened, we tend to react by reasserting our freedom (psychological reactance). When people initially expect to have control over the outcomes of their actions, the first experience of not being
so is likely to produce reactance. Further bad experiences, however, are likely to result in learned helplessness. Rotter’s concept of locus of control refers to individual differences in people’s beliefs about what controls events in their everyday lives (see Chapter 11).

Cognitive motives

Consistency and achievement

One of the most researched cognitive motives is the need for cognitive consistency, which is central to Festinger’s cognitive dissonance theory (see also Gross). Another cognitive motive that has generated an enormous amount of research and theorizing is achievement motivation/need for achievement (nAch). This was one of the 20 human motives identified by Murray in 1938. Murray drew a
sharp distinction between ‘psychogenic’ (or psychological) needs, which are learned, and ‘viscerogenic’ (or physiological) needs, which are innate.

Murray agreed with Freud that people express their true motives more clearly in free association than in direct self-reports (or questionnaire-type personality tests). Based on this belief, Murray devised the Thematic Apperception Test (TAT). This test consists of a series of 20 pictures (Figure 15.7), presented one at a time, 10 in each of two sessions separated by at least 1 day. Slightly different versions are used for men and women, and for boys and girls. The participant is told that the TAT is a test of imagination and asked to make up a story that describes:

- what is happening and who the people are;
- what has led up to the situation;
- what is being thought and what is wanted and by whom;
- what will happen and what will be done.

The pictures are sufficiently ambiguous with regard to the events depicted and the emotions of the characters to allow a wide range of interpretations. How a person interprets the pictures reveals their unconscious motives. Hence, the TAT is a major projective test used in motivation and personality research (see Chapter 19). A person who scores high on nAch is concerned with standards of excellence, high levels of performance, recognition of others and the pursuit of long-term goals (the person is ambitious).

Social motives

According to Geen, social motivation refers to the activation of processes involved in the initiation, direction and energization of individual behaviour ‘... by situations in which other people are in close contact with the individual ...’ It is usually assumed that these situations do not provide specific cues for individual behaviour (they are ‘weak’). Geen contrasts ‘weak’ situations with ‘strong’ situations, such as those in which there is direct social influence (e.g. Milgram’s famous obedience experiments: see Chapter 20). Geen gives three main examples:

- Social facilitation: the enhancing effect on behaviour of the mere presence of others.
- Social presentation: behaving in ways that attempt to present a desirable impression to others.
- Social loafing: the tendency for individual effort to diminish in group task situations, partly as a result of diffusion of responsibility.

Each of these may be thought of as a manifestation of the more general influence of social anxiety, a state created when a person who wishes to make a certain impression on others doubts that this impression can actually be made. But why should the fear of making a bad impression be such a powerful motive for individual behaviour?

One answer can be found at quite a low level of Maslow’s hierarchy, namely love and belongingness. This includes the need for affiliation, the company of other people, especially family, friends and work colleagues, and the need to be accepted by, and included within, society. Certain kinds of conformity can be understood in terms of this basic need (a survival need in Maslow’s terms). But does this need itself stem from some other, even more fundamental need?

According to Greenberg et al. (cited in Geen’s), human culture, which society represents, provides a buffer against facing one’s own vulnerability and mortality. Society provides a ‘cultural drama’ that gives meaning to life and without which the individual would experience a dread of being alive. We are, therefore, motivated to play an approved role in that drama: by meeting cultural standards, the individual achieves the approval and acceptance of others and avoids rejection and isolation. This can be seen in relation to safety needs, the second level of Maslow’s hierarchy, and includes ‘fear of the unknown’. The ultimate example of this is the fear of death (see Chapter 57).

Fiske argues that, from the idea that we need other people for our basic survival, it follows that over time we would have developed some core social motives that interact with the social situation in order to help us survive in groups. We are motivated to get along with other people, because it is adaptive to do so. Fiske defines core social motives as ‘... fundamental, underlying psychological processes that impel people’s thinking, feeling, and behaving in situations involving other people ...’
Lesions in the VMN of the rat's hypothalamus cause hyperphagia, which suggests that it is a feeding centre. However, the effects of lesions to the lateral hypothalamus are much more diffuse than originally thought. Lesions in the VMH syndrome also involves increased sensitivity to external cues of satiation. This also seems to be true of obese humans. Satiation can be seen as a central theme in both Freud's psychoanalytic theory and Skinner's operant conditioning.

The glucostatic theory was meant to account for the relatively short-term processes of eating initiation (and termination), while the lipostatic theory was meant to explain long-term feeding habits and regulation of body weight. They share the belief in predetermined set-points.

The glucostatic theory was meant to account for the relatively short-term processes of eating initiation (and termination), while the lipostatic theory was meant to explain long-term feeding habits and regulation of body weight. They share the belief in predetermined set-points. The other major set-point theory is the lipostatic theory, which focuses on the storage of lipids (fats) in the adipose tissue. It is supported by several observations, including the finding that damage to the lateral hypothalamus affects feeding indirectly by altering the body-weight set-point.

The glucostatic theory was meant to account for the relatively short-term processes of eating initiation (and termination), while the lipostatic theory was meant to explain long-term feeding habits and regulation of body weight. They share the belief in predetermined set-points. They share the belief in predetermined set-points.

REFERENCES

INTRODUCTION

When we compare our experience of the world (in which objects remain stable and constant) with what our sense organs receive in the form of physical stimulation (a state of near-continuous flux), it is almost as if there are two entirely different ‘worlds’. Psychologists call these ‘worlds’ sensation and perception, respectively. Sensations are the experiences that physical stimuli elicit in the sense organs. Perception is the organization and interpretation of incoming sensory information to form inner representations of the external world.

This chapter begins by looking at some basic visual perceptual phenomena, namely form and depth perception, perceptual constancy and visual illusions. Many of the principles that govern human visual perception were first identified by the German school of Gestalt psychology. As Dodwell has observed, ‘To perceive seems effortless. To understand perception is nevertheless a great challenge.’

One response to this challenge claims that our perception of the world is the end result of a process that also involves making inferences about what things are like. Those who subscribe to this end-result view, such as Bruner, Neisser and Gregory, are called top-down (or conceptually driven) perceptual processing theorists. Making inferences about what things are like means that we perceive them indirectly, drawing on our knowledge and expectations of the world. Others argue that our perception of the world is essentially determined by the information presented to the sensory receptors, so that things are perceived in a fairly direct way. The most influential of these bottom-up (or data-driven) perceptual processing theorists is Gibson. Others still, notably Marr, display elements of both approaches (see Gross).

GESTALT PSYCHOLOGY AND PERCEPTUAL ORGANIZATION

Von Ehrenfels claimed that many groups of stimuli acquire a pattern quality that is greater than the sum of their parts. A square, for example, is more than a simple assembly of lines – it has ‘squareness’. Von Ehrenfels called this ‘emergent property’ Gestalt qualität (= form quality). In the early 1900s, Gestalt psychologists (notably Wertheimer, Koffka and Köhler) attempted to discover the principles through which sensory information is interpreted. They argued that, as well as creating a coherent perceptual experience that is more than the sum of its parts, the brain does this in regular and predictable ways. They believed that these organizational principles are largely innate (see Gross).

Form perception

In order to structure incoming sensory information, we must perceive objects as being separate from other stimuli and as having meaningful form.

Figure and ground

The first perceptual task when confronted with an object (or figure) is to recognize it. To do this, we must perceive the figure as being distinct from its surroundings (or ground). A figure’s familiarity can help determine whether it is perceived as figure or ground, but unfamiliar and even meaningless ‘blobs’ are also seen as figures. One of the strongest determinants of figure and ground is surroundedness. Areas enclosed by a contour are generally seen as figures, whereas the surrounding area is generally seen as ground. Size, orientation and symmetry also play a role in figure–ground separation.

Sometimes, though, there may not be enough information in a pattern to allow us to distinguish easily between figure and ground. A good example of this is shown in Figure 16.1, which illustrates the principle underlying camouflage.

In figure–ground reversal, a figure may have clear contours, but it is capable of being perceived in two very different ways: it is unclear which part of it is the figure and which the ground. A famous example is shown in Figure 16.2, usually called Rubin’s vase. Here, the figure–ground relationship continually reverses, so that it is perceived as either a white vase with a black background, or two black profiles on a white background. However, the stimulus is always organized into a figure seen against a ground, and
the reversal indicates that the same stimulus can trigger more than one perception.

The artist Escher used figure–ground reversal in many of his paintings.

A map is another example of figure–ground reversal. We normally see the land as figure and the sea as (back)ground, because we are more familiar with the shape of Africa, say, than with the shape of the Atlantic ocean. An auditory example is the cocktail party phenomenon (see Chapter 13). Here is another example: try repeating ‘over–run’ out loud and you’ll find the two words alternating as figure and ground.

Grouping

Once we have discriminated figure from ground, the figure can be organized into a meaningful form. Gestalt psychologists believed that objects are perceived as Gestalten (= organized wholes, configurations, patterns) rather than combinations of isolated sensations. They identified several laws of perceptual organization or grouping, which illustrate their view that the perceived whole of an object is more than the sum of its parts.

These laws can be summarized under one heading, the law of prägnanz (= precision), according to which, ‘Psychological organisation will always be as good as the prevailing conditions allow. In this definition, “good” is undefined.’

In practice, the ‘best’ way of perceiving is to see things as symmetrical, uniform and stable, and this is achieved by following the laws of prägnanz (Box 16.1).

An evaluation of the Gestalt contribution

A major philosophical influence on Gestalt psychology was phenomenology. This sees the world as we ordinarily experience it as being of central concern. Koffka, for example, believed that the most important question for perceptual psychologists was ‘Why do things look as they do?’ For Köhler, ‘There seems to be a single starting point for psychology, exactly as for all the other sciences: the world as we find it, naively and uncritically.’

The most comprehensive account of perceptual grouping is still that provided by the Gestalt psychologists, and, in Gordon’s view, Gestalt psychology’s discoveries ‘are now part of our permanent knowledge of perception.’

However, many contemporary researchers (e.g. Greene) have argued that, as originally expressed, the various Gestalt ‘laws’ are at best only descriptive and at worst extremely imprecise and difficult to measure. Several studies have attempted to address the various criticisms made of the Gestalt laws. For example, Navon tested the idea that the whole is perceived before the parts that make it up by presenting participants with various stimuli, as shown in Figure 16.8 opposite.

Navon distinguished between the global (or ‘whole-like’ features of a stimulus) and the local (or more specific and ‘part-like’ features). Each stimulus consisted of a large (global) letter made up of many small (local) letters. In some cases, the global and local letters matched (as shown in the stimulus on the left in Figure 16.8), and in some cases they did not match (as shown on the right).

Participants had to identify either the large or the small letter as quickly as possible. Navon found that the time taken to identify the large letter was unaffected by whether the small letters matched or not. However, the time taken to identify the small letters was affected by whether the large letter matched or not: when the large and small letters were different, response times were longer (Table 16.1). This suggests that it is difficult to avoid processing the whole, and that global processing necessarily occurs before any more detailed perceptual analysis.
Box 16.1 Gestalt laws of perception

PROXIMITY

Elements appearing close together in space or time tend to be perceived together, so that different spacings of dots produce four vertical lines or four horizontal lines (Figure 16.3).

Figure 16.3 Proximity

An auditory example would be the perception of a series of musical notes as a melody, because they occur soon after one another in time.

SIMILARITY

Similar figures tend to be grouped together. So, the triangles and circles in Figure 16.4 are seen as columns of similar shapes rather than rows of dissimilar shapes.

Figure 16.4 Similarity

Hearing all the separate voices in a choir as an entity illustrates the principle of similarity.

CONTINUITY

We tend to perceive smooth, continuous patterns rather than discontinuous ones. The pattern in Figure 16.5 could be seen as a series of alternating semicircles, but it tends to be perceived as a wavy line and a straight line.

Figure 16.5 Continuity

Music and speech are perceived as continuous, rather than as a series of separate sounds.

CLOSURE

Closed figures are perceived more easily than open/incomplete ones. So, we often supply missing information in order to close a figure and separate it from its background. By filling in the gaps, the illustrations in Figure 16.6 are seen as a triangle and a seashell.

Figure 16.6 Closure

PART–WHOLE RELATIONSHIP

As well as illustrating continuity and proximity, the three images in Figure 16.7 illustrate the principle that the whole is greater than the sum of its parts. Despite the similarity of the parts (each pattern is composed of 12 crosses), the Gestalten are different.

Figure 16.7 Part–whole relationship

The same melody can be recognized when hummed, whistled or played with different instruments and in different keys.

COMMON FATE

Elements seen moving together are perceived as belonging together. This is why a group of people running in the same direction appear to be unified in their purpose.

Based on Navon.17
Does the global always predominate?

The findings from Navon’s (and others’) experiments clearly support Gestalt laws. But the Gestalt laws are difficult to apply to the perception of solid (three-dimensional, 3D) objects as opposed to two-dimensional (2D) drawings. Our eyes evolved to see 3D objects, and when 3D arrays have been studied, Gestalt laws have not been consistently upheld.16 The world around us comprises ‘whole’ scenes, in which single objects are but ‘parts’.19 Because many of the Gestalt displays involve single objects, they have very low ecological validity that is, they are not representative of the objects and events which organisms must deal with in order to survive.15

Factors such as the sizes of the local and global features, the viewing conditions and the nature of the observer’s task are all likely to play a part in determining the role played by individual features in pattern recognition.20 In everyday life, it is easier sometimes to process ‘forests’ and sometimes to process ‘trees’.14 Some theorists (e.g. Palmer21) have suggested that, under most circumstances, the interpretation of parts and wholes takes place in top-down and bottom-up directions simultaneously, such as in the recognition of parts of a face with and without context. As shown in Figure 16.9, the features that can be recognized easily in context are somewhat ambiguous when seen alone (out of context), but they are recognizable when more detail is provided. (Compare Palmer’s approach with that of Neisser’s analysis-by-synthesis model.)

Marr found the Gestalt principles useful in achieving accurate segmentation—that is, how visual information is used to decide which regions of a visual scene belong together and form coherent structures.22 Marr devised a computer program aimed at achieving segmentation (e.g. of a teddy bear) using the Gestalt principles. He succeeded in obtaining appropriate segmentation of the teddy’s outline, eyes and nose. But some scenes are ambiguous and require using knowledge about objects in order to achieve segmentation (such as two leaves overlapping substantially in a bowl of flowers).

![Figure 16.9](image_url) The features that can be recognized easily in context (a) are rather ambiguous when seen alone—that is, out of context (b)—although they become more recognizable when more detail is provided (c). Based on Palmer.23

DEPTH PERCEPTION

From the 2D images that fall on our retinas, we manage to organize 3D perceptions. This ability is called depth perception, and it allows us to estimate an object’s distance from us. Some of the cues used to transform 2D retinal images into 3D perceptions involve both eyes and rely on their working together. These are called binocular cues. Monocular cues are available to each eye separately.

Non-pictorial (primary) cues

Most preyed-upon non-humans (e.g. rabbits) have their eyes on the side of the head, allowing them to see danger approaching over a wide area. Most predators (e.g. lions) have their eyes set close together on the front of the head, equipping them with binocular vision, which helps in hunting prey. Like non-human predators, humans have predatory vision, which influences the way we perceive the world. Four important non-pictorial cues are retinal disparity, stereopsis, accommodation and convergence. These are all binocular, except for accommodation.

Because our eyes are nearly 8 cm apart, each retina receives a slightly different image of the world. The amount of retinal disparity (the difference between the two images) detected by the brain provides an important cue to distance.

Hold your finger directly in front of your nose. The difference between the two retinal images is large, and this can be shown by looking at your finger first with the left eye closed and then with the right eye closed. When the finger is held at arm’s length, retinal disparity is much smaller.

Ordinarily, we do not see double images because the brain combines the two images in a process called stereopsis (literally, ‘solid vision’). This allows us to experience one 3D sensation rather than two different images.

In accommodation, which is a muscular cue, the lens of the eye changes shape when we focus on an object, thickening for nearby objects and flattening for distant objects.

Convergence, another muscular cue to distance, is the process by which the eyes point more and more inward as an object gets closer. By noting the angle of convergence, the brain provides us with depth information over distances from about 180 cm to 610 cm.24

Pictorial (secondary) cues

Except with relatively near objects, each eye receives a very similar retinal image when looking ahead. At greater distances, we depend on pictorial cues. These refer to features of the visual field itself (rather than to the eyes) and are all also monocular (Table 16.2).

PERCEPTUAL CONSTANCY

Having perceived an object as a coherent form and located it in space, we must next recognize the object without being
Perceptual constancy

‘fooled’ by changes in its size, shape, location, brightness and colour. The ability to perceive an object as unchanging, despite changes in the sensory information that reaches our eyes, is called **perceptual constancy**.

### Size constancy

The image on the retina of an average-height person would be the same size for a dwarf seen from close up or a giant viewed from a distance. Size constancy occurs because the perceptual system takes into account an object’s distance from the perceiver. So, perceived size is equal to retinal image size taking distance into account.

The perception of an after-image demonstrates how distance can be varied without changing the retinal image’s size.

Stare at a bright light for a few seconds and then look away. You’ll experience an after-image. This has a fixed size, shape and position on the retina. Now quickly look at a nearby object and then at an object further away. The after-image seems to shrink and swell, appearing to be largest when you look at a more distant object.

Real objects cast smaller images the further away they are. To maintain perceptual constancy, the brain ‘scales up’ the image (**constancy scaling**). The same constancy scaling is applied to an after-image, producing changes in its apparent size.

### Shape constancy

We often view objects from angles at which their ‘true’ shape is not reflected in the retinal image they project. For example, rectangular doors often project trapezoid shapes (Figure 16.10), and round cups often project elliptical-shaped images. Just as with size constancy, the perceptual system maintains constancy in terms of shape.

However, shape and size constancy do not always work. When we look down at people from the top of a very tall building, they look more like ants to us, even though we know they are people.

### Location constancy

Moving our head around produces a constantly changing pattern of retinal images. However, we do not perceive the world to be spinning around. This is because **kinaesthetic feedback** from the muscles and balance organs in the ear is integrated with the changing retinal stimulation in the brain in order to inhibit perception of movement. To keep the world from moving crazily each time we move our eyes, the brain subtracts the eye-movement commands from the resulting changes on the retina. This helps to keep objects in a constant location.

### Brightness constancy

We see objects as having a more or less constant brightness, even though the amount of light they reflect changes

</tbody>
</table>
according to the level of illumination. For example, white paper reflects 90 per cent of light falling on it, whereas black paper reflects only 10 per cent of light. But in bright sunlight black paper still looks black, even though it may reflect 100 times more light than does white paper indoors. Perceived brightness depends on how much light an object reflects relative to its surroundings (relative luminance).

**Colour constancy**

Familiar objects retain their colour (or, more correctly, their hue) under a variety of lighting conditions (including night light), provided there is sufficient contrast and shadow. However, when we do not already know an object’s colour, colour constancy is less effective. If you have ever bought new clothes under fluorescent light without viewing them in ordinary lighting conditions, you may well agree.

**ILLUSIONS**

Although perception is usually reliable, our perceptions sometimes misrepresent the world. When our perception of an object does not match its true physical characteristics, we have experienced an illusion. Some illusions are due to the physical distortion of stimuli, whereas others are due to our misperception of stimuli.26 An example of a physical illusion is the bent appearance of a stick when placed in water. Gregory identifies four types of perceptual illusion:27

- Distortions (or geometric illusions)
- Ambiguous (or reversible) figures
- Paradoxical figures (or impossible objects)
- Fictions.

**Distortions**

Figure 16.11 shows several examples of distortions. The Poggendorf illusion (Figure 16.11b) is accentuated when the diagonal line is slanted more steeply and when the parallel bars are more separated. As the line is brought closer to the horizontal, the illusion disappears.28 The horizontal–vertical illusion (Figure 16.11d) illustrates our tendency to overestimate the size of vertical objects. This helps to explain why a small tree that we have chopped down looks shorter than it did when it was standing.26

**Figure 16.11** Distortions, or geometric illusions. In the Ponzo illusion (a), the horizontal bar at the top is seen as being longer than the horizontal line at the bottom, even though both lines are the same length. The Poggendorf illusion (b) suggests that the segments of the diagonal line are offset, even though they are not. The line with the outgoing fins in the Müller–Lyer illusion (c) appears to be longer than the line with the ingoing fins, but in fact the lines are the same length. In the horizontal–vertical illusion (d), the vertical line is seen as being longer, although it is the same length as the horizontal line. In Titchener’s circles (e), the central circle in the left-hand group is seen as being larger than the central circle of the right-hand group, but both circles are the same size. Finally, in the twisted card illusion (f), the twisted cards appear to form a spiral pattern, but in fact the circles are concentric.
Ambiguous figures

In addition to Rubin’s vase (see above), two other well-known reversible figures are shown in Figure 16.12. In the Necker cube (Figure 16.12a), the figure undergoes a depth reversal. The cube can be perceived with the crosses being drawn either on the back side of the cube or on the top side looking down. Although our perceptual system interprets this 2D line drawing as a 3D object, it seems unsure as to which of the two orientations should be perceived. Hence, the cube spontaneously reverses in depth orientation if looked at for about 30 s.

Figure 16.12b shows Boring’s ‘old/young woman’. These two are examples of reversible figures in which the change in perception illustrates object reversal. The figure can be perceived as the profile of a young woman’s face with the tip of her nose just visible, or the young woman’s chin can be perceived as the (very large) nose of a much older woman (who also has a very long chin).

Paradoxical figures

Although paradoxical figures look ordinary enough at first, on closer inspection we realize that they cannot exist in reality (hence ‘paradoxical’). Figure 16.13 illustrates three such paradoxical figures.

According to Hochberg, it takes us a few seconds to realize that a figure is impossible. This is because we need time to examine the figure fully or to scan it and organize its parts into a meaningful whole. When we look at a figure, our eyes move from place to place at the rate of about three changes per second. So, when we look at an impossible figure, it takes time for us to scan it and perceive its form; only after this scanning can we appreciate its impossible nature.

Fictions

Fictions help us to explain how we perceive that objects possess specific shapes. The idea that shape is determined by the physical contours of an object (causing edge-detectors in the cells of the visual system to fire) has been challenged by the existence of subjective contours. These are the boundaries of a shape perceived in the absence of physical contours.

In Figure 16.14a, there is no white triangular contour physically present. But we perceive the shape of a white triangle, which appears to be opaque and lighter than the background. There are some contours that are physically present (the overlap of the triangle and the disc), and these
Illusions of shading

According to Ramachandran and Rogers-Rachamandran, the visual image is inherently ambiguous. Perception is partly a matter of using certain assumptions about the

Ilusions of movement

We are surrounded by illusions in our everyday life. The use of perspective cues by artists leads us to infer depth and distance; that is, we add something to a picture that is not physically present, just as we do to the images projected on our television screens. Television pictures also use the illusion of movement. Just as it is possible for changes in patterns of retinal stimulation not to be accompanied by the perception of movement, so it is possible to perceive movement without a successive pattern of retinal stimulation. This is called apparent movement (Box 16.2).

Box 16.2 Some examples of apparent movement

**AUTOKINETIC EFFECT**

If you look at a stationary spot of light in an otherwise completely dark room, the light will appear to move. According to Gregory, this illusion is produced by small and uncontrollable eye movements. Another explanation suggests that it is caused by the absence of a stimulating background to provide a frame of reference for measuring movement. This is supported by the fact that the autokinetic effect disappears if other lights are introduced.

**STROBOSCOPIC MOTION**

The illusion of movement is created by the rapid succession of slightly different stationary images. If these are presented sufficiently quickly (around 16–22 frames/s), an illusionary impression of continuous movement is produced. This is the mechanism by which moving pictures operate. With fewer than 16 frames/s, the moving picture looks jumpy and unnatural. Smooth slow motion is achieved by filming at a rate of 100+ frames/s and then playing back at about 20 frames/s.

**PHI PHENOMENON**

This is a simpler form of stroboscopic motion, in which a number of separate lights are turned on and off in quick succession. This gives the impression of a single light moving from one position to another. Both stroboscopic motion and the phi phenomenon can be explained by the law of continuity (see Box 16.1).

**INDUCED MOVEMENT**

This occurs when we perceive an object to be moving, although in reality the object is stationary and the surroundings are moving. Movie stars, for example, are often filmed in a stationary car with a projection of a moving background behind them. Similarly, when the moon is seen through a thin cover of moving clouds, we sometimes perceive it to be moving very quickly. Another example is the experience of sitting in a car at traffic lights and noticing that we are ‘moving backwards’, when in fact the car at our side is moving forwards.

**MOTION AFTER-EFFECTS**

People who work on inspection belts in factories experience movement after-effects when the belt suddenly stops but is then perceived as moving backwards. Similarly, if you stare at a waterfall and then switch your gaze to the ground surrounding the water, the ground appears to be moving in the opposite direction.

Illusions of shading

According to Ramachandran and Rogers-Rachamandran, the visual image is inherently ambiguous. Perception is partly a matter of using certain assumptions about the
world in order to resolve such ambiguities, and illusions can help to uncover the brain’s hidden rules and assumptions.

- How would you describe the group of disks on the left in Figure 16.15?
- How would you describe those on the right?
- Can you try to explain the different perceptions?

The disks on the left in Figure 16.15 are usually seen as eggs, while those on the right are seen as cavities. The eggs are light on the top, and the cavities are light on the bottom. According to Ramachandran and Rogers-Ramachandran, this reveals an assumption made by the visual system, namely that it expects light to shine from above.25

Now turn the page upside down and look at Figure 16.15 again. All the eggs and cavities instantly switch places.

Ask a friend to hold the page right side up for you. Then bend down and look between your legs at the page (which is now behind you). Again, the switch occurs ‘... as if the sun is stuck to your head and shining upward from the floor’.25

PERCEPTION OF REAL MOVEMENT

The importance of eye movements

To perceive real (actual) movement, there must be changes in the retinal image. Indeed, it seems that the receptors only respond to changes in the environment. The eyes are constantly making minute, oscillatory movements, which keep the receptors stimulated. A device for stabilizing the retinal image shows that these movements are necessary for seeing things at all.35 A tiny slide projector, mounted on a contact lens, is attached to the cornea and a slide projected onto a screen. Since the lens and the projector move with the eye, the retinal image is stabilized. In other words, eye movements and the movement of the image on the screen cancel each other out, so the retinal image stays in the same place. After initially seeing the picture with normal acuity, the image begins to fade within a few seconds and after a minute disappears altogether.

If you turn your head slowly around with your eyes open, or you scan a stationary scene, you create a succession of different retinal images, but you will not perceive movement (location constancy kicks in). So, changes in the retinal image cannot be a sufficient basis for the perception of movement. Conversely, when an object moves across your visual field and you follow the object with your eyes, the retinal image remains the same but you do perceive movement.

Configurational change

Objects moving in the environment usually do so against a background of stationary or differently moving objects. Also, the nose and other anatomical borders to the visual field provide stationary reference points against which to judge movement. This causes a configuration change, or change in the overall pattern and interrelationship between objects. However, although in practice this is often an important source of information, it may not be a necessary one. If a lighted cigarette is moved about in a dark room, the cigarette will be perceived as moving, even though there are no background cues or frames of reference.34 (This should not be confused with the autokinetic effect; see Box 16.2.)

How does the brain do it?

It seems that the brain is capable of distinguishing between eye movements that signal movement of objects (real movement) and those eye movements (and head movements) that do not signal movement. Probably the superior colliculus plays an important role in making this distinction. Gregory describes two systems:34

- The image–retina system, which responds to changes in the visual field that produce changes in the retinal image
- The eye–head system, which responds to movements of the head and eyes.

The perception of movement is the product of an interplay between the two systems.
According to Braddick, the human visual system seems to have two separate systems for measuring the speed and direction of individual features moving in the retinal image: \(^{26}\)

- A long-range, feature-tracking system seems to infer motion from one instant to the next, which underpins our conscious impression of motion in films and television.
- A short-range, motion-sensing system seems to measure motion more directly by signalling changes in the image content over time.

Although neither system is fully understood, the basic requirements are in place even at the retina. P-type ganglion cells respond to abrupt spatial changes in the image, while M-type ganglion cells may respond to abrupt temporal (time-related) changes. Additionally, the temporal cortex contains many cells selective for different types of motion, and most visual cortical cells prefer moving to stationary stimuli. \(^{23}\)

## THEORIES OF VISUAL PERCEPTION

### Classifying theories

As we noted above, one way in which theories of perception differ is in terms of whether they regard perception as a direct (bottom-up, data-driven) or indirect (top-down, conceptually driven) process. Bruce and Green describe these as ‘ecological’ and ‘traditional’, respectively. \(^{37}\) The term ‘ecological’ was used by Gibson, the major bottom-up theorist, to imply that visual information from the whole physical environment is available for analysis by retinal receptor cells.

Another issue that divides theories relates to the nature–nurture debate (see Gross\(^{9}\)). Empiricists regard perception as primarily the result of learning and experience, while nativists believe that perception is essentially an innate ability, requiring little, if any, learning. All the top-down theorists are also empiricists, and the major nativists are the Gestalt psychologists. Gibson was influenced by the Gestalt school, but he is generally regarded as an empiricist. Finally, Marr’s theory has both top-down and bottom-up components, and he too was influenced by some of the Gestalt laws (Table 16.3).

To avoid sensory overload, we need to select from all the sensory stimulation that surrounds us. Also, we often need to supplement sensory information, because the total information that we need might not be directly available to the senses. This is what Gregory means by ‘going beyond the immediately given evidence of the senses’, and it is why his theory is described as constructivist. For Gregory, we make inferences about the information that the senses receive (based on Helmholtz’s nineteenth-century view of perception as consisting of unconscious inferences).

### Gregory’s theory and perceptual constancies

Perceptual constancies tell us that visual information from the retinal image is sketchy and incomplete, and that the visual system has to ‘go beyond’ the retinal image in order to test hypotheses that fill in the ‘gaps’. \(^{26}\) To make sense of the various sensory inputs to the retina (low-level information), the visual system must draw on all kinds of evidence, including distance cues, information from other senses and expectations based on past experience (high-level knowledge). For all these reasons, Gregory argues that perception must be an indirect process involving a construction based on physical sources of energy.

### Gregory’s theory and illusions

Gregory argues that, when we experience a visual illusion, what we perceive may not be physically present in the stimulus (and hence not present in the retinal image). Essentially, an illusion can be explained in terms of a perceptual hypothesis that is not confirmed by the data: our attempt to interpret the stimulus figure turns out to be inappropriate. In other words, an illusion occurs when we attempt unsuccessfully to construe the stimulus in keeping with how we normally construe the world (Box 16.3).

All illusions illustrate how the perceptual system normally operates by forming a ‘best guess’, which is then tested against sensory inputs. For Gregory, illusions show that perception is an active process of using information to suggest and test hypotheses. \(^{38}\) What we perceive is not the data but an interpretation of them, so that ‘A perceived object is a hypothesis, suggested and tested by sensory data.’ \(^{38}\) As Gregory has noted, ‘... this makes the basis of knowledge indirect and inherently doubtful.’ \(^{38}\)
going fins as walls coming towards us. This would make the shaft appear ‘distant’.

- The retinal images produced by the arrows are actually equal. According to size constancy, if equally sized images are produced by two lines, one of which is further away from us than the other, then the line that is furthest from us must be longer. Because this interpretation is taking place unconsciously and quickly, we immediately perceive the illusion.

- However, if the perspective cues are removed, the illusion remains, suggesting that the misapplied size constancy theory is itself misapplied (Figure 16.17). Alternatively, the apparent distance of the arrow could be caused by the apparent size of the arrows rather than, as Gregory claims, the other way around.39

In the Müller–Lyer illusion, we know the arrows are the same length, and yet we still experience the illusion. Our knowledge should enable us to modify our hypotheses in an adaptive way. Although some illusions can be explained in terms of the same unconscious processes occurring (an example being size constancy), not all illusions are amenable to explanation in the way Gregory proposes.39

Gregory argues that when we view a 3D scene with many distance cues, the perceptual system can quickly select the hypothesis that best interprets the sensory data. However, reversible figures supply few distance cues to guide the system. For example, the spontaneous reversal of the Necker cube (see Figure 16.12) occurs because the perceptual system continually tests two equally plausible hypotheses about the nature of the object represented in the drawing.

With the impossible triangle (see Figure 16.13a), our perceptual system makes reasonable, but incorrect, judgements about the distance of different parts of the triangle.

**Misapplied size constancy theory**

According to Gregory, the Müller–Lyer illusion can be explained as follows (Figure 16.16):

- The arrow with the ingoing fins provides linear perspective cues, suggesting that it could be the outside corner of a building. Hence, the fins are seen as walls receding away from us, making the shaft look closer to us.
- In the arrow with the outgoing fins, the cues suggest that it could be the inside corner of a room, and the outgoing fins as walls coming towards us. This would make the shaft appear ‘distant’.

---

**Box 16.3 Explaining the Ponzo illusion**

In the Ponzo illusion (see Figure 16.11a), our system can either:

- accept the equal lengths of the two central bars as drawn on a flat two-dimensional surface (which would involve assuming that the bars are equidistant from us); or
- ‘read’ the whole figure as a railway track converging into the distance, so that the two horizontal bars represent sleepers, the top one of which would be further away from us but appears longer, since it ‘must’ be longer in order to produce the same-length image on the retina.

The second interpretation is clearly inappropriate, since the figure is drawn on a flat piece of paper and there are no actual distance differences. As a result, we experience an illusion.

**Gregory’s theory and perceptual set**

Perceptual set is directly relevant to Gregory’s view that perception is an active process involving selection, inference and interpretation. Allport describes perceptual set as ‘... a perceptual bias or predisposition or readiness to perceive particular features of a stimulus’.40

It refers to the tendency to perceive or notice some aspects of available sense data and ignore others. According to Vernon, set acts as:41

- a selector (the perceiver has certain expectations that help to focus attention on particular aspects of the incoming sensory information);
- an interpreter (the perceiver knows how to deal with the
selected data, how to classify, understand and name them, and what inferences to draw from them).

Several factors can influence or induce set, most of them being perceiver (or organismic) variables. But some relate to the nature of the stimulus or the conditions under which it is perceived (stimulus or situational variables). Both types of variable influence perception indirectly, through directly influencing set, which, as such, is a perceiver variable or characteristic (Figure 16.18, Box 16.4).

An evaluation of Gregory’s theory of perception

- Gregory’s theory raises many important questions that have yet to be answered satisfactorily. For example, if perception is essentially constructive, then we need to know how it gets started and why there is such common experience among different people, all of whom have had to construct their own idiosyncratic perceptual worlds. Also, given that perception is typically accurate (and our hypotheses are usually correct), it seems unlikely that our retinal images are really as ambiguous and lacking in detail as Gregory suggests.

- Gregory has been much more successful in explaining at least some types of illusion than in explaining perception as a whole. His theory may be most relevant when stimuli are ambiguous, incomplete or presented very briefly, or their processing is interrupted. In Gordon’s view, constructivist theories have underestimated the richness of sensory evidence in the real world. For Gordon:

It is possible that we perceive constructively only at certain times and in certain situations. Whenever we move under our...

It is typically copied as PARIS IN THE SPRING/ONCE IN A LIFETIME/A BIRD IN THE HAND. One reason eyewitness testimony is so unreliable is that our general expectation of people is that they will be of ‘average’ height and weight, and this is what almost all eyewitness accounts describe people as being (see Chapter 17 and Gross).
own power on the surface of the natural world and in good light, the necessary perceptions of size, texture, distance, continuity, motion and so on, may all occur directly and reflexively.\(^{15}\)

**Gibson's theory of direct perception**

Constructivists use the retinal image as their starting point for explaining perception. According to Gibson, this approach mistakenly describes the input for a perceiver in the same terms as that for a single photoreceptor, namely a stream of photons.\(^6\) For Gibson, it is better to begin by considering the input as a pattern of light extended over time and space (an **optic array** containing all the visual information from the environment striking the eye of a stationary perceiver).

The optic array provides unambiguous, invariant information about the layout and relevant properties of objects in space. This information takes three main forms: **optic flow patterns**, **texture gradient** and **affordances**. Perception essentially involves picking up the rich information provided by the optic array in a direct way, which involves little or no (unconscious) information processing, computations or internal representations.\(^{23}\)

**Optic flow patterns**

During the Second World War, Gibson prepared training films describing the problems that pilots experience when taking off and landing. He called the information available to pilots 'optic flow patterns' (OFPs). As shown in Figure 16.19, the point to which a pilot moves appears motionless, with the rest of the visual environment apparently moving away from that point. Thus, all around the point there is an apparent radial expansion of textures flowing around the pilot's head.

The lack of apparent movement of the point towards which the pilot moves is an invariant, unchanging feature of the optic array. Such OFPs provide unambiguous information about direction, speed and altitude. OFPs in general refer to changes in the optic array as the perceiver moves about.

![Figure 16.19 Optic flow patterns as a pilot approaches the landing strip. From Gibson.\(^{19}\)](image)

**Texture gradients**

Textures expand as we approach them and contract as they pass beyond our head. This happens whenever we move toward something, so that over and above the behaviour of each texture element there is a higher-order pattern or structure available as a source of information about the environment (and so the flow of the texture is invariant). Texture gradients (or **gradients of texture density**) are important depth cues perceived directly without the need for any inferences. The depth cues described in Table 16.2 are all examples of directly perceived, invariant, higher-order features of the optic array. For Gibson, then, the third dimension (depth) is available to the senses as directly as the other two dimensions, automatically processed by the sense receptors, and automatically producing the perceptual experience of depth.

**Affordances**

The environment contains invariant information, the detection of which has survival value for the perceiver. Affordances are directly perceivable, potential uses of objects, such as surfaces that are stand-on-able or sit-on-able, objects that are graspable or throwable, and things that afford eating (are 'edible'). In other words, affordances are the meanings that an environment has for an animal, and the relationship between perceiver and environment is vitally important.

**An evaluation of Gibson’s theory**

- Gibson was concerned with the problem of how we obtain constant perception in everyday life, based on continually changing sensations. According to Marr, this indicated that Gibson correctly regarded the problem of perception as that of recovering from sensory information 'valid properties of the external world'.\(^{18}\)

- However, as Marr points out, Gibson failed to recognize two equally critical things: 'First, the detection of physical invariants, like image surfaces, is exactly and precisely an information-processing problem... Second, he vastly underrated the sheer difficulty of such detection.'\(^{46}\)

- An interesting study by Lee and Lishman tends to support Gibson’s belief in the importance of movement in perception, and the artificiality of separating sensory and motor aspects of behaviour (Box 16.5).\(^{54}\)

- Gibson’s concept of affordances is part of his attempt to show that all the information needed to make sense of the visual environment is directly available in the visual input (a purely bottom-up approach to perception). Bruce and Green argue that this concept is most powerful and useful in the context of visually guided behaviour, as in insects.\(^{37}\) Here, it makes sense to speak of an organism detecting information available in the light needed to organize its activities, and the idea of it needing a conceptual representation of its environment seems redundant.
Box 16.5 If the room sways, there may be an experiment going on\textsuperscript{54}

Lee and Lishman used a specially built swaying room (suspended above the floor), designed to bring texture flow under experimen-
tal control. As the room sways (so changing the texture flow),
adults typically make slight unconscious adjustments and children
tend to fall over. Normally, the brain is very skilled at establishing
correlations between changes in the optic flow, signals to the
muscles and staying upright.

Arguably, the most important reason for having a visual system is
to be able to anticipate when contact with an approaching object
is going to be made. Lee and Lishman believe that estimating
‘time to contact’ is crucial for actions such as avoidance of
objects and grasping them, and thus represents extremely impor-
tant ecological information. This can be expressed as a formula:

\[
\text{Time to contact} = \frac{\text{size of retinal image}}{\text{rate of expansion of retinal image}}
\]

This is a property shared by all objects and so is another invariant,
demonstrating the unambiguous nature of the retinal image.

Measures of optic flow have also provided some understanding of
how skilled long-jumpers control their approaches to the take-off
position.\textsuperscript{15}

• However, humans act in both a cultural and a physical
environment. It is inconceivable that we do not need any
knowledge of writing or the postal system in order to
detect that a pen affords writing or a post-box affords
posting a letter, and that these are directly perceived invariants.
People see objects and events as what they are in terms of a culturally given conceptual representa-
tion of the world, and Gibson’s theory says much more about ‘seeing’ than about ‘seeing as’.

‘Seeing’ and ‘seeing as’

According to Fodor and Pylyshyn:

What you see when you see a thing depends upon what the
thing you see is. But what you see the thing as depends upon
what you know about what you are seeing.\textsuperscript{55}

This view of perception as ‘seeing as’ is the fundamental
principle of transactionalism. Transactionalists (such as
Ames, cited in Ittelson\textsuperscript{56}) argue that, because sensory input
is always ambiguous, the interpretation selected is the one
most likely to be true given what has been perceived in the
past.

Ames experimented with a distorted room, constructed in
such a way that, when viewed with one eye through a peep-
hole, a person at one end may appear very small and the
person at the other end very tall. When the people cross the
room, they appear to change size. The observer has to
choose between two different beliefs about the world built
up through past experience. The first is that rooms are rec-
tangular, consist of right-angles and so on. The second is
that people are usually of ‘average’ height. Most observers
choose the first and so judge the people to be an odd size.
However, a woman who saw her husband in the room and
judged the room to be odd shows that particularly salient
past experiences can override more generalized beliefs
about the world.

The Ames room is another example of a visual illusion,
and the inability of Gibson’s theory to explain mistaken
perception is perhaps its greatest single weakness. Gibson
argues that most ‘mistaken perceptions’ occur in situations
very different from those that prevail in the natural envi-
ronment. However, to suggest that illusions are nothing but
laboratory tricks designed to baffle ordinary people is not
true, since at least some illusions produce effects similar to
those found in normal perception.

A possible synthesis of Gregory’s and Gibson’s theories

Despite the important differences between Gibson’s and
Gregory’s theories, they also agree on certain points:

Similarities
• Visual perception is mediated by light reflected from
surfaces and objects.
• Some kind of physiological system is needed in order to
perceive.
• Perception is an active process. (In Gibson’s view, ‘a per-
ceiving organism is more like a map-reader than a
camera’.)\textsuperscript{6}
• Perceptual experience can be influenced by learning.

Differences
• Gregory believes that meaningless sensory cues must be
supplemented by memory, habit, experience and so on in
order to construct a meaningful world. Gibson argues
that the environment (initially the optic array) provides us
with all the information we need for living in the
world. Perceptual learning consists not of ‘gluing’
together sensory ‘atoms’ but of coming to differentiate
and discriminate between the features of the environ-
ment as presented in the optic array.
• To the extent that Gibson acknowledges the role of
learning (albeit a different kind of learning from
Gregory), he may be considered an empiricist (see
above), together with his emphasis on what is provided
by the physical world. In other respects, though, Gibson
can be considered a nativist. As we noted earlier, he was
very much influenced by the Gestalt psychologists,
stressing the organized quality of perception. However,
although for Gibson this organized quality is part of the
physical structure of the light impinging on the
observer’s eye, for Gestaltists it is a function of how the
brain is organized.
Eysenck and Keane argue that the relative importance of bottom-up and top-down processes is affected by several factors. When viewing conditions are good, bottom-up processing may be crucial. However, with brief or ambiguous stimuli, top-down processing becomes increasingly important. Gibson seems to have been concerned more with optimal viewing conditions, while Gregory and other constructivists have tended to concentrate on suboptimal conditions. In most circumstances, both bottom-up and top-down processes are probably needed, as claimed by Neisser (Box 16.6).

**CONCLUSIONS**

Form and depth perception, perceptual constancy and visual illusions are all concerned with perceptual organization, and many of the principles governing perceptual organization are commonly referred to as Gestalt laws.

Although Gregory’s constructivist (‘top-down’) and Gibson’s direct (‘bottom-up’) approaches may appear to contradict each other, it is possible to see them as complementary. According to Harris:

*Perception is not just a single task but ... contributes in many different ways to everyday life... Some of these ... are obviously more difficult than others and it seems likely that some can be accomplished directly, as Gibson maintained, whilst others may require sophisticated internal knowledge and are thus better described by the indirect approach.*

**KEY POINTS**

- Sensation involves physical stimulation of the sense organs, while perception is the organization and interpretation of incoming sensory information.
- Gestalt psychologists identified innately determined principles through which sensory information is interpreted and organized. The most basic of these is form perception, which organizes incoming sensory information into figure and ground.
- Laws for grouping stimuli together rest on the belief that the whole is greater than the sum of its parts. These laws can be summarized under Koffka’s law of **prägnanz**. Major Gestalt laws of perception include proximity, similarity, continuity, closure, part–whole relationship and common fate.
- Despite empirical support, Gestalt laws are difficult to apply to 3D perception and to whole scenes (they lack ecological validity).
- Depth perception allows us to estimate the distance of objects from us. Pictorial cues refer to aspects of the visual field and are monocular. Non-pictorial cues include convergence and retinal disparity, which are binocular.
- Perceptual constancy refers to the ability to recognize an object as unchanging despite changes in its size, shape, location, brightness and colour.
- Four main kinds of perceptual illusion are distortions/geometric illusions, ambiguous/reversible figures, paradoxical figures and fictions. Other illusions include those involving apparent movement and shading.
- According to top-down (conceptually driven) perceptual processing theorists, perception is the end result of an indirect process that involves making inferences about the world, based on knowledge and expectations. Bottom-up (data-driven) theorists argue that perception is a direct process, determined by the information presented to the sensory receptors.
- According to Gregory’s constructivist theory, we often supplement perception with unconscious inferences. His misapplied size constancy theory claims that we interpret the ingoing and outgoing fins
of the arrows in the Müller–Lyer illusion as providing perspective cues to distance.

- Perceptual set acts as a selector and interpreter and can be induced by perceiver/organismic and stimulus/situational variables. Perceiver variables include expectations, which often interact with context.
- According to Gibson, the optic array provides information about the layout and properties of objects in space requiring little or no (unconscious) information-processing, computations or internal representations. Optic flow patterns, texture gradients and affordances are all invariant, unchanging and higher-order features of the optic array.
- Gibson overlooked the role of culturally determined knowledge in perception. He also failed to distinguish between ‘seeing’ and ‘seeing as’, the latter forming the basic principle of transactionalism.
- Both Gibson and Gregory agree that perception is an active process, influenced by learning (making them empiricists), although they propose different kinds of learning. Gibson is also a nativist in certain respects and was influenced by the Gestalt psychologists.
- Bottom-up processing (Gibson) may be crucial under optimal viewing conditions, but under suboptimal conditions top-down processing (Gregory) becomes increasingly important.
- According to Neisser’s analysis-by-synthesis model, perception is an interactive process, involving both bottom-up feature analysis and top-down expectations (appearing at different stages of a perceptual cycle).

INTRODUCTION

Learning and memory represent two sides of the same coin: learning depends on memory for its ‘permanence’, and memory would have no ‘content’ without learning. Hence, we could define memory as the retention of learning and experience. As Blakemore says, ‘In the broadest sense, learning is the acquisition of knowledge and memory is the storage of an internal representation of that knowledge …’.1

Both learning and memory featured prominently in the early years of psychology as a science (see Chapter 9). William James, one of the pioneers of psychology, was arguably the first to make a formal distinction between primary and secondary memory, which correspond to short-term and long-term memory, respectively. This distinction is central to Atkinson and Shiffrin’s very influential multi-store model (MSM).2,3

As with other cognitive processes, memory remained a largely unacceptable area for psychological research until the cognitive revolution of the mid-1950s, reflecting the dominance of behaviourism until this time. However, some behaviourists, especially in the USA, studied verbal behaviour using paired-associate learning. This associationist approach was (and remains) most apparent in interference theory, an attempt to explain forgetting. Other theories of forgetting include trace decay, displacement, cue-dependent forgetting and repression.

Several major accounts of memory have emerged from criticisms of the MSM. These include Craik and Lockhart’s levels-of-processing approach,4 Baddeley and Hitch’s working-memory model5 and attempts to identify different types of long-term memory (e.g. Tulving6). Psychologists are increasingly interested in everyday memory rather than studying it merely as a laboratory phenomenon.

THE MEANINGS OF ‘MEMORY’

Memory, like learning, is a hypothetical construct denoting three distinguishable but interrelated processes (Figure 17.1):

- **Registration (or encoding):** the transformation of sensory input (e.g. a sound or visual image) into a form that allows it to be stored. With a computer, for example, information can be encoded only if it is presented in a format that the computer recognizes.
- **Storage:** the operation of holding or retaining information in memory. Computers store information by means

![Figure 17.1 The three processes of memory](image-url)
of changes in the system’s electrical circuitry. In humans, the changes occurring in the brain allow information to be stored, though exactly what these changes involve is unclear.

- **Retrieval:** the process by which stored information is extracted from memory.

Registration can be thought of as a necessary condition for storage to take place, but not everything that registers on the senses is stored. Similarly, storage is a necessary, but not sufficient, condition for retrieval: we cannot recover information that has not been stored, but the fact that we know the information is no guarantee that we will remember it on any particular occasion. This is the crucial distinction between availability (whether or not the information has been stored) and accessibility (whether or not the information can be retrieved), which is especially relevant to theories of forgetting.

**STORAGE**

In practice, storage is studied through testing people’s ability to retrieve. This is equivalent to the distinction between learning and performance: learning corresponds to storage, while performance corresponds to retrieval. But there are several kinds of retrieval (see below). So, if we are tested by recall, it may look as though we have not learned something, but a test of recognition may show that we have. For these reasons, it is useful to distinguish between memory as storage and memory as retrieval. When people complain about having a ‘poor memory’, they might mean storage or retrieval, but they are unlikely to make the distinction (they would simply say ‘I can’t remember’).

As we noted earlier, it was James who first distinguished between primary and secondary memory. Ebbinghaus, the pioneer of memory research, would have accepted it.7 Many psychologists since James have also made the distinction, including Hebb,8 Broadbent9 and Waugh and Norman.10 In Atkinson and Shiffrin’s MSM, primary and secondary memory are called short-term memory (STM) and long-term memory (LTM), respectively (Figure 17.2).2,3 Strictly, STM and LTM refer to experimental procedures for investigating short-term and long-term storage, respectively.

**Sensory memory**

Sensory memory gives us an accurate account of the environment as experienced by the sensory system. We retain a literal copy of the stimulus long enough for us to decide whether it is worthy of further processing. Any information that we do not attend to or process further is forgotten. It is probably more useful to think of sensory memory as an aspect of perception and as a necessary requirement for storage proper (i.e. STM).

The storage (such as it is) occurs within the sensory system that received the information (it is modality-specific). Additional information entering the same sensory channel immediately disrupts the storage. For example, if two visual stimuli are presented within quick succession, memory of the first stimulus may be lost; but if the second stimulus is a sound or smell, it will not interfere with memory of the visual stimulus. Although it is likely that a sensory memory exists for each of our sensory systems, most research has concentrated on:

- **Iconic memory** (an icon is an image), which stores visual images for about half a second;
- **Echoic memory**, which stores sounds for up to two seconds.

We are usually unaware of sensory memory, but if you watch someone wave a lighted cigarette in a darkened room you see a streak rather than a series of points.11 If we had no iconic memory, we would perceive a film as a series of still images interspersed with blank intervals, rather than as a continuously moving scene. Without echoic memory, instead of hearing speech as such, we would hear a series of unrelated sounds.12

**Short-term memory**

Probably less than one-hundredth of all the sensory information that impinges on the human senses every second reaches consciousness. Of this, only about 5 per cent is stored permanently.13 Clearly, if we possessed only sensory memory, then our capacity for retaining information about the world would be extremely limited. However, according to models of memory such as Atkinson and Shiffrin’s MSM, some information from sensory memory is successfully passed on to STM.

Short-term (and long-term) memory can be analysed in terms of the following:

- **Capacity:** how much information can be stored
• **Duration**: how long the information can be held in storage
• **Coding**: how sensory input is represented by the memory system.

**Capacity**

Ebbinghaus’ and Wundt in the 1860s were two of the first psychologists to maintain that STM is limited to six or seven bits of information. But the most famous account is given by Miller in his article ‘The magical number seven, plus or minus two’.

Miller showed how **chunking** can be used to expand the limited capacity of STM by using already established memory stores to categorize or encode new information. If we think of STM’s capacity as seven slots, with each slot being able to accommodate one bit, or unit, of information, then seven individual letters would each fill a slot and there would be no room left for any additional letters. But if the letters are chunked into a word, then the word would constitute one unit of information, leaving six free slots. In the example below, the 25 bits of information can be chunked into (or reduced to) six words, which could quite easily be reduced further to one bit (or chunk) based on prior familiarity with the words:

```
S A V A O
R E E E G
U R S Y A
O O D N S
F C N E R
```

To be able to chunk, you have to know the rule or code, which in this case is: starting with F in the bottom left-hand corner, read upwards until you get to S; then drop down to C and read upwards until you get to A; then go to N and read upwards; and so on. This should give you ‘four score and seven years ago’.

Chunking is involved whenever we reduce a larger amount of information to a smaller amount. This (i) increases the capacity of STM and (ii) represents a form of encoding information, by imposing a meaning on otherwise meaningless material. For example:

- arranging letters into words, words into phrases and phrases into sentences;
- converting 1066 (four bits of information) into a date (one chunk), so a string of 28 numbers could be reduced to seven dates;
- using a rule to organize information: the series 149162536496481100121 (21 bits) is generated by the rule by which $1^2 = 1$, $2^2 = 4$, $3^2 = 9$ and so on. The rule represents a single chunk, and that’s all that has to be remembered.

These examples demonstrate how chunking allows us to bypass the seven-bit bottleneck. Although the amount of information contained in any one chunk may be unlimited (e.g. the rule above can generate an infinitely long set of digits), the number of chunks that can be held in STM is still limited to seven plus or minus two.

**Duration**

A way of studying pure STM was devised by Brown and Peterson and Peterson – the *Brown–Peterson technique*. By repeating something that has to be remembered (maintenance rehearsal), information can be held in STM almost indefinitely. The Brown–Peterson technique overcomes this problem (Box 17.1).

**Box 17.1 The Brown–Peterson technique**

In the Brown–Peterson technique, participants hear various trigrams, such as ‘XPJ’. Only one trigram is presented on each trial.

Immediately afterwards, the participants are instructed to recall what they heard or to count backwards, in threes, out loud, from some specified number for 3, 6, 9, 12, 15 or 18 s (the retention interval). The function of this distractor task is to prevent rehearsal.

At the end of the time period, participants try to recall the trigram.

Peterson and Peterson found that the average percentage of correctly recalled trigrams was high with short delays, but decreased as the delay interval increased. Nearly 70 per cent were forgotten after only a 9-s delay, and 90 per cent after 18 s (Figure 17.3).

![Figure 17.3 Data reported by Peterson and Peterson in their experiment on the duration of short-term memory](image)

In the absence of rehearsal, then, the duration of short-term memory is very short, even with very small amounts of information. If a more difficult distractor task is used, the duration can be made even shorter.

**Coding**

Conrad presented participants visually with a list of six consonants (e.g. BKSJLR), each of which was seen for about three-quarters of a second. Participants were instructed to write down the consonants. Mistakes tended to be related to a letter’s sound. For example, there were 62 instances of ‘B’
be mistaken for ‘P’ and 83 instances of ‘V’ being mistaken for ‘P’, but only two instances of ‘S’ being mistaken for ‘P’. These acoustic confusion errors suggested to Conrad that STM must code information according to its sound. Even when information is presented visually, it must somehow be transformed into its acoustic code (see also Baddeley’s study\(^\text{18}\)).

**Other forms of coding in short-term memory**

Shulman showed participants lists of ten words.\(^\text{19}\) Recognition of the words was then tested using a visually presented ‘probe word’, which was:

- a homonym of one of the words on the list (e.g. ‘bawl’ for ‘ball’); or
- a synonym of one of the words on the list (e.g. ‘talk’ for ‘speak’); or
- identical to one of the words on the list.

Shulman found that homonym and synonym probes produced similar error rates. These results imply that some semantic coding (coding for meaning) had taken place in STM. If an error was made on a synonym probe, then some matching for meaning must have taken place.

Visual images (e.g. abstract pictures, which would be difficult to store using an acoustic code) can also be maintained in STM, if only briefly.

**Long-term memory**

**Capacity and duration**

It is generally accepted that LTM has unlimited capacity. It can be thought of as a vast storehouse of all the information, skills, abilities and so on that are not currently being used but that are potentially retrievable. According to Bower, some of the kinds of information contained in LTM include:\(^\text{20}\)

- a spatial model of the world around us;
- knowledge of the physical world, physical laws and properties of objects;
- beliefs about people, ourselves, social norms, values and goals;
- motor skills, problem-solving skills, and plans for achieving various things;
- perceptual skills in understanding language, interpreting music and so on.

Many of these are included in what Tulving calls semantic memory (see below).\(^\text{6}\) Information can be held for between a few minutes and several years (and may in fact span the individual’s entire lifetime).

**Coding**

With verbal material, coding in LTM appears to be mainly semantic. For example, Baddeley presented participants with words that were:

- **acoustically similar** (e.g. ‘caught’, ‘short’, ‘taut’, ‘nought’); or
- **semantically similar** (e.g. ‘huge’, ‘great’, ‘big’, ‘wide’); or
- **acoustically dissimilar** (e.g. ‘foul’, ‘old’, ‘deep’); or
- **semantically dissimilar** (e.g. ‘pen’, ‘day’, ‘ring’).\(^\text{18}\)

When recall from STM was tested, acoustically similar words were recalled less well than acoustically dissimilar words. This supports the claim that acoustic coding occurs in STM. There was a small difference between the number of semantically similar and semantically dissimilar words recalled (64% and 71%, respectively). This suggests that although some semantic coding occurs in STM, it is not dominant. When an equivalent study was conducted on LTM, fewer semantically similar words were recalled, while acoustically similar words had no effect on LTM recall. This suggests that the dominant code of LTM is semantic. Similarly, Baddeley found that immediate recall of the order of short lists of unrelated words was seriously impeded if the words were acoustically similar, but not if they were semantically similar.\(^\text{18}\) After a delay, however, exactly the opposite effect occurred.

**Does long-term memory use only semantic coding?**

Findings such as Baddeley’s do not imply that LTM uses only a semantic code.\(^\text{21}\) Our ability to picture a place we visited on holiday indicates that at least some information is stored or coded visually. Also, some types of information in LTM (e.g. songs) are coded acoustically. Smells and tastes are also stored in LTM, suggesting that LTM is a very flexible system, as well as being large and long-lasting.

Table 17.1 shows the main differences between STM and LTM.

**RETRIEVAL**

There are many different ways of recovering or locating information that has been stored; that is, ‘remembering’ can

<table>

</tbody>
</table>
take many different forms. Likewise, there are also different ways of measuring memory in the laboratory.

**How is memory measured?**

The systematic scientific investigation of memory began with Ebbinghaus (Box 17.2).7

Other techniques for measuring memory include the following:

- **Recognition**: this involves deciding whether or not a particular piece of information has been encountered before (e.g. in a multiple-choice test, where the correct answer is presented along with incorrect answers). Recognition is a very sensitive form of retrieval.

- **Recall**: this involves participants actively searching their memory stores in order to retrieve particular information (e.g. in timed essays). Retrieval cues are missing or very sparse. The material can be recalled either in the order in which it was presented (serial recall) or in any order at all (free recall).

---

**Box 17.2 Pure memory**7

To study memory in its purest form, Ebbinghaus invented three-letter nonsense syllables – a consonant followed by a vowel followed by another consonant, such as XUT and JEQ.

Ebbinghaus spent several years using only himself as the subject of his research. He read lists of nonsense syllables out loud; when he felt he had recited a list sufficiently to retain it, he tested himself.

If Ebbinghaus could recite a list correctly twice in succession, he considered the list to have been learned. After recording the time taken to learn a list, he then began learning another list.

After specific periods of time, he returned to a particular list and tried to memorize it again. He calculated the number of attempts (or trials) it took him to relearn the list, as a percentage of the number of trials it had originally taken to learn it (a *savings score*).

Ebbinghaus found that memory declines sharply at first, but then levels off. For example, in one set of experiments involving a series of eight different lists of 13 nonsense syllables, he found the following savings scores:

- 58% 20 min after training.
- 44% 60 min after training.
- 34% 24 h after training.
- 21% 31 days after training.

‘... Thus, most of the memory loss occurred within the first minutes after training; once the memory had survived this hurdle it seemed much more stable...’

This finding has subsequently been replicated many times.

---

**Memory-span procedure**: this is a version of serial recall, in which a person is given a list of unrelated digits or letters, and then required to repeat them back immediately in the order in which they were heard. The number of items on the list is increased successively until an error is made. The maximum number of items that can be consistently recalled correctly is a measure of *immediate memory span*.

- **Paired-associates recall**: participants are required to learn a list of paired items (e.g. ‘chair’ and ‘elephant’). When one of the words (e.g. ‘chair’) is re-presented, the participant must recall the paired word (‘elephant’).

---

**THE MULTI-STORE MODEL**

Atkinson and Shiffrin’s MSM (sometimes called the *dual-memory model* because of the emphasis on STM and LTM) was an attempt to explain how information flows from one storage system to another (Figure 17.4).2,3 The model sees sensory memory, STM and LTM as permanent structural components of the memory system (built-in features of the human information-processing system). In addition to these structural components, the memory system comprises more transient control processes. Rehearsal is a key control process serving two main functions:

- to act as a *buffer* between sensory memory and LTM by maintaining incoming information within STM;
- to transfer information to LTM.

Information from sensory memory is scanned and matched with information in LTM. If a match (i.e. pattern
recognition) occurs, then it might be fed into STM along with a verbal label from LTM.

**Evidence for the multi-store model**

Three kinds of evidence are relevant here:

- Experimental studies of STM and LTM (sometimes referred to as *two-component tasks*)
- Studies of coding
- Studies of patients with brain damage.

**Experimental studies of short- and long-term memory**

**The serial position effect**

Murdock presented participants with a list of words at a rate of about one word per second. Participants were asked to free-recall as many of these words as they could. Murdock found that the probability of recalling any word depended on its position in the list (its *serial position*; the graph shown in Figure 17.5 is a *serial position curve*). Participants typically recalled those items from the end of the list first and got more of these correct than earlier items (the *recency effect*). Items from the beginning of the list were recalled quite well relative to those in the middle (the *primacy effect*), but not as well as those at the end. Poorest recall is for items in the middle. The serial position effect holds, regardless of the length of the list.23

The primacy effect occurs because the items at the beginning of the list have (presumably) been rehearsed and transferred to LTM, from where they are recalled. The recency effect occurs presumably because items currently in STM are recalled from there. Because the capacity of STM is limited and can hold items for only a brief period of time, words in the middle are either lost from the system completely or otherwise unavailable for recall. The last items are remembered only if recalled first and tested immediately, as demonstrated by Glanzer and Cunitz in a variation of Murdock’s study (Box 17.3).24

In Glanzer and Cunitz’s study, it is likely that the earlier words had been transferred to LTM (from where they were recalled), while the most recent words were vulnerable to the counting task.25

**Brown–Peterson technique and rehearsal**

When discussing the characteristics of STM earlier, we noted the rapid loss of information from memory when rehearsal is prevented using the Brown–Peterson technique. This is usually taken as evidence for the existence of a STM with rapid forgetting (see below). But the concept of rehearsal itself has been criticized as both unnecessary and too general (Box 17.4).

An earlier study by Glanzer and Meinzer found that participants who were asked to repeat items aloud recalled fewer items than participants given an equal period of silent rehearsal.27 Perhaps in silent rehearsal the material is not merely being repeated but is recoded into a different form that enhances recall.

**Rehearsal and the levels-of-processing approach**

It seems, then, that what is important is the kind of rehearsal or processing, rather than how much. This has been investigated in particular by Craik and Lockhart,7 in the form of the *levels-of-processing approach* (LOP) (see Gross28). Maintenance rehearsal may not even be necessary for storage. Jenkins found that participants could remember material even though they were not expecting to be tested and so were unlikely to have rehearsed the material.29 This is called *incidental learning*. 

---

**Box 17.3 Removing the recency effect**

Glanzer and Cunitz presented two groups of participants with the same list of words. One group recalled the material immediately after presentation, while the other group recalled the material after 30 s. The participants had to count backwards in threes (the Brown–Peterson technique), which prevented rehearsal and caused the recency effect to disappear (Figure 17.6).

**Figure 17.5** Typical serial position curve

**Figure 17.6** Data from Glanzer and Cunitz’s study24 showing serial position curves after no delay and after a delay of 30 s

The primacy effect was largely unaffected.

---

**Figure 17.3** Removing the recency effect24
Craik and Watkins asked participants to remember only certain ‘critical’ words (those beginning with a particular letter) from lists presented either rapidly or slowly.

The position of the critical words relative to the others determined the amount of time a particular word spent in short-term memory (STM) and the number of potential rehearsals it could receive.

Craik and Watkins found that long-term remembering was unrelated to either how long a word had spent in STM or the number of explicit or implicit rehearsals it received.

Based on this and later findings, Craik and Watkins distinguished between:

- **maintenance rehearsal**, in which material is rehearsed in the form in which it was presented (‘rote’);
- **elaborative rehearsal** (or elaboration of encoding), which elaborates the material in some way (e.g. by giving it a meaning or linking it with pre-existing knowledge stored in long-term memory).

Craik and Lockhart also considered that the MSM view of the relationship between structural components and control processes was, essentially, the wrong way round. According to the MSM, the structural components (sensory memory, STM, LTM) are fixed, while control processes (e.g. rehearsal) are less permanent. The LOP model begins with the proposed control processes. The structural components (the memory system) are what results from the operation of these processes. In other words, memory is a by-product of perceptual analysis. This is controlled by the central processor, which can analyse a stimulus (e.g. a word) on various levels:

- At a superficial (shallow) level, the surface features of a stimulus (e.g. whether the word is in lower- or uppercase letters) are processed.
- At an intermediate (phonemic or phonetic) level, the word is analysed for its sound.
- At a deep (or semantic) level, the word’s meaning is analysed.

The level at which a stimulus is processed depends on both its nature and the processing time available. The more deeply information is processed, the more likely it is to be retained.

**Studies of coding**

Table 17.1 indicates that the major form of coding used in STM is acoustic, while LTM is much more flexible and varied in how it encodes information. It also suggests that semantic coding is used primarily by LTM. This is usually taken to support the MSM. However, not everyone accepts this view.

**Box 17.4 Maintenance v. elaborative rehearsal**

Craik and Watkins asked participants to remember only certain ‘critical’ words (those beginning with a particular letter) from lists presented either rapidly or slowly.

The position of the critical words relative to the others determined the amount of time a particular word spent in short-term memory (STM) and the number of potential rehearsals it could receive.

Craik and Watkins found that long-term remembering was unrelated to either how long a word had spent in STM or the number of explicit or implicit rehearsals it received.

Based on this and later findings, Craik and Watkins distinguished between:

- **maintenance rehearsal**, in which material is rehearsed in the form in which it was presented (‘rote’);
- **elaborative rehearsal** (or elaboration of encoding), which elaborates the material in some way (e.g. by giving it a meaning or linking it with pre-existing knowledge stored in long-term memory).

**Chunking and short- and long-term memory**

When discussing the characteristics of STM, we saw that chunking increases the capacity of STM by imposing meaning on otherwise meaningless material. According to Miller, chunking represents a linguistic recoding that seems to be the ‘very lifeblood of the thought process’.

But this cannot occur until certain information in LTM is activated and a match is made between the incoming items and their representation in LTM.

Miller and Selfridge gave participants ‘sentences’ of varying lengths, which resembled true English to different degrees, and asked the participants to recall the words in the correct order. The closer a ‘sentence’ approximated normal English, the better it was recalled. This suggests that knowledge of semantic and grammatical structure (presumably stored in LTM) is used to aid recall from STM.

In a similar study, Bower and Springston presented one group of American college students with letters that formed familiar acronyms (e.g. FBI, PHD, TWA, IBM). A second group was presented with the same letters, but in a way that did not form those acronyms (e.g. FB, IPH, DTW, AIB, M). The first group recalled many more letters than the second group. The pause after ‘FBI’ and so on allowed the students to ‘look up’ the material in their mental dictionaries and so encode the letters in one chunk.

**The study of patients with brain damage**

**Anterograde amnesia and the amnesic syndrome**

If STM and LTM really are distinct, then there should be certain kinds of brain damage that impair one without affecting the other. One such form of brain damage is anterograde amnesia (Box 17.5).

An equally dramatic but in many ways more tragic case is that of Clive Wearing (Box 17.6).

Atkinson and Shiffrin regard the kind of memory deficits displayed by HM and Clive Wearing as ‘perhaps the single most convincing demonstration of a dichotomy in the memory system’. According to Parkin, the amnesic syndrome is not a general deterioration of memory function but is a selective impairment in which some functions, such as learning novel information, are severely impaired, while others, including memory span and language, remain intact.

If amnesic patients do have an intact STM, then they should show a similar recency effect (based on STM) but a poorer primacy effect (based on LTM) compared with normal controls. This is exactly what is found (e.g. Baddeley and Warrington). These results have led most psychologists to accept that, in the amnesic syndrome, STM function is preserved but LTM function is impaired.

However, this difference in STM and LTM functioning could mean that:

- the problem for amnesic patients is one of transfer from STM to LTM, which is perfectly consistent with the MSM; or
amnesic patients have difficulties in retrieval from LTM.\textsuperscript{36,37}

The latter interpretation is more consistent with Craik and Lockhart’s LOP approach.\textsuperscript{4}

Another major implication of cases such as those of HM and Clive Wearing is that the ‘unitary’ LTM of the MSM is a gross oversimplification (see below).

Retrograde amnesia

In retrograde amnesia, the patient fails to remember what happened before the surgery or accident that caused it. Retrograde amnesia can be caused by head injuries, electroconvulsive therapy (ECT; see Chapter 59), carbon monoxide poisoning and extreme stress. As in anterograde amnesia, there is typically little or no disruption of STM, and the period of time for which the person has no memories may be minutes, days or even years. When retrograde amnesia is caused by brain damage, it is usually accompanied by anterograde amnesia. Similarly, patients with Korsakoff’s syndrome (caused by severe, chronic alcoholism involving damage to the hippocampus) usually experience both kinds of amnesia.

Retrograde amnesia seems to involve a disruption of consolidation, whereby, once new information has entered...
LTM, time is needed for it to become firmly established physically in the brain.

**ALTERNATIVES TO THE MULTI-STORE MODEL**

**Multiple forms of long-term memory**

**Episodic and semantic memory**

Despite their brain damage, HM and Clive Wearing retained many skills, both general and specific (e.g. talking, reading, walking, playing the organ). They were also capable of acquiring and retaining new skills, although they did not know that they had them. This suggests very strongly that there are different kinds of LTM. But as far as the MSM is concerned, there is only ‘LTM’ (i.e. LTM is unitary).

Box 17.7 differentiates episodic memory (EM) and semantic memory (SM). Our general knowledge about, say, computers (part of our SM) is built up from past experiences with particular computers (part of EM), through abstraction and generalization. This suggests that, instead of regarding EM and SM as two quite distinct systems within the brain (which is what Tulving originally intended), it might be more valid to see SM as made up from multiple EMs.

**Autobiographical v. experimental episodic memory**

Tulving maintained that EM is synonymous with autobiographical memory (AM). For example, the forgetting of words in a free-recall task can be thought of as a failure in our EM. Clearly, we already know the words as part of our SM, but we fail to remember that they appeared in that particular list just presented to us. However, Cohen argues that learning word lists is not what most people understand by AM. Instead, AM is a special kind of EM, concerned with specific life events that have personal significance. Accordingly, she distinguishes between autobiographical EM and experimental EM; taking part in an experiment in which we are required to learn lists of words is an example of the latter.

**Flashbulb memories**

Flashbulb memories are a special kind of EM, in which we can give vivid and detailed recollections of where we were and what we were doing when we first heard about some major public national or international event.

According to Brown and Kulik, a neural mechanism is triggered by events that are emotionally arousing, unexpected or extremely important, with the result that the whole scene becomes ‘printed’ on the memory. However, Neisser argued that the durability of flashbulb memories stems from their frequent rehearsal and reconsideration after the event. Also, the detail and vividness of people’s memories are not necessarily signs of their accuracy - we can be very confident about something and still be mistaken.

**Procedural v. declarative memory**

Procedural memory (PM) refers to information from LTM that cannot be inspected consciously. For example, riding a bike is a complex skill that is even more difficult to describe. In the same way, native speakers of a language cannot usually describe the complex grammatical rules by which they speak correctly (perhaps because the skills were not learned consciously in the first place). By contrast, EM and SM are both amenable to being inspected consciously, and the content of both can be described to another person.

Cohen and Squire distinguish between PM and declarative memory, which correspond to Ryle’s distinction between knowing how and knowing that, respectively (Table 17.2). Anderson argues that, when we initially learn something, it is learned and encoded declaratively, but with

</table>
practice it becomes compiled into a procedural form of knowledge.46

Regarding the LTM of HM and Clive Wearing, most aspects of their PM seemed to be intact, but both their EM and SM were partially impaired. For instance, HM was given extensive training by Gabrieli et al. in the task of learning the meaning of unfamiliar words that had come into popular use since his operation.47 He made very little progress, despite extensive practice every day for 10 days.

Most other amnesic patients similarly fail to update their SM in order to take account of changes in the world since onset of their dysfunction.48 For example, many such patients do not know the name of the current leader of their country, and they have very poor recognition for faces of people who have become famous only quite recently.49

The major problem seems to involve recent declarative memory. We saw earlier that Clive Wearing denied all knowledge of having learned to mirror-read. Similarly, HM was trained to solve the Tower of Hanoi problem-solving task (see Gross48) over several days, but each time he was presented with the task he denied ever having seen it before. Yet their performance on these two tasks steadily improved. As Rose puts it, ‘… procedural memory continued to testify to the truth of what declarative memory denied’.22

Procedural memory involves more automatic processes and allows patients to demonstrate learning without the need for conscious recollection of the learning process. But declarative learning/memory involves conscious recollection of the past. Damage to a number of cortical and subcortical areas (including the temporal lobes, hippocampus and mamillary bodies) seriously impairs declarative memory in patients with amnesia. PM does not appear to be impaired by damage to these areas.12

The organized nature of memory

As we have seen, chunking is a way of increasing the limited capacity of STM by imposing a meaning on unrelated items

The working-memory model: rethinking short-term memory

In their MSM, Atkinson and Shiffrin saw STM as a system for temporarily holding and manipulating information. However, Baddeley and Hitch criticized the model’s concept of a unitary STM.5 Although accepting that STM rehearses incoming information for transfer to LTM, they argued that it was much more complex and versatile than a mere ‘stopping-off station’ for information.

Short-term memory is an active store used to hold information that is being manipulated. According to Groome et al., working memory (WM) is like the computer screen, a kind of mental workspace where various operations are performed on current data.50 By contrast, LTM resembles the computer’s memory (‘storage memory’), which holds large amounts of information in a fairly passive state for possible future retrieval. Working memory is a cognitive function that:

- helps us to keep track of what we are doing or where we are from moment to moment;
- holds information long enough to allow us to make a decision, dial a telephone number or repeat a strange foreign word that we have just heard.

Instead of a single, simple STM, Baddeley and Hitch proposed a more complex, multicomponent WM.5 This comprises a central executive, which is in overall charge, plus sub- or slave systems, whose activities are controlled by the central executive. These are the articulatory (or phonological) loop (the inner voice) and the visuospatial scratchpad (or sketchpad; the inner eye) (for a more detailed discussion, see Gross28).

An evaluation of the working-memory model

- It is generally accepted that (i) STM is better seen as a number of relatively independent processing mechanisms than as the single unitary store of the MSM; and (ii) attentional processes and STM are part of the same system (they are probably used together much of the time in everyday life).
- The idea that any one slave system (such as the phonological loop) may be involved in the performance of apparently very different tasks (e.g. memory span, mental arithmetic, verbal reasoning, reading) is a valuable insight.
- It has practical applications that extend beyond its theoretical importance,51,52 such as explaining children’s problems in learning to read.
- One weakness of the WM model is that least is known about the most important component, namely the central executive.53 This can, apparently, carry out an enormous variety of processing activities in different conditions. This makes it difficult to describe its precise function, and the idea of a single central executive might be as inappropriate as that of a unitary STM.54

MEMORY AND THE REPRESENTATION OF KNOWLEDGE

What psychologists have traditionally called knowledge is information that is represented mentally in a particular format and is structured or organized in some way.48 This leads to two interrelated questions about the nature of knowledge:

- What format do mental representations take?
- How are these mental representations organized?

This subject area was neglected until quite recently, when attempts to provide a knowledge base for computer systems stimulated an interest in how ‘… this enormously important but complex facility operates in people’.33

Part 2: Developmental, behavioural and sociocultural psychiatry
of information. We do this by organizing it, giving it a structure that it does not otherwise have. As Baddeley says:

The secret of a good memory, as of a good library, is that of organisation; good learning typically goes with the systematic encoding of incoming material, integrating and relating it to what is already known.12

Organization can be imposed either by the experimenter (experimenter organization, EO) or spontaneously by the participant (subjective organization, SO).55 Mandler found that instructions to organize will facilitate learning, even though the participant is not trying to remember the material.56

Schemas and reconstructive memory

As we saw above, Ebbinghaus was the first to study memory systematically, using nonsense syllables. Although this tradition is still popular with today’s memory researchers, Bartlett argued that:57

● Ebbinghaus’s use of nonsense syllables excluded ‘all that is most central to human memory’;
● the study of ‘repetition habits’ had very little to do with memory in everyday life;
● research should examine people’s active search for meaning, rather than their passive responses to meaningless stimuli presented by an experimenter.

Although meaningful material is more complex than meaningless material, Bartlett argued that it too could be studied experimentally. Bartlett’s concept of a schema is central to theories that attempt to explain the structure and organization of knowledge in SM (a major part of LTM). Because of the large amount of work on the organizational aspects of memory, and because of the growing recognition of the need to study meaningful material (as opposed to lists of unrelated words, numbers and so on), there has been a rediscovery of Bartlett’s research into reconstructive memory.

Bartlett concluded from his research findings that interpretation plays a major role in the remembering of stories and past events. Learning and remembering are both active processes involving ‘effort after meaning’ – that is, trying to make the past more logical, coherent and generally ‘sensible’. This involves making inferences or deductions about what could or should have happened. We reconstruct the past by trying to fit it into our existing understanding of the world. Unlike a computer’s memory, where the output matches the input exactly, human memory is an ‘imaginative reconstruction’ of experience.

Bartlett called this existing understanding of the world a schema. Schemas (or schemata):

● provide us with ready-made expectations that help us to interpret the flow of information reaching the senses;
● help us to make the world more predictable;
● allow us to ‘fill in the gaps’ when our memories are incomplete;
● can produce significant distortions in memory processes, because they have a powerful effect on the way in which memories for events are encoded. This happens when new information conflicts with existing schemas (or schemata).

THEORIES OF FORGETTING

In order to understand why we forget, we must recall the distinction between availability (whether or not material has been stored) and accessibility (being able to retrieve what has been stored). In terms of the MSM, since information must be transferred from STM to LTM for permanent storage:

● availability concerns mainly STM and the transfer of information from STM into LTM;
● accessibility is concerned mainly with LTM.

Forgetting can occur at the encoding, storage or retrieval stages (Figure 17.7).

One way of looking at forgetting is to ask what prevents information staying in STM long enough to be transferred to LTM (some answers are provided by the decay and dis-
placement theories). Some answers to the question about what prevents us from locating the information that is already in LTM include those offered by interference theory, cue-dependent forgetting and motivated forgetting (or repression).

Decay theory

Decay (or trace decay) theory tries to explain why forgetting increases with time. Clearly, memories must be stored somewhere, the most obvious place being the brain. Presumably, some sort of structural change (the engram) occurs when learning takes place. According to decay theory, metabolic processes occur over time that cause the engram to degrade (break down), unless it is maintained by repetition and rehearsal. This results in the memory contained within it becoming unavailable.

Hebb argued that while learning is taking place, the engram that will eventually be formed is very delicate and liable to disruption (the active trace).8 With learning, the engram grows stronger, until a permanent engram is formed (the structural trace) through neurochemical and neuroanatomical changes.

Decay in short- and long-term memory

The active trace corresponds roughly to STM, and, according to decay theory, forgetting from STM is due to disruption of the active trace. Although Hebb did not apply the idea of decay to LTM, other researchers have argued that it can explain LTM forgetting if it is assumed that decay occurs through disuse (hence, decay-through-disuse theory). So, if certain knowledge or skills are not used or practised for long periods of time, the corresponding engram will eventually decay away.58

Is forgetting just a matter of time?

Peterson and Peterson’s experiment (see Box 17.1) has been taken as evidence for the role of decay in STM forgetting.16 If decay did occur, then we would expect poorer recall of information with the passage of time, which is exactly what the Petersons reported.

The difficulty with the Petersons’ study in particular, and decay theory in general, is that other possible effects need to be excluded before a decay-based account can be accepted. The ideal way to study the role of decay in forgetting would be to have people receive information and then do nothing, physical or mental, for a period of time. If recall was poorer with the passage of time, then it would be reasonable to suggest that decay had occurred. Such an experiment is, of course, impossible. However, Jenkins and Dallenbach were the first to attempt an approximation to it (Box 17.8).59

Although some data exist suggesting that neurological breakdown occurs with age and disease (e.g. in Alzheimer’s disease), there is no evidence that the major cause of forgetting from LTM is neurological decay.60

Displacement theory

In a limited-capacity STM system, forgetting might occur through displacement. When the system is ‘full’, the oldest material in it would be displaced (‘pushed out’) by incoming new material. This possibility was explored by Waugh and Norman using the serial probe task.10 Participants were presented with 16 digits at the rate of either one or four per second. One of the digits (the ‘probe’) was then repeated,
and participants had to say which digit followed the probe. Presumably:

- if the probe was one of the digits at the beginning of the list, then the probability of recalling the digit that followed would be small, because later digits would have displaced earlier digits from the system;
- if the probe was presented towards the end of the list, then the probability of recalling the digit that followed would be high, since the last digits to be presented would still be available in STM.

When the number of digits following the probe was small, recall was good; but when the number of digits was large, recall was poor. This is consistent with the idea that the earlier digits are replaced by later digits (Figure 17.9).

Since less time had elapsed between presentation of the digits and the probe in the four-per-second condition, there would have been less opportunity for those digits to have decayed away. This makes it unclear whether displacement is a process distinct from decay.

**Retrieval-failure theory and cue-dependent forgetting**

According to retrieval-failure theory, memories cannot be recalled because the correct retrieval cues are not being used. The role of retrieval cues is demonstrated by the tip-of-the-tongue phenomenon (TOT), in which we know that we know something but cannot retrieve it at that particular moment in time (Box 17.9).

Tulving and Pearlstone read participants lists of varying numbers of words (12, 24 or 48) consisting of categories (e.g. animals) of one, two or four exemplars (e.g. dog) per list, plus the category name. Participants were asked to try to remember only the exemplars. Half the participants (group 2) free-recalled the words and wrote them down on blank pieces of paper. The other half (group 1) were given the category names. Group 1 recalled significantly more words, especially on the 48-item list. However, when the participants in group 2 were given the category names, recall improved (Figure 17.10).
recall as during the original learning. In Tulving and Pearlstone’s experiment, the category names were presented together with the exemplars for group 1. Presumably, they were encoded at the time of learning. The ESP explains why recall is sometimes superior to recognition (even though recognition is generally considered to be easier than recall).

Tulving used the term ‘cue-dependent forgetting’ to refer jointly to context-dependent and state-dependent forgetting (Table 17.3). Interference theory

According to interference theory, forgetting is influenced more by what we do before or after learning than by the mere passage of time (see Box 17.8):

- In **retroactive interference/inhibition** (RI), later learning interferes with the recall of earlier learning.
- In **proactive interference/inhibition** (PI), earlier learning interferes with the recall of later learning.

Interference theory has been studied extensively in the laboratory using paired-associate lists. The usual procedure for studying interference effects is shown in Figure 17.11.

Usually, the first member of each pair in list A is the same as in list B, but the second member of each pair is different in the two lists:

- In RI, the learning of the second list interferes with recall of the first list (the interference works backwards in time).
- In PI, the learning of the first list interferes with recall of the second list (the interference works forwards in time).

Wickens found that participants became increasingly poor at retaining information in STM on successive trials. However, when the category of information was changed, they performed just as well as on the first list. So, performance with lists of numbers became poorer over trials, but if the task was changed to lists of letters, it improved. This is known as **release from proactive inhibition**.

**Limitations of laboratory studies of interference theory**

The strongest support for interference theory comes from laboratory studies. However:

- Learning in such studies does not occur in the same way as it does in the real world, where learning of potentially interfering material is spaced out over time. In the laboratory, learning is artificially compressed in time, which maximizes the likelihood that interference will occur. Such studies therefore lack ecological validity.
- Laboratory studies tend to use nonsense syllables as the stimulus material. When meaningful material is used, interference is more difficult to demonstrate.

---

**Figure 17.11** Experimental procedure for investigating retroactive and proactive interference.
When people have to learn, for example, the response ‘bell’ to the stimulus ‘woj’, the word ‘bell’ is not actually learned in the laboratory, since it is already part of SM. What is being learned (a specific response to a specific stimulus in a specific laboratory situation) is stored in EM. SM is much more stable and structured than EM and so is much more resistant to interference effects. No amount of new information will cause someone to forget the things they know that are stored in their SM.60

However, in support of interference theory, it is generally agreed that, if students have to study more than one subject in the same timeframe, then the subjects should be as dissimilar as possible.

Motivated-forgetting theory (repression)

According to Freud, forgetting is motivated rather than the result of a failure to learn or other processes.70 Memories that are likely to induce guilt, embarrassment, shame or anxiety are actively, but unconsciously, pushed out of consciousness as a form of ego defence (see Chapters 15, 19 and 61): ‘The essence of repression lies simply in turning something away, and keeping it at a distance, from the conscious …’71

Unconscious or repressed memories are exceedingly difficult to retrieve (they are inaccessible) but remain available (‘in storage’). They continue to exert a great influence over us, even though we have no awareness of them.

Evidence for repression

Clinical evidence

It is widely accepted that repression plays a crucial role in different types of psychogenic (or functional) amnesia, such as fugue and multiple personality disorder (or dissociative identity disorder) (see Chapter 40 and Gross).72 These disorders involve a loss of memory associated with a traumatic experience (as opposed to brain injury or surgery). A relatively common form of psychogenic amnesia is event-specific amnesia: loss of memory for a fairly specific period of time. For instance, some violent criminals claim they cannot remember carrying out their crimes. Even when we have ruled out both malingering and the effects of intoxication at the time the crime was committed, there is still a substantial number of criminals whose memories of their crimes seem to have been repressed.73 This is especially likely when the victim is a close relative or lover of the murderer and killed in a crime of passion.74

Ian Brady, convicted along with Myra Hindley of the ‘Moors Murders’, repressed memories of his hideous crimes for many years before finally remembering where he had buried his victims.75 However, in a study of children who had seen a parent killed, none showed evidence of repression; on the contrary, the experience tended to be recalled all too frequently.76 This, and the observation that psychogenic amnesia can disappear as suddenly as it appeared, are difficult for motivated-forgetting theory to explain.

Parkin also cites evidence that repressive mechanisms may play a beneficial role in enabling people with post-traumatic stress disorder to adjust.71 For example, survivors of the Holocaust who were judged to be better adjusted were significantly less able to recall their dreams when woken from rapid eye movement (REM) (dream) sleep (see Chapter 10) than less well-adjusted survivors.77

However, ‘repression’ does not necessarily imply a strictly Freudian interpretation. When the concept is considered more broadly than Freud intended – that is, in the general sense that our memory systems can in some way block particular forms of memory – it deserves to be taken seriously.76 This is also the view taken by the British Psychological Society on ‘recovered memories’.78 Similarly, although traumatic experiences can undoubtedly produce memory disturbances, there is greater doubt as to whether Freud’s explanation is the best one.79

Experimental evidence

Levinger and Clark tested Freud’s repression hypothesis (Box 17.10).80

However, other studies show that, although highly arousing words tend to be recalled poorly when tested immediately, the effect reverses after a delay.81 If the words are being repressed, this should not happen (they should stay repressed), suggesting that arousal was the crucial factor.

Parkin et al. replicated the original study but added a delayed recall condition: participants were asked to recall their associations 7 days after the original test.82 The results supported Eysenck and Wilson’s interpretation – higher arousal levels inhibit immediate recall but increase longer-term recall. In a later replication, Bradley and Baddeley...
used an immediate and a 28-day delayed condition. They found clear support for the arousal hypothesis. But later research has not always supported the arousal interpretation, and the question of emotional inhibition remains open.

Recovered memories and the false-memory debate

Since the early 1990s, considerable publicity has been given to court cases in the USA, where parents are being sued for damages by their teenage or adult children who accuse them of child sexual abuse (CSA). Such abuse has been remembered during the course of psychotherapy. It is assumed that these recovered memories (RMs) had been repressed since the alleged CSA happened and that the safety and support provided by the therapist allows the memories to become conscious many years later.

However, accused parents, and retrakters (people who had recovered memories of CSA, accused their parents and then later withdrew the accusations) have also sued therapists and hospitals for implanting false memories (FMs) in their clients’ minds. The False Memory Syndrome Foundation was set up in the USA in 1992, and in 1993 the British False Memory Society was founded, with 1000 families currently on its books. Freud is regarded by many to be at least partly responsible for the phenomenon of false-memory syndrome (FMS).

This brief account of the FM debate raises several, interrelated issues, spanning the psychology of memory and forgetting, the nature of psychotherapy (in particular, Freudian psychoanalysis) and the ethics of psychotherapy in general. The FM debate has caused division among psychologists, as well as between psychologists and psychiatrists. Two key questions are: (i) do RMs exist and (ii) do FMs exist?

Do recovered memories exist?

The answer to this question depends very largely on how the concept of repression is understood. If these memories have been repressed, and are now retrieved from the unconscious during the course of therapy, then there must first be sound evidence for the existence of repression. This is the process that is supposed to keep recollections of the CSA hidden from the abused person in the first place, until many years later, as an adult in therapy, the unconscious is ‘unlocked’.

When discussing repression above, we saw that the strongest evidence is clinical but that this is far from conclusive. We also need to take a closer look at Freud’s view of memory (Box 17.11).

If Freud is right, then RMs can no longer be memories of actual CSA but fantasies of abuse. This reflects Freud’s rejection of the seduction theory in favour of the Oedipal theory (see Gross). According to Esterson (2000, personal communication), Freud’s theory of repression and his therapeutic methods are the basic tools of RM therapists, which makes Freud the arch-enemy of accused parents and the BFMS. But if it is pointed out that RM therapists have misunderstood Freud’s theory of repression and the nature of childhood memories, then this also seems to play into the hands of Freud’s accusers. In other words, if memories are essentially constructed rather than ‘discovered’ or ‘recovered’ (or ‘unearthed’, to use an archaeological analogy that Freud himself used), it becomes easier to understand how FMS occurs: vulnerable patients can easily be ‘persuaded’ that a constructed memory (a fantasy that CSA took place) is, in fact, an objectively true, historically verifiable event (the CSA actually happened).

In defence of Freud, Ofshe (cited in Jaroff) contends that RM therapists have invented a mental mechanism (‘robust’ repression) that supposedly causes a child’s awareness of sexual abuse to be driven entirely from consciousness. According to Loftus:

If repression is the avoidance in your conscious awareness of unpleasant experiences that come back to you, yes, I believe in

---

**Box 17.11 Freud and screen memories**

According to Mollon, it is sometimes asserted that Freud believed that the events of a person’s life are all recorded accurately somewhere in the mind, like video-recordings. They are supposedly preserved in their original form, available but made inaccessible by repression.

However, in a paper on ‘screen memories’, Freud argued that memories, especially of events of long ago, may be constructed like dreams. A screen memory is a memory that is apparently emotionally insignificant but is actually a substitute for a more troubling memory with which it has become associated. But he argued that the distinction between screen memories and other memories from childhood is unclear:

> It may indeed be questioned whether we have any memories at all from our childhood: memories relating to our childhood may be all that we possess. Our childhood memories show us our earliest years not as they were but as they appeared at the later periods when the memories were aroused. In these periods of arousal, the childhood memories did not, as people are accustomed to say, emerge; they were found at that time. And a number of motives, with no concern for historical accuracy, had a part in forming them, as well as in the selection of the memories themselves.

Thus, Freud argued that memories of childhood may not be what they seem. The subjective sense of remembering does not mean that the memory is literally true. Memories are like dreams or works of fiction, constructed out of psychodynamic conflict, serving wish-fulfilment and self-deception. True memories of childhood may simply be unobtainable. Our apparent memories may be fabrications created later.
repression. But if it is a blocking out of an endless stream of traumas that occur over and over that leave a person with absolutely no awareness that these things happen … and re-emerge decades later in some reliable form, I don’t see any evidence for it. It flies in the face of everything we know about memory.89

Many practising psychotherapists would agree with Loftus.

A report published in the British Journal of Psychiatry distinguishes between (i) CSA that is reported in childhood or kept secret although unforgotten and (ii) RMs of CSA, previously completely forgotten, that emerge in adulthood during therapy, usually in women in their thirties or forties.88 For some patients, RMs can escalate into FMS, in which a person’s identity comes to centre around the:

... memory of a traumatic experience which is objectively false but in which the person strongly believes... The individual avoids confrontation with any evidence that might challenge the memory ... 88

Brandon et al. summarize the findings of studies that have compared these two kinds of CSA:

- About 90 per cent of patients with RM are women, while in documented abuse cases the sex ratio is close to 50:50.
- Although only 3 per cent of accusations of RM are made against stepfathers, stepfathers are much more likely to be involved in documented childhood cases.
- Although documented abuse usually involves older children and adolescents, people with RM recall abuse before the age of 4 years or even in infancy.

Do false memories exist?

According to the 1995 British Psychological Society (BPS) report on RMs, CSA that is alleged to have occurred before 4 years of age and that does not continue beyond that age might not be retrievable in adulthood in a narrative form (describable in words).78 Very early memories are implicit rather than explicit, and are reflected in behaviour, outside conscious awareness. This means that we do not need the concept of repression in order to explain the ‘forgetting’ of childhood experiences, but it also implies that some RMs could be false (or at the very least inaccurate).

In a survey of 810 chartered psychologists, about 90 per cent believed that RMs are sometimes or usually ‘essentially correct’, a negligible number believed they are always correct, about 66 per cent believed they are possible, and over 14 per cent believed that one of their own clients had experienced FMs.78

CONCLUSIONS

The fact that FMs can be created does not mean that all RMs are false.89 The BPS has published a draft set of new guidelines for psychologists working with clients in contexts in which issues related to RMs may arise. The preamble states that:

... there can be no doubt for psychologists of the existence of ... [CSA] as a serious social and individual problem with long-lasting effects. In addition, there can be little doubt that at least some recovered memories of CSA are recollections of historical events. However, there is a genuine cause for concern that some interventions may foster in clients false beliefs concerning CSA or can lead them to develop illusory memories.90

KEY POINTS

- Memory can be defined as the retention of learning or experience. Learning and memory are interdependent processes.
- Ebbinghaus began the systematic study of memory, using nonsense syllables. He showed that memory declined very rapidly at first and then levelled off.
- Memory is now studied largely from an information-processing approach, which focuses on registration/encoding, storage and retrieval. Storage corresponds to availability, retrieval to accessibility.
- Techniques for measuring memory include testing recognition, recall (serial or free), paired-associates recall and the memory-span procedure.
- James’s distinction between primary and secondary memory corresponds to that between STM and LTM. Sensory memory is modality-specific.
- The limited capacity of STM can be increased by chunking, which draws on LTM to encode new information in a meaningful way. Rehearsal is a way of holding information in STM almost indefinitely, and the primary code used by STM is acoustic. But semantic and visual coding are also used.
- LTM probably has an unlimited capacity, and information is stored in a relatively permanent way. Coding is mainly semantic, but information may also be coded visually, acoustically and in other ways.
- Atkinson and Shiffrin’s MSM sees sensory memory, STM and LTM as permanent structural components of the memory system. Rehearsal is a control process that acts as a buffer between sensory memory and LTM, and helps the transfer of information to LTM.
- Craik and Watkins’ distinction between maintenance and elaborative rehearsal implies that it is not the amount but the kind of rehearsal or processing that matters.
- According to Craik and Lockhart’s LOP model, memory is a by-product of perceptual analysis, such that STM and LTM are the consequences of the operation of control processes. The more deeply information is processed, the more likely it is to be retained.
- The primacy effect reflects recall from LTM, while the recency effect reflects recall from STM. Together they comprise the serial position effect.
- Studies of brain-damaged patients with amnesia appear to support the STM–LTM distinction. While STM continues to function fairly normally, certain aspects of LTM functioning are impaired.
- LTM is not unitary but comprises semantic, episodic and procedural memory. Autobiographical memory and flashbulb memories are two
kinds of episodic memory. An overlapping distinction is that between procedural and declarative memory/learning.

- Baddeley and Hitch’s working-memory (WM) model rejected the MSM view of STM as unitary. Instead, STM is seen as comprising a central executive, which controls the activities of the phonological loop (inner voice) and visuospatial scratchpad (inner eye).
- Chunking is a means of organizing information, making it easier both to store and to retrieve.
- Bartlett introduced the concept of schema to help explain how we remember meaningful material, such as stories. Reconstructive memory uses schemas (schemata) to interpret new information, making the world more predictable.
- Decay/trace decay theory attempts to explain why forgetting increases over time. STM forgetting is due to disruption of the active trace, and decay-through-disuse explains LTM forgetting.
- Displacement theory is supported by data from Waugh and Norman’s serial probe task. However, displacement may not be distinct from decay.
- According to retrieval-failure theory, memories cannot be recalled because the correct retrieval cues are missing. This is demonstrated by the tip-of-the-tongue phenomenon and the provision of category names. Unlike decay theory, retrieval-failure theory can explain our ability to recall different items on different occasions.
- Cue-dependent forgetting comprises context-dependent and state-dependent forgetting, which refer to external and internal cues, respectively.
- According to interference theory, forgetting is influenced more by what we do before/after learning than by the mere passage of time. Retroactive interference/inhibition works backwards in time, while proactive interference/inhibition works forwards in time.
- According to Freud’s motivated-forgetting theory, unacceptable memories are made inaccessible through repression.
- Although cases of psychogenic amnesia are consistent with Freud’s theory, a strictly Freudian interpretation may not be necessary and experimental support for the repression hypothesis is inconclusive.
- There is currently great controversy over recovered memories (RMs) of CSA and false-memory syndrome (FMS). Some RM therapists are accused of implanting false memories of CSA into clients, while some clients accuse their parents of the abuse.
- Most psychologists and psychiatrists seem to accept the possibility of FMs, but this does not mean that all RMs of CSA are false.

Language and thought

Richard Gross

INTRODUCTION

The relationship between language and thought is one of the most fascinating and complex issues within psychology and has been debated by philosophers for over 2000 years. Our thinking often takes the form of imagery, and our thoughts and feelings are often expressed unconsciously through gestures and facial expressions. Artists ‘think’ non-linguistically. Knowing what we want to say but being unable to ‘put it into words’ is one of several examples of thought taking place without language.1

However, the exact relationship between language and thought has been the subject of much debate among philosophers and psychologists. Views fall into four main categories:

- **Thought is dependent on, or caused by, language:** this view is taken by people working in a variety of disciplines, including psychology, sociology, linguistics and anthropology. Sapir (a linguist and anthropologist) and Whorf (a linguist) were both interested in comparing languages, which they saw as a major feature of a culture. Language is shared by all members of a culture, or subcultures within it, and this makes it a determining influence on how individuals think. Bernstein (a sociologist) focused on subcultural (social class) differences in language codes, which he saw as a major influence on intelligence and educational attainment. Social constructionists (e.g. Gergen) regard language as providing a basis for all our thought, a system of categories for dividing up experience and giving it meaning (see Gross2).

- **Language is dependent on, and reflects, thought:** probably the most extreme version of this view is Piaget’s, according to whom language reflects the individual’s level of cognitive development (see Chapter 8).

- **Thought and language are initially quite separate activities:** they then come together and interact at a later point in development (about age 2 years). This view is associated with the Russian psychologist Vygotsky (see Chapter 8).

- **Language and thought are one and the same:** this rather extreme view is associated mainly with Watson, the founder of behaviourism.

The focus of this chapter is the various versions of the first of these viewpoints.

LANGUAGE AND THOUGHT ARE THE SAME

Watson’s ‘peripheralist’ approach

The earliest psychological theory of the relationship between language and thought was proposed by Watson.3 In his view, thought processes are really no more than the sensations produced by tiny movements of the speech organs too small to produce audible sounds. Essentially, then, thought is talking to oneself very quietly. Part of Watson’s rejection of ‘mind’ was his denial of mentalistic concepts such as ‘thought’ (see Chapters 9 and 14) and hence his reduction of it to ‘silent speech’.

Watson’s theory is called **peripherialism**, because he regards ‘thinking’ as occurring peripherally in the larynx rather than centrally in the brain. Movements of the larynx do occur when ‘thought’ is taking place, but this indicates only that such movements may accompany thinking, not that the movements are thoughts or are necessary for thinking to occur.

Smith et al. attempted to test Watson’s theory by injecting Smith himself with curare, a drug that causes total paralysis of the skeletal muscles without affecting consciousness.4 The muscles of the speech organs and the respiratory system are paralysed, and Smith’s breathing had to be maintained artificially. When the drug’s effects had worn off, Smith was able to report on his thoughts and perceptions during the paralysis.

Additionally, Furth has shown that people who are born deaf and mute and who do not learn sign language can think in much the same way as hearing and speaking people.5 For Watson, deaf and mute individuals should be incapable of thought, because of the absence of movement in the speech organs.
THOUGHT IS DEPENDENT ON, OR CAUSED BY, LANGUAGE

Bruner has argued that language is essential if thought and knowledge are not to be limited to what can be learned through our actions (the enactive mode of representation) or images (the iconic mode).6 If the symbolic mode (going beyond the immediate context) is to develop, then language is crucial (see Gross3).

Social constructionists (e.g. Gergen4) have argued that our ways of understanding the world derive from other people (past and present), rather than from objective reality. We are born into a world where the conceptual frameworks and categories used by people in our culture already exist. Indeed, these frameworks and categories are an essential part of our culture, since they provide meaning, a way of structuring experience of both ourselves and the world of other people. Language is of fundamental importance in this process. This view has much in common with the ‘strong’ version of the linguistic relativity hypothesis (LRH), the most extensively researched of the theories arguing that thought is dependent on, or caused by, language.

The linguistic relativity hypothesis

According to the philosopher Wittgenstein, ‘The limits of my language mean the limits of my world.’9 By this, he meant that people can think and understand the world only through language; and if a particular language does not possess certain ideas or concepts, then these ideas and concepts could not exist for the native speakers of that language.

The view that language determines how we think about objects and events, or even what we think (our ideas, thoughts and perceptions), can be traced to the writings of Sapir10 and Whorf,11 a student of Sapir. Their perspective is often called the Sapir–Whorf linguistic relativity hypothesis (LRH) or, in acknowledgement of the greater contribution made by Whorf, the Whorfian hypothesis. For Whorf:

We dissect nature along the lines laid down by our native languages. The categories and types that we isolate from the world of phenomena we do not find there because they stare every observer in the face; on the contrary, the world is presented in a kaleidoscopic flux of impressions that has to be organised by our minds – and this means largely by the linguistic systems in our minds. We cut nature up, organise it into concepts and ascribe significance as we do, largely because we are parties to an agreement to organise it this way – an agreement that holds throughout our speech community and is codified in patterns of our language.11

According to Whorf’s linguistic determinism, language determines our concepts, and we can think only through the use of concepts. So, acquiring a language involves acquiring a ‘world view’ (or Weltanschauung). People who speak different languages have different world views (hence linguistic ‘relativity’).

Whorf’s evidence

Whorf compared standard average European (SAE) languages, such as English, French and Italian (Indo-European), with Native American languages, particularly Hopi. While in English we have a single word for snow, the Inuit Eskimos have approximately 20 words (including one for ‘fluffy snow’, one for ‘drifting snow’, another for ‘packed snow’ and so on). The Hopi Indians have only one word for ‘insect’, ‘aeroplane’ and ‘pilot’, and the Zuni Indians do not distinguish verbally between yellow and orange.

Whorf also saw a language’s grammar as determining an individual’s thought and perception. In the Hopi language, for example, no distinction is made between past, present and future, which, compared with English, makes it a ‘timeless language’. In European languages, ‘time’ is treated as an objective entity, with a clear demarcation between past, present and future. Although the Hopi language recognizes duration, Hopis talk about time only as it appears subjectively to the observer. For example, rather than saying ‘I stayed for ten days’, Hopis say ‘I stayed until the tenth day’ or ‘I left on the tenth day’.

In English, nouns denote objects and events, and verbs denote actions. But in the Hopi language, ‘lightning’, ‘wave’, ‘flame’, ‘meteors’, ‘puff of smoke’ and ‘pulsation’ are all verbs, since events of necessarily brief duration must be verbs. As a result, a Hopi would say ‘it lightninged’, ‘it smoked’ and ‘it flamed’.

Greene asks us to imagine a Hopi linguist applying a Whorfian analysis to English.12 Would the linguist think that English speakers have ‘primitive’ beliefs, that ships are really female or that mountains have feet, or that ‘driving a car’, ‘driving off in golf’ and ‘driving a hard bargain’ all involve the same activity? Of course not. (See ‘An evaluation of the linguistic relativity hypothesis’ below.)

Testing the linguistic relativity hypothesis

Miller and McNeill distinguish between three different versions of the LRH, all of which are consistent with the hypothesis but vary in the strength of claim they make:13

- The strong version claims that language determines thought.
- The weak version claims that language affects perception.
- The weakest version claims that language influences memory: information that is described more easily in a particular language will be better remembered than information that is more difficult to describe.

The questions and criticisms that we considered above relate mainly to the strong version of the hypothesis, but almost all the research has focused on the weak and weakest versions. One of the few attempts to test the strong version was a study by Carroll and Casagrande (Box 18.1).14

Attempts at testing the ‘weak’ and ‘weakest’ versions of the LRH have typically involved the perception and memory of colour. The Jalé from New Guinea have terms...
in distinguishing orange and yellow fell midway between that of monolingual Zuni and monolingual English speakers. This suggests that the two languages do not determine two different sets of conflicting perceptions but rather determine two sets of labels for essentially the same colour perceptions. Language serves to draw attention to differences in the environment and acts as a label to help store these differences in memory. Sometimes the label we apply to what we see may distort our recall of what was seen, since the label determines how we code our experiences into memory storage (Box 18.2; see also Chapter 17).

So, although there is very little direct evidence to support the strong form of the LRH, there is rather more support for the weaker versions. Language merely predisposes people to think or perceive in certain ways or about certain things. However, Brown and Lenneberg’s results, and those of other researchers using a similar methodology, have been challenged in a way that throws doubt even on the weaker versions.

### Perceiving focal colours

Berlin and Kay used a chart with an array of 329 small coloured chips, comprising almost all the hues that the human eye can discriminate. They asked native speakers of 20 languages other than English (i) to trace the boundaries of each of their native language’s basic colour terms and (ii) to point to the chip that was the best example of each basic colour term. A basic or focal colour was defined by a list of linguistic criteria, including the following:

- A term should consist of only a single unit of meaning (e.g. ‘red’ rather than ‘dark red’).
- A term should name only colours and not objects (e.g. ‘purple’ rather than ‘wine’).

As expected from anthropological research, there was considerable variation in the placement of boundaries; but the choice of best examples was surprisingly similar. The largest clusters were for black and white and red, for which all the 20 languages have colour terms, followed by 19 for green, 18 for yellow, 16 for blue, 15 for brown and purple, 14 for grey, and 11 for pink and orange. Berlin and Kay concluded that ‘colour categorization is not random and the foci of basic colour terms are similar in all languages.’

So, although cultures may differ in the number of basic colour terms they use, all cultures draw their focal terms from only 11 colours: black, white, red, green, yellow, blue, brown, purple, pink, orange and grey. Moreover, the colour terms emerge in a particular sequence in the history of languages (Figure 18.2).

For cultures with only two colours, these will always be black and white, whereas in cultures with three colours, these will always be black, white and red. As Newstead has observed:

This, then, gives a rather different perspective on the use of colour terms. It had been assumed that verbal labels were chosen more or less arbitrarily, and that those chosen influenced
Thought is dependent on, or caused by, language

Part 2: Developmental, behavioural and sociocultural psychiatry

Two separate groups of participants were given identical stimulus figures but two different sets of labels. After a period of time, both groups were asked to reproduce the figures. The drawings of both groups were distorted in comparison with the original stimulus according to which label had been presented (Figure 18.1).

By this, Heider (sometimes referred to as Rosch, her married name) means that her data are explained better in terms of physiological factors underlying colour vision than in terms of linguistic factors. Thus, people are sensitive to focal colours because the human visual system processes reality in a certain way. Indeed, evidence suggests that focal colours can be discriminated before any verbal labels for them have been learned. Bornstein, for example, has argued that preverbal infants categorize the visible spectrum in a similar way to adults, namely on the basis of the relatively discrete hues of blue, green, yellow and red.

However, Kay (cited in Ross) denies that there is any evidence to support a physiological explanation. In addition, a study of another New Guinea people, the Berinmo, casts doubt on Heider's interpretation and seems to support the weakest and weak versions of the LRH (Box 18.4).
An evaluation of the linguistic relativity hypothesis

Berry et al.28 and Jackendoff29 have argued that Whorf’s evidence was anecdotal rather than empirical and that he exaggerated the differences between Hopi and other languages. Moreover, far from having ‘over 20’ words for ‘snow’, the Inuit Eskimos have relatively few such words30 and no more than do English speakers.30 According to Pagel, Whorf simply got his facts wrong.31

There is an important difference between a language’s grammar and our perceptual experience. The fact that Hopi can be translated into English (and vice versa) implies a universally shared knowledge of the world that is independent of the particular language in which it is expressed.31

A crucial question that Whorf seems to have overlooked is why Eskimos have so many names for snow (if, indeed, they do) and SAE languages so few. One answer is that the more significant an experience or some feature of our environment is for us, the greater the number of ways of expressing it in the language. In other words, while Whorf argued that language structures the Eskimo’s world, it could equally well be argued that the Eskimos’ language develops as a result of their different perception of the world.32

According to Solso:

The development of specific language codes ... is dependent on cultural needs; the learning of these codes by members of a language group also involves the learning of significant values of the culture, some of which must be related to survival ... 33

Solso’s view is supported by the fact that English-speaking skiers learn to discriminate between varied snow conditions and invent a vocabulary to describe these differ-
ences. Such terms include ‘sticky snow’, ‘powder’, ‘corn’ and ‘boilerplate’ (or ice).34 Similarly, the Hanunoo people of the Philippines have modified their language in response to environmental conditions. For example, women have developed a more complex vocabulary for shades of blue to distinguish the colours of dyed textiles that have been introduced into their society.35

It is now widely accepted that Whorf overestimated the importance of language differences. As Berry et al. have observed:

Language as an instrument for thinking has many cross-culturally variant properties. As humans, we may not all be sharing the same thoughts, but our respective languages do not seem to predestine us to different kinds of thinking.28

What language may do, however, is affect the ease of information processing. Newstead,20 for example, describes research conducted by Hunt and Agnoli that supports this view.36 The English word ‘seven’ has two syllables, whereas the equivalent French word (‘sept’) has only one. The English word ‘eleven’ has three syllables, whereas the French word ‘onze’ has one. Hunt and Agnoli argue that, when a name is shorter, information is processed more quickly, and so French speakers would have an advantage over English speakers when performing mental arithmetic involving these numbers, at least in processing terms.

According to Price and Crapo, the study of semantic domains (e.g. colour naming) helps us to discover what is important in the daily lives of different cultural groups and demonstrates the changing cultural history of a society.35 Similarly, Kay (cited in Ross25) claims that his research into focal colours has been interpreted by some as undermining the LRH as a whole. But he and Berlin were concerned with one restricted domain, namely colour. Even if it is accepted that the colour perception research does not support the LRH, there is no reason to rule it out in relation to other domains (Box 18.5).

Although this shows that the LRH may be correct:

... it is unlikely that the various languages of the world are so different from one another, in underlying conceptual structure, that the ways their speakers think are incommensurable.25

The linguistic relativity hypothesis, social class and race

Social-class differences in language and thought

Stones gives examples of imaginary conversations on a bus between a mother and child:37

Box 18.5 ‘There’s a fly to the north of your nose’

Ross cites a study of speakers of Guugu Yimithirr (a language of Australia).25 Like several world languages, Guugu Yimithirr lacks subjective terms equivalent to ‘left’ and ‘right’ and instead uses absolute directions akin to ‘north’ and ‘south’. In such a language, you might say ‘There’s a fly to the north of your nose.’

If Guugu speakers are presented with an arrow pointing to their left, they will later draw it pointing to the left only if they are still facing in the direction in which they saw the arrow originally. If they turn round, they will draw the arrow pointing to the right – that is, in the same absolute direction as the original arrow.

This illustrates strikingly how linguistic categories can mould thought and behaviour.25

- Mother: Hold on tight.
- Child: Why?
- Mother: Hold on tight.
- Child: Why?
- Mother: You’ll fall.
- Child: Why?
- Mother: I told you to hold on tight, didn’t I?
- Mother: Hold on tight, darling.
- Child: Why?
- Mother: If you don’t you’ll be thrown forward and you’ll fall.
- Child: Why?
- Mother: Because if the bus suddenly stops, you’ll jerk forward on to the seat in front.
- Child: Why?
- Mother: Now, darling, hold on tightly and don’t make such a fuss.

Restricted and elaborated codes

Bernstein was interested in language’s role as a social, rather than an individual, phenomenon, especially its relation to cultural deprivation.38 He showed that there were generally no differences between the verbal and non-verbal intelligence test performance of boys from public schools and boys from lower-working-class homes. But the latter often showed considerable differences, with non-verbal performance sometimes being as much as 26 points better than verbal performance. Bernstein argued that working-class and middle-class children speak two different kinds (or codes) of language, which he called restricted code and elaborated code, respectively (Table 18.1).

Bernstein saw the relationship between potential and actual intelligence as being mediated through language; consequently, the lack of an elaborated code would prevent working-class children from developing their full intellectual potential. The different language codes underlie the whole pattern of relationships (to objects and people) experienced
by members of different classes, as well as the patterns of learning that their children bring with them to school.

In support of Bernstein’s views, Hess and Shipman found that social-class differences influence children’s intellectual development. In particular, there was a lack of meaning in the mother–child communication system for low-status families. Language was used much less to convey meaning (to describe, explain, express and so on), and much more to give orders and commands to the child (see the two mother–child conversations above).

However, instead of seeing ‘restricted’ and ‘elaborated’ as distinct types of language code, they are better thought of as two ends of a continuum. Also, the terms ‘restricted’ and ‘elaborated’ imply a value judgement of middle-class speech as being superior to working-class speech (closer to ‘standard’ or ‘the Queen’s’ English). The lack of objectivity makes this judgement difficult to defend.

**Black English**

A version of English spoken by segments of the African-American community is called ‘black English’. When asked to repeat the sentence ‘I asked him if he did it, and he said he didn’t do it’, one 5-year-old girl repeated the sentence like this: ‘I asks him if he did it, and he says he didn’t did it, but I knows he did’. Bernstein argued that black English is a restricted code and that this makes the thinking of black English speakers less logical than that of their white elaborated-code counterparts.

One major difference between black English and standard English relates to the use of verbs. In particular, black English speakers often omit the present tense copula (the verb ‘to be’). So, ‘He be gone’ indicates the standard English ‘He’s been gone for a long time’, and ‘He gone’ signifies ‘He’s just gone’. Black English is often described as ‘sub-standard’ and regarded as illogical rather than ‘non-standard’. According to Labov, black English is just one dialect of English, and speakers of both dialects are expressing the same ideas equally well.

**Black English and prejudice**

Although the grammatical rules of black English differ from those of standard English, black English possesses consistent rules that allow the expression of thoughts as complex as those permitted by standard English. Several other languages, such as Russian and Arabic, also omit the present-tense verb ‘to be’, and yet we do not describe these languages as ‘illogical’. This suggests that black dialects are considered substandard as a matter of convention or prejudice rather than because they are poorer vehicles for expressing meaning and logical thinking. However, because the structure of black English does differ in important ways from standard English, and since intelligence tests are written in standard English, black English speakers are at a linguistic disadvantage (as, indeed, are white working-class children: see Gross).

**Language in context**

Labov also showed that the social situation can be a powerful determinant of verbal behaviour. A young boy called Leon was shown a toy by a white interviewer and asked to tell him everything he could about it. Leon said very little and was silent for much of the time, including when a black interviewer took over. However, when Leon sat on the floor and shared a packet of crisps with his best friend and with the same black interviewer introducing topics in a local black dialect, Leon became a lively conversationalist. Had he been assessed with the white or black interviewers on their own, Leon might have been labelled ‘non-verbal’ or ‘linguistically retarded’.

---

Black children may actually be bilingual. In their home environments, the school playground and their neighbourhoods, they speak the accepted vernacular. In the classroom, however, and when talking to people in authority, they may adopt standard English, with which they are unfamiliar; this results in short sentences, simple grammar and strange intonation. Out of school, their natural language is easy, fluent, creative and often gifted. So, although black English is certainly non-standard, it is another language with its own grammar, which is certainly not standard (Box 18.6).

Box 18.6 ‘Ebonics’: an ongoing debate

‘Ebonics’ is a fusion of the words ‘ebony’ and ‘phonics’ and was coined in 1975 as an alternative for the term ‘black English’. In 1996, Ebonics (or African–American vernacular English, AAVE) was officially recognized by the Oakland public school board in California, and schools were ordered to teach 28000 black children in their ‘own tongue’. The board claimed that Ebonics was a separate language, genetically rooted in the West African and Niger–Congo language system, rather than a dialect of standard American English.44,45

In early 1997, the school board edited its statement so that the word ‘genetically’ referred to linguists’ use of the word for the roots of a language rather than to a gene pool. They also indicated that it was not the intent to teach in Ebonics, but rather to have teachers use the vernacular to be able to understand their children.46

Both conservatives and liberals in America claim that the decision to require Ebonics to be taught would be ‘political correctness run amok’.47 Educationalists such as Zinberg disagree. In her view, many students are ‘... bewildered, then angered and finally alienated from the schools where their language and self-esteem are belittled by a seemingly insensitive system’.48

Although regional dialects in the USA are diverging, there is no evidence of convergence between black and white vernaculars.49 By contrast, black and white British people still speak the same language, partly because there is no segregation in housing in Britain as there is in the USA (Labov, cited in Hawkes48).

Language IS dependent on, and reflects, thought

According to Piaget, children begin life with some understanding of the world and try to find linguistic ways of expressing their knowledge.49 As language develops, it ‘maps’ on to previously acquired cognitive structures, and so language is dependent upon thought.50 For example, a child should begin talking about objects that are not present in his or her immediate surroundings only after object permanence has developed (i.e. understanding that things continue to exist even when they are not being perceived). Similarly, children who could conserve liquid quantity (understanding that, when liquid is poured from one container into a taller, thinner container, the quantity of liquid remains the same) understood the meaning of phrases and words such as ‘as much as’, ‘bigger’ and ‘more’. However, children who could not conserve did not improve their performance of the correct use of these words after receiving linguistic training.51

In Piaget’s view, children can be taught words but they will not understand them until they have mastered certain intellectual skills during the process of cognitive growth. So, language can exist without thought, but only in the sense that a parrot can ‘speak’. Thought, then, is a necessary forerunner to language if language is to be used properly.

Contrary to Piaget’s view that thought structures language, Luria and Yudovich suggest that language plays a central role in cognitive development (Box 18.7).52

THOUGHT AND LANGUAGE AS INITIALLY SEPARATE ACTIVITIES

For Vygotsky, language is by far the most important psychological tool the human species possesses, capable of trans-
forming how we think about the world and altering ‘the entire flow and structure of mental functions’. So, while for Piaget thought is prior to language (the development of representational thinking enables the child to use words), Vygotsky sees language as prior to thought (developing the ability to use words makes representational thought possible).

According to Vygotsky, language and thought begin as separate and independent activities. Early on, thinking occurs without language (consisting primarily of images) and language occurs without thought (as when babies cry or make other sounds to express feelings, attract attention or fulfil some other social aim). But at about age 2 years, prelinguistic thought and pre-intellectual language ‘… meet and join to initiate a new kind of behaviour [in which] thought becomes verbal and speech rational’ (Figure 18.3). Vygotsky believed that between the ages of 2 years and 7 years, language performs two functions:

- An internal function, which enables internal thought to be monitored and directed
- An external function, which enables the results of thinking to be communicated to others.

However, children cannot distinguish between the two functions and, as a result, their speech is egocentric (Box 18.8): they talk out loud about their plans and actions, and they can neither think privately nor communicate publicly to others. Instead, they are caught somewhere between the two and cannot distinguish between ‘speech for self’ (what Piaget calls autistic speech) and ‘speech for others’ (socialized speech).

Vygotsky believed that around age 7 years (when children typically enter Piaget’s concrete operational stage of cognitive development: see Chapter 8), overt language begins to be restricted to communication, while the thought function of language becomes internalized as internal speech (verbal thought). For Piaget, egocentric speech is a kind of ‘running commentary’ on the child’s behaviour. At about age 7 years, it simply fades away and is replaced by socialized (or communicative) speech.

**An evaluation of Vygotsky’s position**

A considerable body of research into inner speech has largely supported Vygotsky’s account, demonstrating how closely language and thought become intertwined during development.

Egocentric speech commonly accompanies problem-solving, even in young children. But with increasing age, egocentric speech becomes less and less audible, eventually becoming silent. For example, Bivens and Berk observed 6- and 7-year-olds as they worked on maths problems. This was repeated 1 and 2 years later. The overall incidence of egocentric speech was extremely high and remained high over the 3 years of observation, but task-relevant speech increased greatly and the nature of the speech changed: there was more inaudible muttering and lip movements. These changes were paralleled by the children’s greater ability to inhibit extraneous movements and restlessness and to pay closer attention to the task. This is consistent with Vygotsky’s belief that inner speech is used increasingly to aid the child’s self-regulation/self-control (Box 18.9).
Both inner speech and egocentric speech differ from speech for others in that they do not have to satisfy grammatical conventions. Thus, both are abbreviated, incomplete, and concerned more with the essential meaning rather than how the meaning is expressed. For Vygotsky, inner speech is a ‘dynamic, shifting and unstable thing which “flutters” between word and thought’ (see Figure 18.3).

Overt speech can sometimes resemble inner speech in its abbreviated nature, long after egocentric speech has been replaced. For example, people who know each other well may talk in an abbreviated form that they would not use with strangers. Understanding occurs because, the more familiar we are with others, and the more experiences we have in common, the less explicit our speech has to be. ‘Coffee?’, for example, asked with a rising inflection and in a particular context, would be interpreted as ‘Would you like a cup of coffee?’ This is similar to how adults interpret the holophrastic speech of young children. In Bernstein’s terms, we use restricted code when talking in familiar surroundings to familiar others, whose view of the world we assume is similar to our own.

**CONCLUSIONS**

Although there are many examples indicating that thought can occur without language, the exact relationship between thought and language remains unclear. What is certain, however, is that no one account of this relationship is true, with all others being false; several theoretical perspectives can claim some support from the experimental literature. However, since language represents such a central feature of culture, both shaping it and being shaped by it, any theory that fails to take account of cultural factors is likely to be inadequate.

**Box 18.9 Language and self-regulation**

According to Luria, a colleague and supporter of Vygotsky, there are three stages in children’s ability to use language for directing their behaviour.57

1. Up to about age 3 years, another person’s verbal instructions can trigger but not inhibit an action. For example, given a rubber bulb to squeeze, children will correctly squeeze in response to ‘Squeeze!’ but ‘Stop!’ will simply make them squeeze again.

2. Around 4–5 years, the child responds to instructions in an impulsive way: told to squeeze when light comes on, the child squeezes repeatedly. The child is responding more to the energizing quality of speech than to its content (the louder the instructions, the more often the child squeezes).

3. After about 5 years, the child responds to the contents of speech and becomes capable of using it to inhibit or activate their behaviour.

Both inner speech and egocentric speech differ from speech for others in that they do not have to satisfy grammatical conventions. Thus, both are abbreviated, incomplete, and concerned more with the essential meaning rather than how the meaning is expressed. For Vygotsky, inner speech is a ‘dynamic, shifting and unstable thing which “flutters” between word and thought’ (see Figure 18.3).

Overt speech can sometimes resemble inner speech in its abbreviated nature, long after egocentric speech has been replaced. For example, people who know each other well may talk in an abbreviated form that they would not use with strangers. Understanding occurs because, the more familiar we are with others, and the more experiences we have in common, the less explicit our speech has to be. ‘Coffee?’ , for example, asked with a rising inflection and in a particular context, would be interpreted as ‘Would you like a cup of coffee?’ This is similar to how adults interpret the holophrastic speech of young children. In Bernstein’s terms, we use restricted code when talking in familiar surroundings to familiar others, whose view of the world we assume is similar to our own.

**KEY POINTS**

- According to Watson’s peripheralism, thought is no more than sensations produced by tiny movements of the larynx, too small to produce audible sounds. Although these movements accompany thought, they are not necessary for thinking to occur.
- Contrary to Watson’s view, thinking can occur despite complete paralysis, and people who are born deaf and mute are also capable of thinking.
- Bruner argues that language is essential for thought and knowledge to progress beyond the enactive and iconic modes of representation to the symbolic mode.
- Social constructionists claim that conceptual frameworks and categories provide meaning within a culture, a way of structuring our experience of ourselves and the world.
- According to the Sapir–Whorf LRH, language determines how we think about objects and events, and even what we think. This is related to linguistic determinism.
- The ‘weak’ and ‘weakest’ versions of the LRH have typically been tested through perception and memory of colour. The fewer colour words there are in a language, the more difficult native speakers should find tests of colour perception and memory.
- Early studies seemed to support these two versions. But although cultures may differ in the number of basic colour terms they use, all cultures draw their colour terms from only 11 focal colours, which emerge in a particular sequence in the history of languages.
- Whorf’s evidence was anecdotal rather than empirical, and he exaggerated the differences between Hopi and other languages. Also, he mistakenly equated language’s grammar with perceptual experience. Translation between languages implies a universally shared knowledge of the world independent of any particular language.
- Bernstein claimed that working-class children speak a restricted code and middle-class children an elaborated code. The relationship between actual and potential intelligence is mediated through language, so working-class children are prevented from developing their full intellectual potential.
- Differences between standard and Black English have resulted in the latter being called substandard rather than non-standard. According to Labov, this is an expression of prejudice.
- Black children may be bilingual, using the accepted register fluently at home and with their peers, but adopting unfamiliar standard English in the classroom.
- According to Piaget, language ‘maps’ on to previously acquired cognitive structures, so that language is dependent on thought. Words can be understood only if certain intellectual skills (e.g. object permanence, conservation) have already been mastered.
- For Vygotsky, language and thought are initially separate and independent activities. At around age 2 years, pre-linguistic thought and pre-intellectual language begin to interact to form verbal thought and rational speech.
Between the ages of 2 years and 7 years, language performs both internal and external functions. The child's failure to distinguish between them results in egocentric speech. For Vygotsky, this indicates the separation of the two functions. According to both Vygotsky and Luria, language plays a vital role in self-regulation and self-control.

INTRODUCTION

The concept of personality is an everyday one. People seem to have distinct ways of behaving towards the world that are characteristic of them. Some people appear cheerful, others morose; some seem warm, others cold and distant. The concept of personality disorder is an important one in clinical practice. However, it has proved remarkably difficult for personality researchers to reach a consensus on how personality is structured, how important it is in everyday life and even what it is.

Various attempts have been made to define personality. Carver and Scheier suggested: ‘Personality is a dynamic organization, inside the person, of psychophysical systems that create a person’s characteristic patterns of behaviour, thoughts, and feelings.’ The Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) states that personality is ‘enduring patterns of perceiving, relating to, and thinking about the environment and oneself that are exhibited in a wide range of social and personal contexts.’

The central idea is that an individual’s behaviour is not driven solely by their environment but is influenced across situations by something characteristic of them personally.

There are some immediate difficulties with the idea of personality. First, there is huge disagreement about what personality is, with a range of startlingly different theories and explanations as to how it arises. Disturbingly, it is known that our subjective belief in personality is, at least in part, misleading. If we see you at a party telling jokes and ask you why, then you are likely to respond with a reason such as ‘To make people laugh’, ‘To break the ice’ or ‘Because it is a good way to get to know people’. If, on the other hand, we point out someone else at the party who is telling jokes and ask you why they are doing that, then you are much more likely to respond with a description that calls on their personality, such as ‘He’s a funny man’, ‘He’s a real extrovert’ or ‘He’s always like that’. In other words, we tend to explain our own behaviour as reasoned but attribute that of others to enduring personal characteristics consistent across situations – that is to their personality. This effect has been called the ‘fundamental attribution error’ and, more recently, the ‘correspondence bias’; it arises, in large part at least, because we have access to our own thoughts and motives but not to those of others. The tendency to see people in terms of personality is compounded by an erroneous tendency to believe that certain characteristics cluster together (e.g. warm and generous, old and wise) and our tendency to use these ‘representations’ in our dealings with others.

Approaches to the study of personality have tended to take one of two approaches, which Allport called the nomothetic approach and the idiographic approach.

Nomothetic approaches assume that everyone has the same basic elements to their personality but that they differ from each other in how strongly each of those elements are represented. So, if we believe that every human being has a sense of humour but that some people have a strong sense of humour while others have a weak sense of humour, then we are taking a nomothetic approach to personality. However, many theories of personality are not primarily nomothetic. If we believe that a person can have unique characteristics or that some people have characteristics that many others do not have, then that is an idiographic theory. It is possible to believe that some people are greedy and some are not: they are not just low on greediness – rather, they lack greediness altogether. For the latter category, measuring the greed level makes as much sense as measuring the colour of water. What makes the distinction particularly important is in our assumptions about measuring personality. Under a nomothetic approach, it is possible, at least in theory, to identify the key personality dimensions common to every person, and to measure where an individual lies on each of these dimensions using a standardized questionnaire or observation system; the information obtained will allow us to completely describe a person’s personality. With an idiographic approach, we cannot specify in advance which dimensions will be important to any individual. With a nomothetic approach to personality, each person is unique in the combination of amounts of particular personality elements they happen to have; with an idiographic approach, people differ in personality because they have different elements to their personality.

In areas where personality is an important concept, for instance in personnel selection and in clinical practice, people tend to act as though personality is made up of a
mixture of nomothetic and idiographic elements. Many personality theorists, including Allport, accept that personality is made up of both elements. Nonetheless, the distinction is a useful and helpful one in thinking about personality.

In order to illustrate some of these issues, we will first look at three different personality models and then look at some of the overall issues in personality theory. The three types of model we will look at are trait models, humanistic approaches and cognitive approaches. There are other theories that merit attention, particularly the psychoanalytical model, but we have chosen these three models because they illustrate key general issues. For the reader who wishes to look more widely at the area, there are a number of excellent textbooks that provide overviews of the field (e.g. Larsen and Buss8 and Ryckman9).

TRAIT MODELS

Trait models are perhaps the personality models that most closely resemble what might be called ‘natural’ theories of personality – the way that we see others in everyday life. They are nomothetic theories par excellence seeking to identify traits, enduring dimensions of personality shared by everyone, and then distinguishing between individuals by measuring the amounts of each of these traits that an individual has. Trait theorists make a number of general assumptions: that traits are relatively stable over time, that their levels differ among individuals, and that they influence behaviour. People are expected to have unique combinations of scores on the different dimensions. Critical to understanding trait theories is to understand that they are based on a particular statistical technique, factor analysis. The strengths and weaknesses of trait theory are ultimately derived from the strengths and weaknesses of factor analysis.

Trait theories have a long history. Hippocrates (460–377BC) was an early trait theorist. He suggested that humans have four basic humors and that the amount of each determines an individual’s personality.

One of the best known modern trait models is that of Cattell.10 Cattell assembled a very large number of questionnaire items thought to measure aspects of personality. He then administered these to large numbers of respondents. The problem was to identify common elements within this large body of items. Some items were clearly measuring the same underlying concept, so that if an individual scored highly on item A, then they would be very likely to score highly on item B – that is, their scores would be strongly correlated. Cattell used factor analysis to reduce a large number of items to a small number of overall dimensions and to identify which items best measured those overall dimensions.

Cattell came up with 16 factors. A widely used questionnaire derived from his factor analyses is called the 16PF (PF = personality factor). He also looked at personality by using ratings by observers of actual behaviour using a similar approach, and got a good overlap on 12 of the 16 factors with the questionnaire approach. He tried to use specially designed tasks as a third check, but with rather less satisfactory results.10

However, factor analysis is a modelling technique. Unlike statistical tests of significance, there is no single correct answer. In fact, there are, in theory, an almost infinite number of possible answers to the question ‘What factors underlie this dataset?’ The answer will also differ according to whether one assumes that different personality dimensions must be wholly uncorrelated or whether some degree of correlation occurs between different underlying traits.

By making different assumptions, Cattell was able to derive a smaller number of second-order factors. These can be regarded as higher-level classifications. The easiest way to understand this is by analogy. The cat Felis silvestris catus can be classified as a member of the species F. sylvestris, as a member of the genus Felis, as a Felid, as a carnivore, and so on. Each of these levels is correct, but they all address somewhat different questions.

The most studied alternative model is that of Eysenck.11,12 Eysenck also used a pool of questionnaire items. He derived two independent uncorrelated main dimensions, introversion–extroversion and neuroticism. High neuroticism scorers tend to be high in anxiety and depression (e.g. Weinstock and Whisman13) rather than necessarily attracting a neurotic-spectrum diagnosis. Later, Eysenck added a third factor, psychoticism. The name of the latter factor is unfortunate: high scorers seem to be eccentric or unsocialized rather than psychotic per se, and the label generated some controversy.8

Eysenck produced a questionnaire called the Eysenck Personality Questionnaire (EPQ),14 which measured all three items as well as including a ‘lie scale’. This was originally intended to identify people who were trying to ‘fake good’ on the questionnaire – in other words, to appear ‘better’ than they were in reality. In fact, it seems to measure social acceptability, the tendency of some respondents to questionnaires to give socially acceptable answers rather than seeking to deliberately mislead. Eysenck also viewed intelligence as a key characteristic of the individual. There have been differences of opinion among personality theorists about whether intelligence should be viewed as a personality dimension or something separate.

Eysenck’s personality dimensions match up rather well with Cattell’s second-order factors, the two most important of which are exvia–invia, roughly introversion–extroversion, and anxiety. It is possible to argue that they are tapping similar key underlying dimensions. However, the exact structure of personality suggested by the two workers remains markedly different at lower levels of their models.

Eysenck believed that his main factors would reflect underlying biological differences between individuals. For instance, he believed that extroverts would differ from introverts in their degree of brain arousal, specifically differing in the balance of inhibition and excitation of the
brain by the ascending reticular activating system. In order to test this hypothesis, a number of studies compared introverts with extroverts on physiological measures gathered under conditions of various degrees of stimulation (e.g. Gale\textsuperscript{19}). In addition, neuroticism, Eysenck thought, was related to autonomic nervous system lability, and he tentatively suggested that psychoticism might be related to hormone levels, particularly androgens. The evidence in favour of these various propositions has been very mixed, and most modern researchers would take the view that these hypotheses are, at best, oversimplifications.

More recently, there has been an emerging consensus on a five-factor personality model often nicknamed ‘the big five model’ (e.g. John,\textsuperscript{16} McCrae and John,\textsuperscript{17} Saucier and Goldberg\textsuperscript{18}). This includes the higher-order factors from both Eysenck and Cattell. The factors are extroversion, agreeableness (warmth v. cold), conscientiousness, emotional stability (Eysenck’s neuroticism) and intellect/openness to experience (a mix of intelligence and imaginativeness). The convergence of different models at higher levels on these factors, particularly extroversion, emotional stability and intelligence, does suggest that there are underlying measurable traits, but it does not tell us how important these are in absolute terms as determinants of behaviour.

Trait theories have more or less replaced the older type theories. Trait theories assume, for instance, that extroversion and introversion are points on a continuum, while type theories (e.g. Jung and Hull\textsuperscript{19}) take the view that some people are one and some the other. Although type theories attract little attention these days, they form the basis for some standardized measures, for instance the Myers–Briggs type indicator still sometimes used in personnel selection and similar applications. Perhaps the most recent type theory to reach prominence was in the 1950s, when Friedman and colleagues suggested that a particular personality type, ‘type A’, was associated with a higher risk of coronary heart disease than ‘type B’.\textsuperscript{20} Although subsequent research has not always upheld this proposition, the concept has passed into popular speech.

COGNITIVE MODELS – KELLY’S CONSTRUCT THEORY

Many people thinking about personality take a different perspective from trait theorists. Perhaps the strongest alternative approach is that emphasizing cognition. Instead of people’s behaviour being determined by underlying traits, it is determined by how they construe particular situations, their characteristic ways of thinking about the world and how they interpret particular situations. Many therapists favour cognitive models. They do not necessarily deny the existence of traits, but they are less interested in them because they see them as being difficult to change. Cognitions, however, are theoretically and practically changeable. Cognitive-behavioural therapy (CBT) is based on a model that emphasizes the importance of thoughts, perceptions and feelings as determinants of behaviour.

Unfortunately, there is no single model of cognition underlying CBT, partly because CBT therapists tend to be more interested in changing behaviour and symptoms than in personality per se. Static personality factors – those less susceptible to change – are of little interest to most therapists. CBT therapists have also tended to concentrate narrowly on particular aspects of cognition relevant to the condition they are treating, such as anxious thoughts, rather than trying to derive some overall model of personality.

Kelly’s personal construct theory\textsuperscript{21} is included here mainly because it shows the characteristics of a fully formed cognitive model (see Fransella\textsuperscript{22} for a more recent summary). Although this theory enjoyed considerable attention in the past as a basis for therapy, the rise of CBT and the somewhat weak therapeutic results\textsuperscript{23} have led to its relative eclipse. A technique for measuring personality derived from it, the repertory grid,\textsuperscript{21,24} attracted a great deal of interest, but again its utility, consistency and reliability proved disappointing in practice. Nonetheless, it illustrates how such models work and their potential limitations.

Kelly’s view was that the way we behave is fundamentally determined by how we perceive the world and how we have learnt to react to it. In fact, most of our cognitive structures are learnt. It is not a necessary tenet of trait theories that traits are innate or biologically determined; however, they are usually assumed to be so. Kelly, however, was clear not only that our perceptions of the world and our responses to it could change but also that we were constantly monitoring the effectiveness of our view of the world by predicting and then seeing whether those predictions come true. The model is that of ‘humans as scientists’, and Kelly suggested that we are all, to an extent, scientists acting on the world and getting feedback from it, on the basis of which we change our cognitive structures. Kelly believed that one source of psychopathology was a situation where cognitive structures did not fit the needs of particular situations or where they were positively harmful. Specifically, for Kelly, these were where a person’s constructs were such that they could not adequately monitor feedback from the world or where the structures were in such a mess or so rigid that they could not be changed easily in response to feedback that they were inadequate. These are propositions that most modern CBT therapists would have no difficulty with, although they might disagree greatly with the details of his theory.

Kelly envisaged cognitive structures as being hierarchical bipolar constructs, such as warm–cold. If we have this construct, he said, then we see people as either warm or cold. There are no degrees of constructs, only either/or. However, constructs such as warm–cold do not exist in isolation but are linked hierarchically and laterally to other constructs and, taken together, we are able to utilize structures made
out of constructs to see gradations in the world, even though the constructs themselves are categorical.

One of the difficulties of this sort of theory is that it is very difficult to fit emotion into it. Kelly himself struggled with the issue and made a number of propositions about how it might be dealt with. However, none of these was very satisfactory. More recently, research has managed to integrate cognition, perception and emotion in a much more effective manner (e.g. investigations into the neural systems underlying human behaviour demonstrate that the mechanisms of emotion and cognition are intertwined from early perception to reasoning\textsuperscript{25,26}). At the same time, we understand much more about how perceptions of the world are organized within the brain and how they are turned into action, and it may be that the time is right for another attempt to formulate a cognitive theory of personality.

**HUMANISTIC THEORIES**

It is exceedingly difficult to pigeonhole humanistic theories of personality or to define exactly what makes a humanistic theory, but they do have a number of features in common. One thing they share is the idea that every person has a unique experience of the world and that to understand their personality it is necessary to understand their experience. Humanistic theories are, thus, idiographic theories par excellence. There is also a strong undercurrent of the idea of the importance of people reaching their full potential. Growth is a key concept, and hence these ideas are represented strongly in areas such as life coaching and self-help organizations. They are also very important in many counselling approaches.

The apothecary of this view of personality probably comes in Maslow’s theory of self-actualization (see Maslow and Hoffman\textsuperscript{27}). Life for Maslow was a process of striving to reach the highest level of functioning one can. He viewed humankind as individuals seeking to climb a pyramid of levels of personal integration. The theory concentrates on this process of self-actualization, and people can be located according to their degree of progress towards this fulfilment of human potential.

Probably the most important humanistic theorist, however, was Carl Rogers because his ideas formed the basis of client-centred counselling, a particularly important strand in the counselling movement. For Rogers, personality was about how a person sees themselves, their self-image, and their interactions with others and the world. He saw these things as being unique to the person and, although he had little or no interest in traits, he would probably have regarded these as artificial externally imposed structures. People could grow and change by reflecting on their experiences and, if they were having difficulties, seeing opportunities for alternative ways of looking at things and of living. In order to do this, the therapist had to create an environment in which the client felt able to look at these issues. This environment was best created through ‘unconditional positive regard’, and the therapist needed to react to the client with empathy, warmth and genuineness. Perhaps the most familiar therapeutic technique was reflecting back to the client important things that they said in order to facilitate their thinking about them and moving forward. This is not simply parroting, but rather the therapist and the client seek to identify and explore important themes in the client’s experience. Thus, Rogers’ theory is based around therapy and its importance and, essentially, around the idea that the client can heal themselves; it is the main job of the therapist to facilitate this rather than to offer advice.

**GENETICS**

In recent years, there has been an increasing tendency to try to link traits to underlying genetic factors, whether directly to specific alleles or more generally through twin studies (e.g. Birley et al.\textsuperscript{28}). While one could imagine an idiographic model of personality being partly determined by genes, in practice most genetic theorists are concerned with the explanation of traits, particularly with the ‘big five’ traits, although some researchers have sought to identify genetic linkages to other characteristics of the individual such as fearlessness, impulsive non-conformity\textsuperscript{29} and even sexual orientation\textsuperscript{30}.

Twin studies are the main tool for estimating the probable size of behavioural genetic effects. Summaries of the behavioural genetic data for many of the major personality traits – extraversion, agreeableness, conscientiousness, neuroticism, openness to experiences – yield heritability estimates of around 50 per cent.\textsuperscript{31} Studies have also yielded surprisingly large values for genetic components for other traits such as emotionality, sociability, persistence, fear and distractibility.\textsuperscript{32} Most studies have found surprisingly low values for familial influences. In twin studies, monozygotic (MZ) twins are compared against dizygotic (DZ) twins and, ideally, non-twin siblings. MZ twins share all their genes and their intrauterine environment, DZ twins share half their genes (if they are the same sex) and their intrauterine environment, and non-twin siblings share half their genes but do not share an intrauterine environment. Most of the information is contained within the MZ–DZ twin contrast. A comparison between the degree of agreement for MZ twins and the degree of agreement for DZ twins allows a calculation of the proportions of the variance in a particular behaviour attributable to genes, shared environment (particularly family and intrauterine environments), and individual developmental history and experience. Furthermore, it is the proposed heritability of personality that is believed to be responsible for the fact that personality traits remain fairly stable over time.\textsuperscript{31,33–35}

However, although these studies suggest a genetic influence on personality, possibly a sizeable one, the estimates
of the size of such an effect are subject to several possible errors. Twin models make important assumptions about the underlying genes, particularly no dominance effects (interactions between alleles at a single locus), no epistasis (interactions between alleles at different loci), and, ideally, many genes of small effect. These assumptions are very unlikely to be true for every trait. There are also assumptions about the statistical distributions of behaviour and genes. It is assumed that the environment experienced by MZ twins is no more similar than that of DZ twins and, although some evidence is put forward that there are few differences in, for instance, sharing rooms or property, it is not clear how relevant some of these data are to the underlying issue. The difficulty is that if these assumptions are not met, then the effect is, in the main, to inflate the apparent size of the genetic component. The apparent size of familial influences will be reduced.36

Much effort has gone into identifying candidate alleles and measuring their association with personality. Unfortunately, to date the outcomes of these studies have often been inconsistent. A good example is the proposed linkage between alleles of the DRD4 dopamine receptor gene and novelty-seeking behaviour. Early reports were positive, but a more recent meta-analysis was negative.37 Nonetheless, this approach would seem to be the most promising avenue of research into the impact of genes on personality.

Many researchers hope that genetic studies will cast new light on the underlying structure of personality. Although one would hope that this is true, there is something of a circularity here. In order to accurately identify allelic influences on personality, we have to be able to identify and delineate the aspect of personality that we expect those alleles to affect. If the boundaries of a trait are defined poorly, or we cannot measure it accurately, or we identify a single underlying trait as several traits, or incorrectly combine several underlying traits into a single trait, then we make identifying allelic influences much more difficult. Thus, our uncertainties about the nature of personality are likely to weaken behavioural genetic studies.

PERSONALITY DISORDER

Personality disorder per se is dealt with in Chapter 43. Here we are concerned with the extent to which the idea of personality disorder overlaps with ideas about personality. Personality disorders are treated in DSM-IV and the International Classification of Diseases, 10th revision (ICD-10), as typological and idiographic — some people have one, and others do not. It is not possible to have ‘a bit of a personality disorder’. However, this may owe more to the need to classify and pigeonhole for diagnostic purposes than to any underlying assumed structure to personality disorder. Research is complicated by our poor understanding of the structure of personality disorder, particularly at the level of the individual disorder, with many patients meeting the criteria for more than one diagnosis. Unlike with axis I disorders, DSM-IV more or less encourages mix-and-match multiple diagnoses. Indeed, the relationship between axis I and axis 2 disorders remains an area of some uncertainty, with many patients at least effectively having both.

It has always been difficult to link personality disorder on to the sorts of theory discussed in this chapter. It would be possible in practice to describe personality disorders in terms of any of the sorts of theory, or none, and it is possible to find just that in the literature. However, most researchers have concentrated on trait approaches, the idea that people with personality disorders might have extreme scores on particular traits or, more likely, some combination of trait scores that account for their condition. Widiger and colleagues describe how extremes on either end of specific trait dimensions can be associated with personality disorders.38 For example, someone with a combination of high levels of hostility and a lack of trust in others might be disposed to paranoid personality disorder. According to Ball, ‘the application of personality trait models to the conceptualization of personality disorders has forged a much needed integration of what were separate areas of study for most of the 20th century’.39

A considerable amount of effort has gone into carrying out personality profiling of people with personality disorders over many years, with generally rather disappointing results. However, more recent applications of the ‘big five’ framework have been more successful, with several studies reporting fair predictive values for ‘big five’ factors (see Saulsman and Page40 for a meta-analytical review of the empirical literature). Unfortunately, there has not always been good agreement about what trait patterns predict particular personality disorders, which may owe as much to the weaknesses of diagnostic criteria as to the weaknesses of personality theory.

Existing research is incomplete, and where it will end up is open to speculation. However, the picture does not, to our eye, suggest that personality disorder can be wholly ascribed to some combination of ‘big five’ traits. Either there is an idiosyncratic component, something that people with personality disorder have or lack that others do not, or some trait or traits outside the ‘big five’ are important, or it may be impossible to adequately describe personality disorder within a trait framework at all and we may need to look at other possible ways to describe personality.

SUMMARY

Personality has been studied systematically by psychologists for almost 100 years. It is hard not to feel disappointed at the lack of consensus on crucial issues such as what it is and how it is structured. Personality tests were, at one time, used quite widely in clinical practice. They have gradually fallen into disuse in most areas of clinical work (although
not in areas such as personnel selection) because they proved of very limited value in determining treatment and in understanding patients’ problems. There is now speculation that a five-factor model (FFM) diagnosis would prove to have considerable clinical utility, but, at the time of writing, there have been only four published studies on the use of the FFM by practising clinicians. Estimates of the percentage of variance in behaviour accounted for by personality measures are usually low, although there is evidence that interaction between personality and situation may be more important. At one level this is hardly surprising: the behaviour of an individual at a funeral would be likely to be very different from their behaviour at a party, regardless of personality. Weaknesses in current models and measures of personality obviously weaken the ability of personality theorists to predict behaviour. Nonetheless, the acid test of the value of future research into personality will be precisely the extent to which new approaches and new measures are able to predict real-life behaviour.

KEY POINTS

- There is no agreement about what personality is and how it is structured.
- Different theorists have taken radically different approaches to personality.
- In recent years, there has been a growing consensus around a five-factor model of personality.
- Personality usually explains only a small part of the variance of human behaviour.
- Although there has been much interest in possible genetic influences on personality, this is an area with more promise than hard data.
- The link between ‘personality’ and ‘personality disorder’ is unclear; the two fields of enquiry have developed more or less separately.

INTRODUCTION: WHY PSYCHIATRISTS ARE SOCIAL PSYCHOLOGISTS TOO

‘No man is an island’ might be said to be the catchphrase and guiding philosophy of social psychologists. This is the branch of psychology that focuses on how what we do, feel and think is influenced by others. Oftentimes those outside the field find it difficult to discern the precise difference between social psychology and sociology, but as a general rule, although the areas of interest of the two fields often overlap, social psychologists tend to be more quantitative and to deploy more experimental methods.1

Since medicine frequently involves interactions between people, perhaps most notably between doctors and patients, social psychological theory and findings have much to offer in understanding the outcomes that occur when doctors and patients encounter each other.

As we will see, social psychology has made important contributions to understanding many of the behavioural phenomena with which psychiatrists must grapple daily, such as aggression. It has also been influential in the introduction of new treatment approaches, such as cognitive-behavioural therapy (CBT).

SOCIAL PSYCHOLOGY AND AGGRESSION

Social psychology has been seen as productive in understanding many of the phenomena that psychiatrists must deal with clinically. Perhaps one of the most famous examples is aggression.

The traditional Freudian view of aggression is that this arises out of inner drives. For example, a child’s unconscious desire to possess the opposite-sex parent sexually inevitably elicits aggression to the other, same-sex parent, who is now perceived as a threat.

A later theory was the frustration-aggression hypothesis produced by John Dollard, an anthropologist/sociologist based at Yale who suggested that it is not only the inner drive that needs to be studied but also the idea that aggression occurs when that drive is frustrated by an environmental obstacle, which then generates exasperation. Wherever you saw aggression, if you dug deeper you would find a frustrated goal. Simplistic though this theory is now perceived as being, it is still more sophisticated than many lay views of aggression. Consider, for example, modern media theorizing about the causes of terrorism.

The frustration-aggression theory was more complex than even this simplistic summary, because the two elements in the system appeared to act synergistically. Frustration generated aggression, while the aggressive drive was also more likely to be frustrated.

However, the proposal suffered from the neglect that many people are frustrated but not all turn to aggression, and so inhibition mechanisms combined with individual variability were relatively ignored aspects of the whole aggression story.

At least with the development of the frustration-aggression hypothesis, the environment entered academic thinking about the causes of aggression as opposed to the more inner-world theorizing of the psychoanalytical view.

Albert Bandura, a social psychologist based at Stanford University, pioneered one of the ultimate developments of inputting the environment into the genesis of aggression, and moving away from purely internal mechanisms, with his famous ‘social learning’ theory.

Hostility, like most other behaviours, is viewed as learned from the environment. This theory posits that, for learning to occur, suitable opportunities for witnessing similar behaviours must pertain, and reinforcing conditions must also be involved, so allowing the behaviour to be mimicked and produced again and again.

Social learning would be the background theory on which ideas that television, film and video games contribute to increased aggression in viewers are based. This is because the theory emphasizes just how easily we are influenced by others. Reinforcement might be subtle, in the form of identification with role models and admired others, leading to the expectation of increased status amongst peers if aggression is exhibited.

Social learning is not a pure behaviourist theory, which would instead rely on the environment as the sole shaper of behaviour. Instead, Bandura’s view was that ‘reciprocal...
determinism’ occurred. Others’ as well as your own behaviour becomes an environmental influence. You shape the environment, which in turn moulds you. Behaviourism tends to see us as passive recipients of influence rather than active contributors to the transforming effect of our world.

**SOCIAL PSYCHOLOGICAL THEORIES ABOUT RELATIONSHIPS**

Social learning theory appears to be a modern link between behaviourist and contemporary cognitive learning theories, because it invokes cognitive routes such as attention, memory and motivation in order to explain the chain of internal or mental processes that mediate between an environmental stimulus and its ability to influence a person’s eventual behaviour.

Similar theories in social psychology that appear to have their roots in stimulus–reward behaviourism include social exchange theory. This posits that one key way of thinking about relationships and why they occur, as well as why they end or how long they endure, is that relationships are sources of rewards and costs. Tangible benefits of relationships include material compensations, such as a father extending a loan to his son, as well as less tangible compensations, such as attention, approval and status.

According to social exchange theory, we engage in relationships very much with a sense of this exchange. Some people give much of themselves and make sacrifices in their relationships, but they do so in order to obtain something from others. The theory suggests that the benefits we gain from, and the sacrifices we make for, relationships must evolve into some kind of equilibrium in terms of the value we place on what we gain and invest for relationships to endure. The theory could be criticized as relying on people to constantly and rationally self-interestedly determine the cost–benefit pros and cons of all their relationships.

This perspective appears to be based on a view that we see others as means to our ends as opposed to being reinforced just by having relationships in themselves. Also, it does not appear to leave much room for altruism.

Social psychologists might be forgiven for being somewhat cynical about concepts such as altruism following their intensive investigation of why a large crowd of people can witness another person being criminally attacked and yet not intervene to help. The research literature began after an infamous case where numerous bystanders failed to assist a victim of serious crime – Kitty Genovese – who was supposedly stabbed to death in 1964 in front of numerous witnesses who failed to offer her assistance. Since then, the phenomenon has been referred to as the ‘bystander effect’.

The social psychological research finds that, paradoxically, the larger a group witnessing a crime or a person needing assistance, the less likely any one individual within that group is to take it upon themselves to intervene. The most popular theory to explain this finding is the ‘diffusion of responsibility’ effect, whereby if you are alone witnessing a crime you tend to feel more personally responsible if nothing is done, in comparison with how you feel if others are around and similarly doing nothing.

Another social psychological factor could be group influence. We view the inertia or otherwise of others as determining our assessment of what is going on. Perhaps if no one else is doing anything, then we have misread the predicament and the serious injury that we appear to be witnessing is not really occurring.

The bystander effect is a good example of social psychology in action – it reveals that our behaviour is governed by complex processes involving the impact of others combined with how we are thinking about other people and what they would think about us.

**SOCIAL PSYCHOLOGY OF PERSUASION AND INFLUENCE**

Another example of social psychology in action would be in the area of persuasion. Much of the work of healthcare professionals, and perhaps particularly psychiatrists, centres on the art of persuasion. Psychiatrists need to persuade patients to accept treatment or a medical understanding of their experiences, for example hallucinations.

One technique developed from a famous strand of social psychological research is referred to as the ‘foot-in-the-door’ technique. The experiments follow a particular strand whereby subjects are asked for a small favour, followed later by a much bigger favour. The second request involves much more trouble or sacrifice for the subject. The intriguing finding from social psychology is that you are much more likely to secure agreement to the bigger request if you have presaged it with a smaller one.

So, for example, psychologists might venture into a suburban neighbourhood and ask residents if they would allow a large and ugly poster in support of a local charity or good cause to be displayed at home. Not surprisingly, only a small number of residents might say yes to this request.

In the second condition of the experiment, the psychologists go to a similar neighbourhood but this time ask the residents to sign a petition or wear a small innocuous badge in support of the same charity or good cause. This is such a small task, and therefore a small yes for most people, that they agree to this apparently inconsequential request readily.

Later, the psychologists return to the same neighbourhood and now ask for the large poster, which was usually rejected in the first condition of the experiment, to be hung in the home. However, on this occasion many more people agree to put up the poster, compared with when they were asked without a presaging minor request. The theoretical reasons for why so many more people agree to the large...
poster after first agreeing to the small badge or favour are many and varied.

One theory is about the idea that, once you start saying yes, it is much more difficult to say no. Another theory is that, having accepted the badge or signed the petition, it does not seem to make sense to reject the poster. People like to be consistent and accepting wearing the badge means that you agreed with the principle of supporting the charity, so why now reject the poster? This is an important social psychological principle, which is that apparent consistency seems to be extremely important to most people. We shall come back to this principle shortly when we explore the issue of cognitive dissonance.

Another interesting idea is that, having said yes to the badge, you identified yourself as a supporter of the charity or good cause and therefore your identity was now tied up with the cause. To reject the large poster was now in conflict with this newly established identity.

By starting with small yeses and building to a bigger one, you are using powerful social psychology that makes it much more likely that you will secure the big yes at the end. Controversy remains in the field about how effective the foot-in-the-door technique would be when dealing with more strongly held opposing views.

An almost opposite social psychological principle appears to be in play in another famous series of experiments, which lead to what is termed the ‘door-in-the-face’ technique. Here, in marked contrast to the foot-in-the-door approach, the key idea is to elicit a ‘no’ with your first request. This sets up a situation where paradoxically you appear much more likely to get a ‘yes’ with the real request that you have been storing up and building up to all along.

These experiments follow a pattern that would be something along the lines of psychological experimenters going into the high street to ask passers-by to donate blood or make a commitment to help with a blood-transfusion drive. In the first condition, the experimenters stop people and ask them, but as usual they get a limited response.

In another condition, the experimenters stop people and ask for big donations or large personal commitments to assist with the blood-transfusion drive. Unsurprisingly, given the large scale of the ‘ask’, very few people indeed volunteer.

In a third condition of the experiment, they indeed start similarly to the second condition by asking for a large personal commitment to a massive blood-donation drive. But, after this ‘big ask’ was tried first, upon hearing the refusal, the experimenter says something like: ‘OK, we understand this is a big ask but as the blood transfusion truck is just round the corner why not just donate one pint today and we’ll forget the other rather demanding scheme?’

Many more people end up giving a pint of blood after they were first asked to give much more than if they were just asked for the pint up front.

Why is this?

One theory is that, in asking for so much more and then scaling down the request, it appeared that the blood-transfusion people had made a concession – they had conceded that the first request was too much and were now asking for much less. There is a natural human tendency to reciprocate – that is, once one person has made a concession in a negotiation, it seems only natural to reciprocate with a concession yourself, in this case agreeing to giving a small amount of blood.

Another explanation relies on a ‘perceptual contrast’ effect, which is that donating a pint of blood does not now seem that big an ask if it were preceded by a much bigger request. The contrast between the two renders the final request appearing much smaller in size.

### COGNITIVE DISSONANCE

Returning to the foot-in-the-door technique and the theory that consistency is extremely important to people, this argument has been one of the most productive in social psychology. It has opened up a field referred to as ‘cognitive dissonance’.

Cognitive dissonance theory has become one of the most dominant ways of accounting for many otherwise puzzling behavioural phenomena. The key idea behind cognitive dissonance is that we like to think of ourselves as rational, reasonable and consistent beings; therefore, if we come to notice that our performance is at variance with consistency, we will tend to modify our attitudes or behaviour, in order to bring consistency back into the frame. This drive for consistency is so powerful that it can have a massive effect, although an often unconscious one, on our attitudes and behaviour.

The theory is largely the brainchild of one of the most famous social psychologists of the twentieth century, Leon Festinger, who came up with the idea following what appeared to him to be a puzzling incident involving rumours following an infamous Indian earthquake of 1934. Festinger noticed that rumours of a worse earthquake to come did not appear to be based on hard evidence or logic but could instead be explained by an idea: that people at an unconscious level needed to consistently account for their high levels of anxiety.

Cognitive dissonance theory has a wide range of applications. For example, as argued by Robert Oxoby, it effectively accounts for the puzzling tendency of people who work in hazardous industries to ignore safety regulations more than people who do not work in such dangerous predicaments. The argument from cognitive dissonance theorists goes something like this: those who toil in a dangerous occupation must experience dissonance between their choice to work in such a perilous area and their understandable fear of injury. Oxoby contends that it is impossible to keep turning up to work with such high anxiety and also to reconcile the idea that you are a rational intelligent
person and yet you are making such a decision to put yourself in such danger.6
Reducing dissonance in this context takes the form of mentally minimizing the probability of injury in your own mind. Because you resolve the inner conflict by deciding that it is not that dangerous, it is inevitable according to cognitive dissonance theory that people exposed to daily danger will come to reduce the assessment of the risk in their own minds, compared with people who are not so exposed.
Indeed, cognitive dissonance works the other way for people outside the industry.8 If the industry is well paid, then we who are not working there will reason to ourselves that it makes sense that we do not take these big rewards because it is just too dangerous.

One key flaw with cognitive dissonance theory is that individual variability may not be properly taken account of over the need for consistency, and indeed this drive may often be subsumed under other more pressing needs. Thus, it may be an effect that emerges in the rarefied atmosphere of controlled laboratory conditions but not so much usefully in the more messy real world.

MEASUREMENT OF ATTITUDE

Cognitive dissonance theory hinges not only on the experimental demonstration of behaviour change but also on the ability to measure attitude reliably. Attitudes and their measurement are a cornerstone of social psychological research and have been influential on psychiatric journals as well.

The scientific approach to an attitude and its formal measurement derives from social psychology, where an attitude is measured as a psychological tendency that is expressed by evaluating a particular entity with some degree of favour or disfavour. So, patients prefer a nice waiting room and charming nurses, and this contributes to their ‘attitude’ to the hospital, clinic or treatment.
Thurstone scales, first developed by Louis Leon Thurstone in 1928, were the first attempt to scientifically measure attitudes, and this derived from first finding a large number of attitudinal statements towards the object being measured, such as attitudes to religion.3
One statement might be that ‘belief in religion is irrational’: Independent judges are asked to rate the statements in terms of degree of negativity or positivity towards religion. Once there is a convergence in the judges’ ratings of these statements in terms of their ranking along a spectrum of positivity and negativity (e.g. the above statement is rated as an extremely negative view), they are put to the population to be tested. Anyone who endorses the above statement is measured as having a very negative attitude to religion.
Several problems arise out of this technique: it is complex statistically and procedurally, and it crucially hinges on the assumption that the judges used for scale construction are similar in outlook to the population intended to be tested.
In contrast to Thurstone scales, the most popular method for measuring attitudes today uses Likert scales.10 Likert scales involve measuring a person’s level of agreement with a statement, so the format of a typical five-level Likert item is: Strongly disagree, Disagree, Neither agree nor disagree, Agree, Strongly agree.
Likert scales suffer from statistical problems when differences between groups are analysed, as not only means but also variances might contrast. There are also problems over recurring patterns of responding, such as central tendency bias, which is a tendency for responses to cluster around the middle of the rating scale offered, and acquiescence bias, which is about the general tendency to agree rather than disagree.

When social psychologists look for correlations between attitudes or possible descriptions, they uncover three basic factors. A factor is a term derived from social statistics and is a hypothetical construct that is supposed to explain real-world outcomes.

So, intelligence quotient (IQ) was a factor that first emerged when statistically examining correlations across a wide range of examination results in school students. It was noticed that some students tended to do well across all subjects, while others tended to do, roughly speaking, equally badly across all subjects.

If your score in mathematics bore no relationship whatsoever to your score in anything else, then a factor could not emerge. But if those students who scored high in maths tended to score high in other subjects, then perhaps something more is going on underneath the data, such as a general cognitive ability factor.

Across attitudes, three general factors appear to emerge: evaluation, potency and activity. Evaluation as a factor loads highest on adjective pairs that are most similar to ‘good–bad’. The ‘strong–weak’ adjective pair defines the potency factor. The adjective pair ‘active–passive’ defines the activity factor. This factorial structure makes intuitive sense from an evolutionary standpoint.

Osgood’s semantic differential technique measures these three factors.11 It contains sets of adjective pairs such as warm–cold, bright–dark, beautiful–ugly, sweet–bitter, fair–unfair, brave–cowardly and meaningful–meaningless. In questionnaires, these are generally seven steps apart so you can record how close your attitude is to fair or unfair when, for example, your attitude to the National Health Service (NHS) is measured. For example, a scale for rating how a person feels about smoking may include the following:

<table>
<thead>
<tr>
<th>FOOLISH</th>
<th>PLEASANT</th>
</tr>
</thead>
<tbody>
<tr>
<td>-3</td>
<td>3</td>
</tr>
<tr>
<td>-2</td>
<td>2</td>
</tr>
<tr>
<td>-1</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>+1</td>
</tr>
<tr>
<td>+2</td>
<td>+2</td>
</tr>
<tr>
<td>+3</td>
<td>+3</td>
</tr>
</tbody>
</table>

Semantic differential scales do not have individualized questions as Likert scales do, and they do not specify mathematically the levels of agreement or disagreement.
There appears to be an evolutionary underpinning to the factors that emerge from attitude scaling. In ancient times, when personal safety was the paramount issue in our minds, when we met someone we did not already know well, and therefore could be sure we knew their personality disposition, there was possibly survival value in a rapid summary analysis of all their readily apparent characteristics.

The most efficient approach would be along the lines of determining instinctively and primarily whether this stranger represented a danger. This translates into modern attitude measurement of the strongly emergent factor of: is the person good or bad? The next: is the person strong or weak? If the stranger is strong and bad, then this is a much more hazardous encounter than if they are weak and bad.

The evaluation, potency and activity factors are key according to Osgood’s system to understanding how people’s attitudes to another person or a phenomenon are likely to translate into real-world action. If your attitude to a third runway at Heathrow Airport is measured and no difference can be found along the evaluation, potency and activity factors from another person, then, although you may have answered some attitude questions differently, is there an essential contrast in your attitude to the third runway that is in any way meaningful in terms of what you might do about it? Factor analysis is a statistical technique that originated in psychometrics.

There are many problems with all these different essentially mathematical and statistical approaches to methods of measuring attitudes, but the generic issue is the relatively low correlations that stubbornly persist between attitude and actual real-world behaviour.

Possible reasons for this include the conundrum that most attitude measurement does not properly consider two crucial social psychological issues. Subjects may be loath to tell you directly what they really think; for example, they may not own up to racist attitudes or stigmatizing attitudes to mental illness, because these are not opinions that are socially acceptable.

Attitudes also make sense only in terms of an appreciation of the implicit trade-offs involved. Charming nurses who have a lot of time to spend with you may not, for example, turn out to be quite so vital to patients when attitudes to this are rated if they understood that this benefit could be bought only at the expense of numbers of nurses.

This more realistic concept of preferences comes from economics, where preferences are defined as individuals’ ‘utility’ for consuming healthcare goods and services. The assumption is that we aim to maximize our utility. Economic theory argues that utilities or benefits can be measured in money-equivalence terms. In other words, the real strength of preferences is the monetary compensation that would leave people indifferent between having a given utility change and not having the change (i.e. willingness to pay or willingness to accept).

If you could be given a money substitute for charming nurses, then how much would compensate you for their absence? This figure in comparison with the monetary value for what you would accept to forgo clean waiting rooms tells us which you really prefer.

The technique currently popular in social psychology that takes this point on board is called ‘conjoint analysis’. This assumes that individuals make trade-offs within a resource constraint.

Attitude researchers have also long been sceptical of assuming that our reports of our own attitudes are not tempered by concerns over impression management. So, attitudes towards immoral or illegal behaviour need to be probed in a more sophisticated manner other than just eliciting attitudes on simple scales that measure intensity of evaluation.

Response latency measures are one of the currently favoured approaches. These yield evaluations that are unlikely to be consciously controlled or censored, as pointed out by Laurie Rudman, a social psychologist based at Rutgers University in the USA in a review of attitude measurement. This is because they are taken from reaction time tasks that measure people’s attitudes or beliefs indirectly (i.e. without asking people how they feel or think).

That is, people’s attention is focused not on the attitude object but on performing an objective task, and attitudes are then inferred from systematic variations in task performance.

For example, in the Implicit Association Test, automatic pro-white bias is indicated when people show faster performance categorizing pleasant words and white people (and unpleasant words and black people) together, compared with categorizing unpleasant words and white people (and pleasant words and black people) together. Thus, implicit attitudes can be characterized as the automatic association people have between an object and evaluation (whether it is good or bad).

**IMPRESSION MANAGEMENT**

Susan Fiske, Amy Cuddy and Peter Glick based at Princeton University, Northwestern University and Lawrence University, respectively, all in the USA, have published an intriguing outline as to how the key factors that emerge in attitude research are linked with impressions that we create in others and therefore what the most effective way of creating a good impression might be, based on evolutionary theory.

In our evolutionary past, we often met strangers and had to make some key decisions that would determine our future survival. At the heart of these quandaries was the basic issue: does this stranger intend to harm me? A subsidiary question then became: if they do intend to harm me, how likely are they to inflict significant damage?

Another way of thinking about these crucial social decisions that we are probably making at an unconscious level...
all the time, whenever we encounter someone, is that we are constantly evaluating how ‘warm’ or otherwise another person is and how ‘competent’ they are.

Warmth as a quality has particularly vital evolutionary significance, as it translates into an assessment of whether another intends to harm or help us. Competence may seem a slightly strange quality to place so high up on the scale of fundamental assessments that we make of others, but again this has huge evolutionary significance because it relates to the question of whether another has the ability to enact their intentions. There is little real point to a helpful but incompetent person – you would not find them of positive survival value in the jungle.

Fiske and colleagues point out that psychology first got a hint that this assessment of warmth lay at the foundations of our assessments of others with one of the most famous experiments in social psychology. In 1946, Solomon Asch, perhaps the most famous social psychologist of all time, examined how impressions of others are formed using a list of adjectives – for example, ‘determined’, ‘practical’, ‘industrious’, ‘intelligent’ and ‘skilful’; the list of adjectives also included either ‘warm’ or ‘cold’, depending on the experimental condition. The power that was uncovered of the term ‘warm’ versus ‘cold’ as primary to our assessment of another’s personality, and its ability to profoundly alter impressions, continues to surprise to this day.

Asch found that a ‘warm’ intelligent person is perceived to be wise, whereas a ‘cold’ yet intelligent person is viewed as ‘sly’. No other personality attribute has been found in the half-century since Asch’s experiment to profoundly alter our view of another.

How warm someone is, is linked profoundly to our sense of their fundamental intent, including linked issues such as friendliness, helpfulness, sincerity, trustworthiness, morality, fairness, generosity, sincerity, tolerance and understanding, so all of these overlap with the warmth–trustworthiness dimension. The competence dimension, on the other hand, reflects personality attributes that are related to perceived ability, including intelligence, skill, creativity, efficiency, foresightedness and ingeniousness.

Other research confirms that our sense of another’s warmth and competence accounts for over 80 per cent of our perceptions of everyday social life. When we try to interpret the behaviour or form impressions of others, warmth and competence account almost entirely for how we characterize them.

Fiske and colleagues point out that the evidence suggests that warmth judgements are primary: warmth is judged before competence, and warmth judgements carry more weight in affective and behavioural reactions. From an evolutionary perspective, the primacy of warmth is fitting because another person’s intent for good or ill is more important to survival than whether the other person can act on those intentions.

So, social psychology has developed an understanding of person perception – how we perceive others founded on measurement of attitude, otherwise known more colloquially as impression formation and impression management.

We are all involved in impression management, trying to influence others’ perception of ourselves. For example, wearing a smart suit at an interview is an attempt to create a certain impression. This deploys a branch of person perception known as the ‘halo effect’. The halo effect is about the recurrent finding that we seem to assume that characteristics cluster, for example that attractive people are more intelligent and outgoing. This may explain why attractive people attract more lenient sentences from juries. Somehow, we assume that attractive people are less guilty.

In wearing a smart suit at an interview, we are deploying the psychology that the person who looks intelligent and organized is indeed this way when it comes to doing the job. This is a major assumption, but the halo effect demonstrates a huge number of assumptions we make when it comes to person perception. Indeed, it is theorized that, as we often have to make snap judgements in social interaction, it makes sense to jump to conclusions and to stereotype. For example, we automatically assume that an elderly person will have a cluster of personality characteristics that differ from a younger individual, without bothering to actually check that this is so.

The problem with using person perception findings too readily is that there is also individual variation in perceptions. Some people are more skilled than others in working out intentions behind impression-management techniques such as wearing a smart suit.

Theory of mind

A branch of social psychology comes into play here that is referred to as ‘theory of mind’. First-order theory of mind is the theory or account you have of what is going on in your own mind. Second-order theory of mind is the theory you have of what is going on in another’s mind. So, you might theorize that a smartly dressed person is intelligent, organized and cooperative. However, third-order theory of mind is thinking what the other person is thinking about what you are thinking. So, as an interviewer, you might realize that the person is wearing a smart suit merely in order to impress you superficially, and therefore you may discount this behaviour.

Theory of mind is gathering influence in understanding the psychological deficits that may be at the heart of disorders such as autism and schizophrenia.

It might be that much puzzling behaviour becomes more explicable once it is understood from a theory-of-mind perspective. It might be, for example, that, with delusion formation, the key issue becomes not that people believe they are the next coming of the messiah but that theory-of-mind deficits mean that they do not grasp the personal repercussions of openly venturing these beliefs to the mental health services. Theory of mind hinges on the issue of ability to
take perspectives other than one’s own as lying at the heart of communication, social skill and discourse.

Theory of mind underpins relationships because, in order to conduct relationships successfully, we need to be able to theorize at a lay level about what is going on in others’ minds.

**IMPROVING YOUR RELATIONSHIPS**

This naturally leads on to another favourite topic of social psychology – relationship formation. This is founded on the question: how does how we perceive others guide us in forming affiliations with them?

Part of the answer comes from research by a team of psychologists led by Rachael Potter from Southwest Minnesota State University in the USA, who examined a key issue, our fear of rejection from others.21

The authors point out the need to be accepted by others is one of the most profound of all human motivations, and therefore it follows that rejection is frequently extremely painful. Their argument is that, because this is such a dreadful outcome, a group of us start to over-monitor our environment – the faces and behaviour of those we are talking to – on the lookout for early signs of rejection.

Psychologists such as Potter use the buzz term ‘interpersonal rejection sensitivity’ to describe this phenomenon. It is basically a tendency to anxiously expect, readily perceive and overreact to rejection. ‘Rejection sensitivity’ is now thought to lie at the heart of poor social skills and unease, because a state of social hypervigilance associated with anxious expectations of rejection naturally tends to distort perceptions of others’ behaviour. This in turn produces an often defensive reaction in the perceiver, which in itself undermines relationships.

So, these psychologists are arguing that the tragic irony of interpersonal rejection sensitivity is that it creates a vicious cycle of self-fulfilling prophecies in the form of actual rejection following from the imagined rejection.

For example, another group of psychologists, led by Geraldine Downey at Columbia University in New York, found that people who enter romantic relationships with anxious expectations of rejection tend to too readily perceive intentional rejection in the ‘insensitive’ behaviour of their new partner.22 Lo and behold – what then happened was that these ‘rejection-sensitive’ people and their romantic partners became dissatisfied with their relationships. The rejection sensitivity led to jealousy and hostility in those who were rejection-sensitive, and it was this diminished supportiveness that subsequently produced their partners’ dissatisfaction.

Given that being too sensitive to interpersonal rejection produces such terrible social outcomes – either you avoid social encounters altogether and therefore do not learn how to become more socially skilled, or when you enter relationships you are too needy or anxious and this messes things up – why are people some so interpersonally sensitive in the first place?

A collaboration between psychologists based in the USA and Australia, led by Nathan Gillespie at the Queensland Institute of Medical Research, found that just under a third of how sensitive you were to rejection was the proportion accounted for by genes. This is good news for those of us who are not the most socially assured in the world, because it suggests that there is quite a lot we can still do about the problem, even if dealt a poor social skills hand in the game of life.21

Rachael Potter’s group found that bullying and teasing during childhood seemed to account for a large part of the story as to why some of us are more sensitive to rejection than others.21 If bullying and teasing lead to low self-esteem and feelings of inadequacy, then perhaps the direct antidote is acceptance by others – the problem is if you expect to be rejected, then you tend not to be so socially competent.

Social psychology has a lot to say on the issues of self-concept and related matters such as self-esteem and personal identity. Social psychology argues that these apparently ‘self’ concepts are in fact very social. The views we develop on ourselves might appear intensely private and personal, but ultimately they tend to derive from what we understand others think of us. If you were bullied at school and you deduced that you were viewed with contempt by others, then this will contribute to low self-esteem because you internalize others’ views of you.

Getting on with and managing others’ views of you – impression management being a cornerstone of this project – then appears a way to boost self-esteem. Through greater social skills, we derive more social rewards from others in the form of rewards and praise, and so we enter a positive feedback loop whereby self-esteem is raised.

In order to learn how to be more socially assured, it is useful to break down the skill into its component parts. These are described by social skills specialists as abilities in the areas of initiating relationships, self-disclosure, asserting displeasure with others’ actions, providing emotional support, and managing interpersonal conflicts.20

People who expect rejection tend not to self-disclose about themselves because they are embarrassed about themselves, and yet it is only through self-disclosure that others come to know us and feel closer to us. Asserting displeasure is oddly enough a vital social skill, as otherwise we find ourselves in relationships that irritate us and lead to gradual building resentment.21

Social skills rely on some other deeper psychological abilities. These are described by Nathan Gillespie’s team as including ‘need for approval’ and ‘fragile inner self’. Need for approval is the extent to which we subjugate our personal needs in order to keep others happy, so as to avoid rejection, and this will tend naturally to produce low ability to assert displeasure with others’ actions. Fragile inner self refers to our fear of being rejected or ridiculed.
It would seem that the needier you are of others, the less you are able to be a socially rewarding person to be with. You have to give first in order to get.

But what about those people apparently at the other end of the scale of social skill, the socially powerful among us – how do they achieve this? A group of psychologists at the University of Illinois using personality testing examined the link between personality and the attainment of leadership or higher-status positions in student organizations at universities. The research has made an important contribution to our understanding of what the secret ingredient is to the personality type who climbs the greasy pole of power in organizations.

The pursuit of power appears to be a fundamental determinant in eventual success in status attainment. Status, and in particular relative status between people, appears to be a key influence on how relationships are conducted and how much influence we have over others. Status-seeking, argue the researchers in this study, could be considered a primary and universal human motive, although this appears to have been surprisingly relatively neglected by psychological researchers.

A large part of the strain of working in medicine as a doctor or nurse could be said to centre on issues linked to frustrations over a lack of personal influence over others, including colleagues and patients.

This research found that some essential personality characteristics were linked strongly to how much influence you attained over others. These characteristics included extroversion (being sociable and socially confident) and conscientiousness (fulfilling obligations). The authors argue that extroversion facilitates getting noticed and conscientiousness enables potential leaders or seekers after higher status to present themselves as role models.

Although many people are often extremely conscientious, they may not realize that ‘getting noticed’ is key to achieving higher status and may need to draw more attention to themselves or the valuable role they play in the organizations in which they work.

Interestingly, this research found that extroversion and conscientiousness were not sufficient key predictors of who attained formal executive power or genuine high formal status, which was instead linked most closely with having an ‘ambitious power orientation’.

Also particularly notable was that the attainment of prestigious offices in democratic organizations where you needed to court the favour of an electorate was associated with high ‘agreeableness’. Agreeableness, argue the authors of this study, provides the necessary social skills to offset the negative impressions that colleagues often have of overtly ambitious individuals.

So, the art of attaining higher status or power appears to revolve around a delicate combination of both ambition and likeability. Perhaps many of us try too hard to be liked and therefore lose power that way. Most power in the social world is deployed most effectively by getting people to think the way you want them to – so they end up agreeing to your plan without feeling coerced. This is wielding power through cooperation rather than conflict.

One famous social psychology technique used to explore cooperation between people is to use experiments that take the form of inviting subjects to participate in a game called the ‘ultimatum’ game, which is basically a way of exploring and measuring cooperation between two people. Classically, the game is played between a ‘proposer’ and a ‘responder’, whereby the proposer is given by the experimenter a sum of money to divide with the responder. The proposer must suggest a way of dividing the funds, and the responder can decide whether or not to accept the offer. The key twist in the game is that, if the responder accepts the offer made by the proposer, then the two are allowed to split the money accordingly and therefore keep the bounty. However, if the responder rejects the offer made by the proposer, then neither party gets to retain any cash.

Theoretically, since the responder had no capital at all given to them in the first place, then any offer at all made by the proposer, no matter how inequitable (e.g. ‘I keep £95 and offer you £5’ rather than the equitable 50/50 split), makes logical sense to accept. Accepting £5 means that you are still £5 better off than having nothing at all. Accepting a low offer is rational, given that the key alternative is no money at all, but it is also in the responder’s self-interest to accept any offer, no matter how low, because it is not self-interested to make oneself poorer by refusing an offer, particularly when no work had to be done for the money in the first place.

Yet, the astonishing result found repeatedly when both psychologists and economists play this ultimatum game in their laboratories is that offers below 20 per cent are usually rejected by responders, even when this amounts to a substantial amount, such as the equivalent of half a day’s pay.

The other intriguing finding is that offers by proposers tend to be near the 50 per cent mark, so many are making much more generous offers than they theoretically really need to.

What is going on? The answer is important because these findings run counter to current prevalent wisdom that our behaviour is motivated by and largely accounted for by self-interested attitudes.

A relatively new theory proposed by Terence Burnham, an economist based at Harvard University who has published a novel take on the ultimatum game experiments, is that what the experiment demonstrates is that we are quite willing to suffer a personal loss if that stops someone else getting ahead – particularly if it looks like they are doing better than us.

In other words, it is not that we seek money, but more that we seek to have more money relative to others. So, if everyone else does better than us – even if we have more as well – then we end up more upset than if we had not gained at all.
It is this relativity of success that Burnham’s work emphasizes. To put it another way, all doing well turns on social comparison – more money is not the problem, even if it does buy us wonderful things such as greater freedom and more control over our own lives. The key issue instead becomes how we compare what we have with what others have.

Burnham came to this conclusion because his twist on the ultimatum game experiments was to obtain saliva samples from the participants in order to investigate whether the testosterone levels of the male players affected their strategy. The results described in *Proceedings of the Royal Society* are quite startling: responders who reject a low offer had an average testosterone level more than 50 per cent higher than the average of those who accept. Five of the seven men with the highest testosterone levels in the study rejected a $5 ultimate offer from a starting stake of $50, but only one of the 19 others made the same decision.

High testosterone in men is associated with greater competitiveness, risk-taking and a drive for greater social dominance. Those who win at games appear to have consistently higher testosterone than losers. It would appear that those who are keenest to win at social comparison are most likely to reject low derisory offers – they in particular can not stand others getting on and moving past them, even if they are benefitting as well.

Burnham’s results ask a startling question about the whole point of money – which is in fact to produce a sense of social superiority. Money has meaning in terms of a social universe only because what we really want is relative rather than absolute prosperity – we would actually much prefer to be absolutely poorer if we at the same time became the richest people (in comparison to others) in the village or on the desert island.

There is absolutely no point in being a multimillionaire on a desert island if no one knows about it, and similarly there is little benefit in being a multimillionaire if everyone else is one as well.

But there are other interpretations of this kind of ultimatum game result. For example, Darine Zaatari and Robert Trivers from the Center for Human Evolutionary Studies at Rutgers University in the USA found that more physically symmetrical men are also more likely to make small initial offers (and, in turn, reject relatively larger ones).27

Psychologists have found that how symmetrical your body and face appear is to be a profound measure of not only physical attractiveness but also your body’s ability to cope with a wide range of environmental stressors during development, ie resistance to parasites, immunological strength, ability to escape predators, speed, strength, and mental acuity.

Zaatari and Trivers argue that this superior genetic quality, as displayed by people with more body symmetry, increases their ability to gain access to resources without cooperation, for example by physical aggression.27 Zaatar and Trivers point out that previous research confirms that symmetrical men are more likely to be aggressive and to start and participate in fights, and have a high opinion of their ability to win when it comes to violence. This bias makes sense if their physical symmetry is a measure of general physical and genetic fitness. The interesting thing about aggression as a strategy is that it could be said to be the negotiating opposite of cooperation.27

Zaatari and Trivers contend that aggression permits the seizing of another’s resources without having to bother offering any cooperative benefit in return. Weaker men are more likely therefore to seek to try a cooperative strategy, as they have most to lose from a confrontational strategy. Sure enough, Zaatar and Trivers found that more asymmetrical men (and therefore the less genetically fit) were more likely to make more generous offers in ultimatum games, supposedly in order to induce a more cooperative relationship with the other party. Symmetrical males made significantly lower offers than asymmetrical males. For the stronger man, why bother to offer to cooperate when you can take aggressively anyway?27

Sometimes players adopt an aggressive strategy in order to create an intimidating impression – we may readily accept a low offer if we feel the alternative is having our head bitten off. How much of the low offer strategy is a bluff, though, as opposed to comprising an iron fist in a relatively velvet glove?

One reason those offered low sums in the ultimatum game might decline such offers is that they are thinking of what happens in the future of this relationship – if you accept a lower offer now, maybe that means the person making the offer will continue to make low offers in the future. If you refuse the low offer, then it means that the person making offers in the future may be more inclined to up the offer. This way of thinking about relationships puts the issue of power at their heart.

Dacher Keltner and colleagues at the University of California at Berkeley documented some of the surprising personal psychological benefits of being a ‘high-power’ individual and demonstrated that suffering from ‘low power’ was accompanied by profound emotional burdens.28 They found that because elevated power is associated with increased rewards and freedom, it was associated strongly with ‘approach-related’ tendencies – in other words, high-power individuals tend to be more assertive and exploratory in human affairs, take more risks and try out more novel activities. Reduced power, on the other hand, was inevitably accompanied by a constant sense of increased ‘threat, punishment, and social constraint’, and thereby this activated what the psychologists referred to as ‘inhibition-related tendencies’. Low-power individuals tend to be less assertive and constantly living in a climate of fear and anxiety about what higher-power people around them will do to them.28

As a result of this research, Keltner and colleagues conclude that power is associated with more positive mood and a tendency to focus on any potential rewards in the environment. They also conclude, perhaps more surprisingly, that certain cognitive skills such as thinking for oneself and
more lucidly are likely to be associated with higher power. Perhaps most intriguingly for the various sex and financial scandals in which our leaders tend to be trapped so commonly, they also conclude that high power is linked with more ‘disinhibited behaviour’ – in other words, people higher up the power tree tend to take more risks and indulge their fantasies, while the rest of us cowering below tend to restrain ourselves more, perhaps cognizant of what the higher-power authorities might do to us.  

The authors of this study argue that reduced power is associated with more negative mood and constant vigilance for threat and punishment, which, among other consequences, is likely to lead to lower creativity. There is also a tendency to be preoccupied with others’ interests and those features of the self that are relevant to others’ goals, in other words trying to please others by modifying the self to fit in. All of this naturally leads to more inhibited social behaviour and less assertiveness.

The bottom line that Keltner and colleagues are making is that suffering from low power when it comes to your impact on others at work or at home has massive psychological consequences in terms of your mood and behaviour and the whole way you think about the world. This in turn probably has surprising implications for your general physical health. Keltner and colleagues paint a picture of the relatively powerless being under chronic strain, which in turn probably has a negative impact on their health.

**OBEDIENCE**

People of low power tend to obey others – indeed, that is one of the signals of their low power. But social psychologists have been interested to see whether, when people perform actions, we should consider the drivers of their actions as lying within them or within their situation. When Nazis brought to trial after the Second World War claimed to be ‘just following orders’, was this an adequate account of why they committed atrocities, or was the reason to be found in their personalities?

The personality theory produced a literature devoted to the ‘authoritarian personality type’ primarily ignited by Theodore Adorno and colleagues in the 1950s. They argued that early childhood experiences, based on Freudian theory, could be linked to adult tendencies to prefer conservative conventional political views and to favour obedience to strong leaders.

In contrast to this trait or personality basis for behaviour, an alternative tradition developed in the 1960s; this was a situationist school, which preferred to contend that we do what we do because of the predicament in which we find ourselves. We need to refer more to the situation than to the personality.

Stanley Milgram’s ‘obedience to authority’ experiments conducted at Yale University in the early 1960s are perhaps the most famous empirical counter to the authoritarian personality type theory. Milgram found that 65 per cent of ordinary members of the public were willing to administer apparently deadly electric shocks to a clearly distraught victim simply because an authority figure commanded them to. Not all of these ordinary subjects surely could score high on Adorno’s F scale measuring authoritarianism?

Actually, the ‘shock box’ from which the electric shocks were apparently administered was in fact a home-constructed prop, and the ‘learner’ who was being punished for failing to learn was an actor who did not actually get shocked.

But it was not only the result of the experiment that was groundbreaking. That a clear majority of the subjects administered what they believed to be life-threatening 450-V shocks simply because a white-coated authority figure commanded them to was shocking. However, Milgram had pioneered a new experimental paradigm that invoked aspects of theatre in social psychology experiments. It was key to his work that, although the subjects were debriefed afterwards, the experience felt profoundly real and impactful during their time in the laboratory.

However, the field has since been plagued with controversy over the ethics involved in the use of deception and stressful stimuli, and as a result the experimental paradigm that Milgram initiated has not been clearly developed since.

Controversy also remains over the interpretation of Milgram’s results. Are people really as passive in the face of authority as his results indicated? Milgram’s own data revealed that if just one other subject was witnessed rebelling and refusing to obey the experimenter, then compliance rates dropped dramatically in those subjects waiting in line to take part. In the real world, is it not the case that some disobedience to authority is a regular feature of everyday life?

The practical implication is that the key to disobeying authority appears to be to find collaborators, band together and disobey as a group.

Exactly why the passive compliers obey remains controversial to this day. The latest incarnation of a social psychological account is that the subjects who obey do so because they accept definitions of action provided by the apparently legitimate authority figures governing them. So, although it is the subject who indeed performs the final action, they do so only because they have allowed someone else, an authority, to define its meaning.

In Abu Ghraib, for example, the soldiers abusing and torturing prisoners did not define their actions in that way. Instead, they probably saw themselves as defensively trying to save their own country by using legitimate methods to extract information or attain compliance.

The attempt to lay the blame of causation at the door of the situation or the inner drives of the individual relates to a broader field referred to as attribution theory. This is a branch of social psychology that focuses on the nature of explanation for events, particularly human behaviours.

It has been determined that, although there are myriad possible attributions or explanations for behaviours, these...
different explanations can be classified most usefully into three key dimensions in terms of their own impact on our behaviour and attitudes. These dimensions are whether the causes for a behaviour are internal (i.e. you are an aggressive impatient person) or external (the traffic warden was being particularly provocative). Another dimension is stability – will the causes change over time or not? The final dimension is controllability – can you or someone else affect them over time?

CBT for depression is founded partly on the finding that people with low mood tend to make a particular constellation of attributions about the causes of negative life events that may have befallen them recently. These are that the bad thing that happened is down to the individual – ‘It’s my fault, there is nothing I can do about it because I am just that way, and this will continue for ever more.’ Exploring and shifting attributions is theorized to be a key part of producing change in psychotherapies such as CBT.

So, we can see that social psychology has important contributions to make in all branches of psychiatry, from theorizing about aetiology, to pioneering new treatments.

**KEY POINTS**

- Social psychology theories of aggression include the following:
- Frustration–aggression hypothesis – note the contrast with strict Freudian ideas.
- Social learning theory – note the contrast with simple behaviourism.
- Social psychology theories of relationships include social exchange theory.
- The bystander effect predicts some counterintuitive and surprising human behaviour.
- Theories of persuasion include foot-in-the-door and door-in-the-face techniques.
- Cognitive dissonance invokes the drive for consistency as important and predicts some counterintuitive outcomes in attitude change.
- Contrasting approaches to measurement of attitudes include techniques subsumed under the names of Osgood, Likert and Thurstone.
- Response latency and the implicit association test are newer approaches to get past the problem of people telling us what they think we want to hear when we probe their attitudes.
- The halo effect is important in impression management and may derive from evolutionary antecedents.
- Theory of mind has vital influence on sophisticated impression management techniques.
- Interpersonal rejection sensitivity can lead to self-fulfilling prophecy.
- People who tend to be successful in relationships display predictable social psychological personality characteristics and strategies.
- The attainment of interpersonal power can be charted from a social psychological perspective.
- Personal sense of power in the social world produces profound mental health implications.
- Worrying and surprising levels of obedience have been predicted by a variety of social psychological theories.

**REFERENCES**

INTRODUCTION

Social science is a generic term for a range of disciplines that are concerned with structural level processes of a social system and their impact on social organization, social groups and individuals. It includes sociology, anthropology, economics and political science.

SOCIAL DIVISIONS AND THE SOCIAL PATTERNING OF MENTAL HEALTH

The main divisions in British society, as in other advanced industrial nations, are based on social class, gender and ethnicity. These divisions are associated with social inequalities and, to varying degrees, social stratification. Social stratification is the arrangement of individuals into social strata, or layers, in a hierarchy of advantage reflecting their relative power in society. An individual’s location within the social structure affects her or his life chances – the chances of sharing in society’s cultural and material rewards such as education, employment, income and health.

Social class

Social classes may be defined as ‘segments of the population sharing broadly similar types and levels of resources, with broadly similar styles of living and (for some sociologists) some shared perception of their common condition’. In the UK, the most common measure of social class is based on occupation. Socioeconomic status (SES) is a term for a comparable concept commonly used in North America. The National Statistics Socio-economic Classification (NS-SEC), introduced for the analysis of the 2001 Census, groups occupations into 14 operational categories (based on their market positions), which can be combined into eight classes for analytical purposes. These in turn can be collapsed into a five-class version – managerial and professional; intermediate; small employers and own-account workers; lower supervisory and technical; and semi-routine and routine – or a three-class version – managerial and professional; intermediate; and routine and manual.

There are marked social class differences in diagnosed psychiatric disorders, including schizophrenia, alcoholism, drug addiction and organic psychoses, and common mental disorders, with highest rates in the lower social classes. Types of treatment are also related to social class and poverty. People from lower social classes are more likely to be admitted to hospital, to remain hospitalized for longer and to receive physical forms of care such as electroconvulsive therapy (ECT), while people from higher social classes are more likely to be treated on an out-patient basis and to receive treatments such as psychotherapy.

The higher rates of psychiatric disorders among individuals in the lowest social classes are generally seen as the product of the adverse life situations they experience, deriving from economic hardships and the range of negative life events associated with poverty and social disorganization. The consequences of material deprivation include higher stress from crime, traffic, pollution and poor housing. Manual jobs entail little control and satisfaction and are more subject to redundancies, all of which contribute to lower levels of self-esteem.

Class differences in psychiatric morbidity may also arise as a consequence of processes associated with mental illness itself. Individuals who become mentally ill may find it difficult to perform adequately in more skilled and demanding jobs and over time may drift down the occupational hierarchy. This has been noted particularly in relation to individuals suffering from schizophrenia, where downward social mobility has made the class gradient even more marked.

Gender

Gender refers to differences in social characteristics assigned to males and females. Gender roles refer to roles in society typically assigned to men (breadwinner, fighter) or
women (homemaker, carer). Gender stereotypes are preconceived ideas about appropriate styles of behaviour for men (active, aggressive) and women (passive, compliant). The system of male dominance over women is called patriarchy.

In industrialized societies, women generally have lower mortality rates than men but higher rates of morbidity. This is particularly noticeable in relation to psychiatric illness, where women have almost twice the rates of neurotic disorders, affective psychoses and dementia. One set of explanations for these differences relates to women’s disadvantaged position within society generally and the particular nature of their domestic roles. Women have fewer resources and less influence in society and are more likely to be in subordinate and dependent positions. Their domestic roles are characterized by boring, repetitive and non-productive activities, social isolation, and little social recognition or prestige. This produces low levels of chronic stress, the effects of which are exacerbated by the lack of structure in their work, which allows women time to brood over their problems. An increasing proportion of women work outside the home and may benefit from this additional source of rewards, but they may also suffer from the double burden of employment and domestic roles, which generates stress as a result of both role accumulation and role conflict.

Other explanations point to the importance of gender stereotypes in producing higher rates of psychiatric illness among women. One version of this argument suggests that gender role socialization, which emphasizes passivity, helplessness and dependence as appropriate feminine behaviour, produces learned helplessness. This means that women are less able to cope with stressful situations and hence are at greater risk of depression. The other version suggests that higher rates of minor psychiatric morbidity may also be an artefact of women’s illness behaviour. Gender stereotypes may make it easier for women to acknowledge their emotions and to seek professional help when in difficulty, while their roles as mothers and carers may themselves bring them into contact with doctors. Cultural stereotypes may also predispose doctors to diagnose mental illness more readily in women.

‘Race’ and ethnicity

Ethnicity denotes membership of a social group with a distinct culture – expressed in a common language, religion, dress, diet and other symbols – and some sense of a common origin or homeland. It needs to be distinguished from ‘race’, which is a classification system based on visible physical characteristics, and immigrant status, which refers to place of residence. Discrimination based on race or ethnicity is racial prejudice or racism. Institutional racism is the systematic disadvantage of people from ethnic minorities built in to the way institutions operate, which may be unintentional and go unrecognized.

In the 2001 census, 7.9 per cent of the population of England and Wales described themselves as belonging to a non-white ethnic group, and one in 12 of the population was born overseas. Although immigration has occurred throughout British history, since the middle of the twentieth century immigration has involved migrants from further away and with different languages, religions and skin colours. Public policies and attitudes were initially based on assumptions of acculturation – the adoption by people from minority groups of the norms, values and traditions of the host population – and assimilation – the decline of distinct ethnic identities and their social significance. Subsequently there has been greater recognition of multiculturalism – the valuing of the distinctiveness and diversity of ethnic minority cultures – although this in turn is being questioned on the grounds of its perceived consequences for social cohesion.

Compared with people from the white population, people from non-white ethnic minorities have been disadvantaged in a number of ways, for example in relation to education, policing, housing and healthcare. However, there is considerable diversity among ethnic minorities, and this is also reflected in differences in their life experiences. In terms of labour market participation and occupational attainment, for example, Chinese and Indian minorities are doing as well as the white majority, while Pakistani and Bangladeshi minorities are doing significantly worse.

There are striking differences in rates of diagnosed psychiatric disorder between different ethnic groups, with higher rates of schizophrenia among the Afro-Caribbean and Irish populations and lower rates of mental illness generally among the Asian populations. Early explanations for these patterns emphasized the effects of migration, as either selecting for emigration individuals with schizophrenia or a predisposition for schizophrenia or as creating stress among immigrants, which precipitated schizophrenia among those people predisposed to it. With the end of large-scale immigration to Britain in the 1970s and the observation of increased rates of schizophrenia among second-generation British-born Afro-Caribbean people, research has focused more on the responses of the host population, in terms of hostility and discrimination, and the material deprivation, frustrated ambitions and social stress they produce.

Alternative approaches point to the way social and cultural factors affect both the expression and the recognition of mental illness. For example, noisy, antisocial behaviour in public is likely to attract the attention of the authorities, as is black skin colour. Young male Afro-Caribbeans in Britain are much more likely than their white counterparts to come into contact with psychiatric services through the police and more than twice as likely to be admitted as a result of a compulsory detention order and to be detained in locked wards. For a doctor who does not understand the person’s cultural beliefs or practices, it may be difficult to determine whether problematic behaviour is evidence of schizophrenia or any of the other possibilities (e.g. religious fervour, youthful rebelliousness, criminal intentions).
Similarly, doctors, particularly inexperienced general practitioners (GPs), may find it difficult to understand the significance of symptoms presented by Asian patients from cultures where depression and anxiety are somatized and much morbidity may go unrecognized. In addition, mental illness carries a particularly high degree of stigma in some cultures, which discourages seeking help from the health services and means that, especially among women, minor psychiatric morbidity may be contained within the nuclear or extended family. These considerations taken together have led some authors to argue that misdiagnosis is common and that the pattern of mental illness among ethnic groups presented by official statistics is a distorted and unhelpful representation of psychiatric need.5,19

ILLNESS IN SOCIETY AND THE SOCIAL ROLE OF MEDICINE

The sick role and the doctor–patient relationship

Illness may be regarded as a form of deviance in as much as it inhibits an individual's ability to perform his or her usual social roles and hence disrupts the smooth functioning of society.20 In order to cope with this threat to social order, society must develop mechanisms of social control to keep the deviance within manageable bounds and to return the individual to normal social roles. This it does by creating an approved social role for the deviant – which Parsons called the 'sick role' – and by recruiting others to a reciprocal social role – that of the doctor – to help the deviant return to normality. The doctor and patient may thus be seen as occupying a pair of reciprocal and complementary roles that share the same aim of returning the patient to normal social functioning.

Parsons went on to specify the reciprocal rights and obligations of doctors and patients. He saw the sick role as an essentially undesirable, temporary role that imposes on the individual entering it the obligation to leave it as soon as possible. To this end, patients are accorded two privileges: they are allowed to shed normal roles and responsibilities (e.g. work roles or household responsibilities), and they are regarded as being not responsible for the illness (relieving the individual of any sense of moral culpability and allowing the disavowal of inferiority) and as being in need of care in order to return to health. These privileges confer considerable benefits on patients and are thus conditional on them accepting other obligations: they must want to get well as soon as possible and must seek help from the doctor to achieve this; and they must then cooperate with the doctor in his or her investigations, accept the doctor's advice and follow the doctor's recommended treatment. Failure to fulfil these obligations may lead to the label of 'malingering' and the withdrawal of the benefits of the sick role.

Parsons viewed the doctor as society's gatekeeper, determining the official labelling of conditions as 'health' or 'sickness' and thus controlling access to the sick role. The medical profession alone has the authority to legitimize an individual's claim to illness or, conversely, to impose on an individual the diagnosis of illness. This may be particularly important in relation to psychiatric disorders, where conditions may be ill-defined, ambiguous or contentious.

Parsons described the doctor's role as complementary, but not equal, to that of the patient. Whereas the patient is expected to cooperate with the doctor, the doctor occupies a position of authority in relation to the patient. The doctor is given the right to examine the patient physically, to enquire into intimate areas of the patient's life, and to exercise considerably autonomy in their professional practice. In return for these rights, the doctor is expected to apply their specialist knowledge and skills for the benefit of the patient and community and to follow the rules of professional practice. The potential tensions arising from the personal nature of medical practice are reduced by the further obligations on the doctor to remain objective and emotionally detached and to use their privileged position for the benefit of the patient and not for personal or professional advantage.

Although Parson's analysis has proved extremely useful to understanding the social role of medicine, it has been widely criticized for placing too much emphasis on the consensus between doctors and patients. Friedson, by contrast, emphasized the differences in knowledge, interests and expectations that can lead to tensions and conflict between doctors and patients.21 Conflicts may arise, for example, between the competing interests of individual patients (e.g. for the doctor's time and attention); between the interests of a patient now and in the future (e.g. between the immediate relief provided by tranquillizers and the long-term potential for dependency); between the interests of the patient and the interests of the patient's family (e.g. in deciding on whether to hospitalize a depressed patient); and between the doctor's duties to the patient and the doctor's duties as an agent of the state (e.g. in deciding whether a stressed patient's request for a sick note for time off work is warranted or not). This model suggests that the face-to-face consultation between doctor and patient may be understood as a process of negotiation, with both the doctor and the patient having their own agenda and using interaction strategies in an attempt to achieve their objectives.22

Illness behaviour and the clinical iceberg

Parson's formulation of the sick role assumes that individuals who experience illness seek professional help as soon as possible. A number of empirical studies, however, have shown that patients are much more likely to deal with their symptoms themselves, either ignoring the symptoms or using non-prescribed medicines, alternative practitioners or self-help groups, and only rarely consult a doctor. The vast amount of illness in the community, unseen by the medical
profession, is known as the clinical iceberg. Much mental illness, because it is highly stigmatizing, is likely to remain unrecognized and untreated in the community.

Whether and when individuals seek help from a doctor depends on a number of factors, both in their social environment and in the organization and provision of healthcare services. Mechanic used the term ‘illness behaviour’ to describe the way individuals perceive, evaluate and act upon pain, discomfort or other signals of organic malfunction. Illness behaviour is influenced fundamentally by the social meanings attributed to symptoms, often by friends or colleagues, who may constitute a lay referral network, which suggest appropriate ways of dealing with them. Most symptoms tend to be normalized – that is, seen as the expected consequences of everyday life – and adjustments made to accommodate them. For example, families of schizophrenic patients have been found to tolerate symptoms for considerable periods, defining the symptoms as signs of malice or religious zeal and compensating for them by altering their own behaviour and expectations. Help may be sought only when something happens to disrupt this pattern of accommodation. The kinds of thing that happen to cause this are known as triggers to action. Zola identified five such triggers – interference with work; interference with personal relationships; sanctioning; interpersonal crisis and temporizing of symptomatology – and argued that doctors need to understand and address these contextual issues as much as the symptoms themselves.

The way healthcare services are organized and provided can also influence illness behaviour by altering the balance of perceived costs and benefits of seeking medical help. A range of social and psychological costs to patients may be reduced by changing the times and locations of clinics – for example, siting them in health centres rather than in hospitals – or by altering the attitudes and responses of clinic staff.

Mental hospitals and the sociology of residential institutions

Goffman used the term ‘total institution’ to describe places such as large mental hospitals where inmates are segregated from the wider society and live in a social world of their own. In total institutions, all aspects of life are conducted in the same place and under a single authority. Daily life is characterized by batch living, with activities carried out as part of a group and the usual distinction between work, leisure and home life removed. A clear differentiation is made between the managers and the managed (binary management) and the behaviour of inmates is highly regulated. There is an institutional perspective and hence the assumption of an overall rational plan.

Institutionalization is the process whereby individuals admitted to large institutions gradually withdraw from normal life and become dependent on the structures of the institution. It starts with admission procedures and continu-
refers to the process of expansion by which more and more areas of life become subject to medical definitions and management. Aspects of daily life become defined as illnesses (e.g. anorexia, alcoholism) to be treated and cured and individuals turn to their doctors for solutions (e.g. tranquillizers, diet pills) to their problems of living. Medicalization increases the remit of the medical profession and, through the sick role, diminishes the responsibility of the individual. Public morality in areas of personal behaviour is maintained, but under the auspices of medicine rather than religion or the law.

Psychiatry has been a particular target for critics of medicine, who see psychiatry as an institution of social control. In his historical analysis of the origins of mental hospitals, Foucault saw asylums as representing a new age of incarceration and the new medical discourses – which presented ‘reason’ as the source of healthy civilization and ‘madness’ as a sickness to be cured – as part of the process of normalization and self-discipline. Foucault rejected the notion that asylums arose from a desire to provide more humane care for ‘mad’ people and instead saw them as a way of persecuting those people who did not act rationally and as reinforcing social control. They served the interests not of the patients but of the professions and bureaucracies whose authority was grounded in the dominant discourses of an increasingly rational world.

Kennedy developed a somewhat different argument in relation to twentieth-century practices, making the case that, by defining deviant behaviour as illness and offering to cure it, the psychiatric profession helps to reinforce accepted ways of thinking and legitimates the punitive treatment of people who do not conform. The fact that many people are being treated in hospital not because they want to be there but because others such as relatives, neighbours or the police want them there has been taken to indicate that psychiatric legislation and psychiatry are much more about the social control of people whose behaviour is causing problems for others than they are about caring for sick people themselves. According to Szasz, the myth of mental illness persists in modern societies not because of its scientific validity but because it is such an effective means of social control.

FAMILIES, FAMILY LIFE AND EXPRESSED EMOTION

There is a growing diversity in the forms of family and household arrangements in contemporary Britain, with increases in the proportion of people living in households comprising single people, cohabiting couples, lone parents and dependent children, and step- or reconstituted families (a couple living together with children from one or more previous relationships). This diversity is the result of a number of current demographic trends, most notably the decline in marriage and increase in cohabitation, the rising rates of birth outside marriage, and the increase in divorce and remarriage. These trends in turn can be seen as reflecting the effects of an increasing individualism or individualization of society – the breakdown in normal social constraints and fixed guidelines for living, and the opening up of greater individual choice in the way individuals can lead their lives. Although this widens the scope for individuals to pursue personally fulfilling goals, greater choice also creates greater uncertainty and the potential for conflict within relationships. These changes have significant implications for mental health: lone-parent and reconstituted families have been shown to experience more life events in their own lives and in the lives of friends and relatives, while two-parent families provide greater protection from economic hardship and two- (birth) parent families provide greater family support.

Family relationships and environment have also been shown to affect mental health, most notably in relation to expressed emotion (EE). Expressed emotion is a construct encompassing critical, hostile or emotionally overinvolved attitudes on the part of a family member towards a relative with a disorder or impairment. Although EE is now a well-validated predictor of poor clinical outcome for a wide range of psychiatric disorders, it was originally developed as a measure of the emotional climate of families of schizophrenic patients who had been discharged from hospital, demonstrating that high levels of EE were related significantly to higher rates of relapse. Early conceptualizations of EE focused on the contrasting styles of low-EE families (tolerant, non-intrusive, sensitive to patient needs) and high-EE families (intolerant, intrusive, adopting inappropriate and inflexible strategies in dealing with difficulties). More recent work has focused on the role of attributions in understanding differences in the way families respond to patients, and evidence is accumulating that critical relatives are more likely than non-critical relatives to hold patients responsible for their difficulties.

SOCIAL FACTORS AND MENTAL ILLNESS

Social factors are aspects of the social environment that elicit recurrent stressful experience and increase risk of physical and mental illness. Social factors commonly associated with the onset of a broad range of psychiatric disorders include low educational attainment, unemployment, poverty, poor housing, family breakdown, family dysfunction (e.g. childhood abuse, neglect, domestic violence, substance misuse) and neighbourhood disorganization (e.g. drugs, crime, urban decay).

An important mediating factor is social support – the ties that an individual has with other people or groups that provide a sense of self-worth (of being loved and valued) and other resources. Social support includes instrumental, informational, appraisal and emotional dimensions. It acts to
buffer the negative effects of social adversity and to reduce the likelihood of subsequent psychiatric disorder by enhancing adaptive coping. Social capital is a related concept at a neighbourhood level that refers to aspects of social organization, such as trust among neighbours, norms of reciprocity and group membership, that facilitate collective action.

Depression

Research on social factors and depression has focused on life events and social support. Life events are sudden changes, positive or negative, which disrupt the normal course of an individual’s life. By disrupting social life to the point where previous norms and values are no longer appropriate, severe events may give rise to anomie or a sense of normlessness. Brown and Harris initially argued that it is only this type of event – life events that involve long-term threat – that is important in the onset of depression in women. This points to the importance of the meaning of events, which can be determined only by considering them in the context of individual lives. For example, the birth of a baby has different meanings for a middle-class couple with a house and a garden and for a woman living in a bed-and-breakfast accommodation with two other children and whose partner is in jail. In recent refinements of their work, Brown and Harris have identified losses involving humiliation or entrapment as particularly important in the onset of depression and ‘fresh start’ experiences (which promise new hope) as important in remission.

Brown and Harris also argue that the influence of life events depends on the existence of vulnerability factors, which increase susceptibility to depression. These include loss of mother before 11 years of age; absence of a confiding relationship with a partner; lack of employment outside the home; and three or more children under 15 years of age living at home. Vulnerability factors contribute to low self-esteem, which reduces the ability to cope with life events and reflects low social support. Working-class women are likely to experience higher rates of both severe life events and vulnerability factors than middle-class women.

Schizophrenia

The most convincing evidence for the role of social factors in schizophrenia comes from research in a number of European countries that found high rates among first- and second-generation immigrants from a wide range of ethnic and geographical backgrounds. According to Cantor-Graae and Selten, the most likely explanation for markedly raised rates of schizophrenia in such disparate groups as Africans and Greenlanders is chronic experience of discrimination or long-term exposure to social defeat. These authors base their argument on the observation that the relative risk of schizophrenia is especially high in groups with black skin colour and originating in a developing country or of second-generation immigrant status (for whom being treated as an ‘outsider’ in their country of birth may be particularly distressing). Incidence rates in this population are lower in neighbourhoods with higher proportions of ethnic minority residents, most likely because of the protection they offer against discrimination and isolation. The social defeat hypothesis also proposes that stress related to social rank may be particularly harmful.

In non-immigrant populations, urban birth or upbringing, social and material deprivation, childhood victimization, substance misuse (most notably cannabis use in adolescence) and ‘psychotogenic’ neighbourhoods have been shown to be related to raised incidence of schizophrenia.

Alcohol and illicit drug addiction

Although growing medicalization of everyday life is reflected in the range of behaviours that are now regarded as addictive, including shopping, computer games, the Internet and sex, addiction to or dependence on alcohol and illicit drugs remains the main focus of public concern. Alcohol consumption and drug-taking are most likely to start in adolescence, but progression to dependence or addiction is less common. Men are more likely than women to have illicit drug and alcohol problems, possibly because they are exposed to heavier alcohol use and more drug-taking, although this may be changing.

Problematic substance misuse is more likely to take root in deprived neighbourhoods where local people feel cut off from mainstream society and powerless to change their environment; where selling illegal drugs can appear to be an efficient way of earning a living; and where law-breaking and violence associated with drug-dealing and drug-using may seem glamorous and attractive. Substance misuse is also associated with poor attachment to or communication with parents; childhood conduct disorder; and low school grades, truancy and exclusion from school. Many illegal substances are expensive and need to be acquired through illegal means, resulting in high rates of criminality and periods in prison among problematic substance users. Substance misuse is also associated with increased levels of violence and the risk of danger to self and others.
longer integrated into society and are excluded from adequate social participation. This is known as social exclusion, a concept that conveys the multiple, complex and interlocking social problems experienced by people with mental health problems.45

DEVIANCE, STIGMA AND PREJUDICE

The process of socialization means that members of a social group are likely to share similar conceptions of appropriate attitudes and behaviour, but it does not mean that all think or act in a way that is acceptable to the group. Behaviour that contravenes the norms of the group is considered deviant behaviour. Deviance can be defined only in relation to some notion of normality, and one of the functions of identifying deviant behaviour is to clarify norms and values and to reinforce definitions of normal behaviour. However, in the context of late modernity – where established ways of doing, thinking and being are constantly questioned and social life is characterized by ambivalence, insecurity and disorder – distinctions between normal and deviant behaviour may be increasingly difficult to make.

Deviance that contravenes fundamental social values attracts particular social disapproval and may be stigmatizing. Goffman defined stigma as an attribute, trait or behaviour that is considered shameful or disgraceful and that symbolically marks the possessor as unacceptable, inferior or dangerous.46 In a society that values rationality, control and achievement, psychiatric disorders carry strong negative meanings and are highly stigmatized.

Deviance that is immediately visible to others, such as psychotic behaviour, is discredited and creates problems for the stigma bearer in ‘the management of tensions’ generated during social interaction. Deviance that is not immediately visible, such as a diagnosis of schizophrenia, is discreditable and requires the stigma bearer to ‘manage information’ about the stigmatized attribute (e.g. through ‘passing’ as normal, ‘covering’ or withdrawal). Enacted stigma refers to a stigma bearer’s experience of discrimination; felt stigma refers to the fear of discrimination and is more prevalent, and hence more disabling, than enacted stigma.

Individuals who are stigmatized are perceived in terms of a stereotype – as an example of a ‘type’ of individual – that has negative connotations. The stereotype evokes emotional reactions in others, such as fear, contempt and disgust, and a social response of distancing, rejection or withdrawal. As a result, the stigmatized person is set apart and may feel depersonalized, rejected and disempowered. Pilgrim suggests that the basis of the prejudice against people with mental health problems is a cultural stereotype that incorporates a lack of intelligibility, a lack of social competence and the presence of violence.47

PRINCIPLES OF CRIMINOLOGY AND PENOLOGY

Criminology and understanding crime

Criminology is concerned with the causes, consequences, forms and incidence of a particular category of deviance – crime. Crime is difficult to define as it is impossible to identify activities that would be regarded as criminal in all societies at all times.48,49

Although early criminological research attempted to identify what distinguished criminals from non-criminals in terms of biological or personality characteristics or psychopathology, more recent research has been concerned with explaining the causes of criminal behaviour.

Functionalist theories see deviance and crime as an inevitable and integral part of society and look to explain excessive levels of crime. Merton’s strain theory suggests that, in any particular society, the scope and character of deviance will depend on how well society makes cultural goals (e.g. financial success) accessible to its population by providing institutionalized means (e.g. schooling, job opportunities) to achieve those goals.50 The disparity between what society expects individuals to achieve and what individuals come to realize they will actually achieve creates strain (which Merton called anomie). Where structural inequalities prevent individuals from achieving their goals through legitimate means, some individuals will turn to illegitimate means – crime – in order to achieve them; others will reject society’s goals and the conventional means of achieving them and retreat into deviant or unconventional subcultures; and others will go further, rebelling against both the goals and the conventional means of achieving them and advocating radical alternatives to the social order.

The theory of deviant subcultures suggests that delinquency among working-class youths is a consequence of status frustration and a reaction against the norms of middle-class society. Cohen suggested that working-class boys are alienated and frustrated at school and so seek self-respect by building a deviant subculture.51 Others have argued that an individual’s tendency towards conformity or deviance depends on the relative frequency of association with other people who encourage conventional or deviant behaviour (peer pressure) and that criminal deviance results in part from the availability of opportunities for illegal behaviour.

Interactionist theories focus on the complex process of becoming a deviant or criminal. Labelling theory draws attention to the importance of reactions of other people to deviant behaviour in ‘creating’ deviance.52 Most deviant behaviour is normalized and accommodated (cf. illness behaviour) until something happens to make it intolerable to others (e.g. it becomes more visible or threatening). At this point, it may be labelled as one of a number of types of behaviour, including criminal behaviour and mental illness.
Labelling refers to the process whereby individual characteristics are identified and given a particular meaning by other people. Both convicting an individual and giving a diagnosis are acts of labelling primary deviance. Secondary deviance (or deviance amplification) refers to the change in behaviour that occurs as a consequence of labelling. Once an individual has been convicted of a crime or diagnosed as mentally ill, social expectations promote behaviour that conforms to this label. In this sense, agencies of social control (e.g. law, medicine) act as amplifiers or even manufacturers of deviance. Labelling individuals in this way has a profound effect because deviance is a master status that overshadows other aspects of identity. It also creates outsiders and may provoke individuals to adopt a deviant lifestyle and begin a deviant career.

Critical criminology and conflict theorists see crime not as a problem of individual offenders or strains in society but as a process related to wider economic and political structures of power. They are concerned with exploring why and how the activities of some groups – for example, black working-class youths – come to be subjected to criminal law and question the way in which mechanisms of social control are used.48 Theories based on classical Marxism focus on the way in which social norms and laws support the interests of the rich and powerful, while the new criminology focuses on the various ways in which capitalism itself produces crime and criminals.53

A further development is left realism, which takes seriously the impact of crime on victims and seeks to produce realistic ways of dealing with crime.54 It sees deep structural inequalities as the root cause of crime and focuses on the ‘square of crime’ – the state, society, offenders and victims – each element of which, and their interrelationships, must be explored and addressed.

Penology and the principles of punishment

Penology is the study of punishment imposed by the judiciary in accordance with penal law and administered by penal institutions. In liberal democratic societies, such punishment generally equates to some form of deprivation, which may entail the loss of liberty (curfew, imprisonment), time (community service), money (fines, compensation orders) or reputation (‘naming and shaming’).

There are four types of justification for judicial punishment.59 Three are concerned with preventing future crimes and reflect utilitarian and consequentialist philosophies and reductivist aims:

- **Deterrence** aims to prevent criminal activity through the development and application of effective and efficient sanctions. It is based on the assumption that criminal behaviour is rational, self-interested and freely chosen, and that the wellbeing of the community can be protected by providing rational individuals with good reasons not to commit crimes. Critics point to the limited conception of human action and the lack of attention to social and material context. In addition, punishment may be a deterrent only when apprehension and conviction are certain, punishment is severe and the link between the crime and its punishment is clear to the offender.
- **Rehabilitation** has the aim of reintegrating the offender into society after a period of punishment and so requires that the content of the punishment is designed to achieve this end. It is based on the belief that change and improvement are possible (through a range of interventions, including individual and group therapy, education and training) and that crime is best prevented by addressing directly the social, economic and personal factors that are the causes of crime. Critics point to limited evidence of its effectiveness or object on moral grounds to the deterministic view of human behaviour and the social engineering approaches to behaviour change that it implies.
- **Incapacitation** has the aim of protecting potential victims, and the community more generally, by removing the offender’s ability to commit further crimes through some form of incarceration or, at the extreme, capital punishment. Selective incapacitation is based on the view that a small number of offenders commit a relatively large amount of crime and involves identifying those offenders likely to re-offend and giving them long prison sentences. Critics point to the difficulty in predicting who will re-offend (and hence how much crime will be prevented) and question the justice of punishing someone not for what they have done but for what it is thought they might do if left at liberty.

The fourth type of justification for judicial punishment – retribution – is concerned solely with punishing crimes that have already been committed. It is based on the view that, in committing a crime, the offender has disturbed the moral equilibrium of the community and that, in order to restore that equilibrium, the offender must be identified and punished. In other words, society has a moral obligation to punish wrongdoers, and wrongdoers deserve their punishment. The punishment should always fit the crime and should be proportionate to the harm done rather than adjusted to the circumstances of the offender. Critics argue that it is, in essence, simply a primitive demand for vengeance and that it is not morally justifiable to inflict punishment for its own sake when no positive good can be achieved.

Rather than trying to define a good justification for punishment, some penologists question its necessity or desirability as the usual response to crime. Abolitionists have advocated the abolition of the death penalty or imprisonment as a response to all but exceptional crime. The restorative justice movement aims to abolish not only imprisonment but punishment generally, seeking to shift the focus from the offender to the victim, with the intention of securing recompense and reconciliation between offender and victim.
KEY POINTS

- There are marked differences in rates of mental illness by social class and, for particular conditions, by gender and ethnicity.
- Type of treatment differs between social classes, with higher rates of hospitalization and physical treatments among people from lower classes.
- Social factors play a significant role in the onset of a wide range of mental health problems.
- Mental illness and criminal behaviour are forms of deviance. Medicine and the law are key social institutions for controlling deviance.
- Stigma is an attribute that is considered shameful and marks the possessor as inferior or unacceptable.
- The stigma of mental illness contributes to discrimination, social and material disadvantage, and social exclusion.

REFERENCES

INTRODUCTION

Culture plays a significant role in people’s lives. The way people dress, behave, eat, drink and generally deal with emotional distress and idioms to express their distress are all influenced by culture. Culture and society define what is deviant and what is normal and where and how people seek help. In this chapter we propose to define culture and to describe its impact on mental illness and its management.

THEORETICAL BACKGROUND

What is culture?

The word ‘culture’ has been described as ‘one of the two or three most complicated words in the English language’, and as a result many misunderstandings ensue. It has been described as being used in three main ways:

- Culture as a supposed ‘civilizing’ process, from migratory to agrarian to urban societies, which have become more cultivated in a historical sense, or contemporaneously of an artistic or rarefied existence. Both imply that a higher or better level has evolved.
- Culture as collective identity with the setting apart of one group of people from another on the basis of historical lineage, language, religion, gender or ethnicity.
- Culture as it is currently used in anthropology, as a ‘way of life’, with all the norms, values, customs, beliefs and practices that form a complex system.

We all carry different cultures with us, such as cultures related to gender, specialties and work-related milieu. Conflation of these different ways of looking at culture can lead to problems. The first definition is often associated with notions of class and superiority. However, the other definitions also use different sources of identities to create complex levels of influence. Cultural identity is fluid and changes with exposure to other cultures and different components work at different levels. For example, an Indian person may well behave differently in an Indian formal setting than in a formal British setting.

An individual’s culture consists of different elements, including age, gender, nationality, ethnicity, language, religion, politics, sexual orientation and career. Some elements may have stronger meanings than others. The term ‘subculture’ is also used without an exact definition. There are important components in the construction (Table 22.1).

Table 22.1 Summary of important components in cultural identity construction

Variations in presentation of any health issue can be influenced by a variety of different forces in an individual’s identity, as represented in Figure 22.1.
We will argue that culture, made up of many aspects of these, forms a strong mediating role in the presentation, identification and management of mental health problems.

Key concepts in cultural psychiatry
In the history of cultural psychiatry, the argument between universalism and relativism across cultures is relevant in our understanding of the role of culture in the genesis and presentation of symptoms.

Universalist position
This is often taken by psychiatrists and argues that people are primarily of one type, i.e. one species. It is at this level of ‘sameness’ that most of the aetiological factors influencing mental disorders act. All members of the species are potentially affected by these genetic or environmental pressures, which result in variation. The symptoms of a disorder, its course and its outcome are taken to have a ‘normal expected’ path, with deviation from it explainable by the lesser effects such as social pressures.

Relativist position
This is the position espoused by many anthropologists, who argue that people are one species but are also members of many other groupings. It is at these lower-than-species level groupings that aetiological factors influencing mental disorders can act. Variation may be due to cultural pressures against which different individuals or different groups may react differently. As such, the symptoms of a disorder and its course can have many different understandable outcomes, with any attempt at creating a ‘normal’ outcome resisted. Attempts at understanding the process can be done only by also recognizing the relative position of the observer.

Psychiatry is affected by the contemporaneous socio-political context. Many of the early works on phenomenology were influenced by the colonial activities of European nations of the time. Imposition of European-style management of psychotic mental disorders occurred globally, and asylums for the custodial care of the long-term mentally ill were built. Orientalist understanding of the presentations of mental disorders also occurred and in various forms remains today. Kraepelin concluded that his basic forms of dementia praecox existed in Javanese people, ‘though racial characteristics, religion and customs’ might modify their clinical manifestations.5 It was assumed that there was a fully explainable biological causative pathway for mental disorders, with culture playing a peripheral pathoplastic effect. Now this is viewed as naive.

Cultural psychiatric studies, along with many others, spent much of the latter part of the twentieth century adjusting to this legacy. The civil rights movement in the USA successfully challenged the notion of racial supremacy within the West, even if its impact is still ongoing today. Various guises of sociopolitical accommodation of immigrant groups across Western Europe and the USA have also resulted in the advancement of concepts that help to explain aetiology of mental disorders. In particular, the concept of acculturation is important and defined as ‘the process of cultural and psychological change that takes place as a result of contact between cultural groups and their members’6.

This contact can be brief, such as a holiday, be the result of a war, conquest or colonization, or be the result of immigration processes. A relationship between assimilation and integration between different groups is represented in Figure 22.2.

From the 1960s onwards, large cross-national epidemiological studies were undertaken under the auspices of the

---

Figure 22.2 Acculturation strategies in ethnocultural groups and in the larger society. Based on John Berry’s model of acculturation.
World Health Organization (WHO). Such universalist ventures occurred while anthropological concepts were influencing psychiatric practice.

**Etic**

This description accounts for culturally neutral observations, in which the same entities can be identified across different cultures. The term is derived from linguistics and is short for phonetic, i.e. ‘sounds like’. The WHO’s multi-country studies on a number of psychiatric conditions are more etic in origin. They are useful in understanding the application of epidemiological methods. They have significant face validity because, in every culture that has been studied, clusters of symptoms such as feeling bad or hearing voices have been described.

**Emic**

This description accounts for culturally meaningful observations, which grow out of the culture and vary between cultures. This is derived from linguistics too and is short form for phonemic. More emic traditions also exist. The advocacy by Kleinman of a philosophical category fallacy for phonemic. More emic traditions also exist. The advocacy by Kleinman of a philosophical category fallacy in psychiatry is the most famous relativist critique. It argues against the presumption that psychiatric categorizations have the same meaning between cultures.

Tseng highlights differences in various roles that culture plays in relationship to psychiatric disorders. The impact of culture on psychopathology has also been classified in a further way, depending on how causative or associative it is seen to be (Table 22.2).8

Table 22.2 Summary of Tseng’s description of effects on psychopathology

<table>
<thead>
<tr>
<th>Effects</th>
<th>Description</th>
</tr>
</thead>

**CULTURE AND MENTAL DISORDERS**

In this section we illustrate some of the cultural factors in major psychiatric disorders.

**Schizophrenia and psychoses**

Because of the perceived importance and striking pathology, schizophrenia was the first of the mental disorders to be studied across cultures. Determining the homogeneity of the pathophysiological process is a major difficulty due to the lack of an objective test. There is little doubt that a relapsing and remitting psychotic condition occurs in all human cultures of a sufficient size that have so far been studied. Positive symptom constellations are similar across cultures, namely hallucinatory voices in the third person, thought withdrawal or broadcast, and the sense of surroundings being imbued with special meaning. Negative symptoms also display commonalities across cultures, including psychomotor poverty, social withdrawal and amotivation. Age and sex distribution also appear similar.

Two major large-scale studies occurred in the 1960s – the International Pilot Study of Schizophrenia (IPSS)9–11 and the Determinants of Outcome of Severe Mental Disorders, a WHO ten-country study.12–14 These were some of the first key studies to gather information in an epidemiologically valid way, reducing but not eradicating observer bias through the use of standardized assessment tools. They looked for and found commonalities but ignored differences in their discussion of the implications of their findings. However, it is in those differences that greater understanding of the actual disorder process may occur.

**Comparison of rates of schizophrenia**

It is important to stress that the rates show variation according to methodologies. The following rates are summarized in greater detail in other work.15

**Prevalence**

- Developed country studies: 2.4–7.0 per 1000.
- Developing country studies: 1.4–7.3 per 1000.

**Incidence**

The time at which symptoms reach a threshold of recognition is prone to significant national and cultural variance. Based on International Classification of Diseases, version 8 (ICD-8) or version 9 (ICD-9) ‘broad’ definitions of schizophrenia, the incidence is between 0.17 and 0.54 per 1000 population per year. Using the more restrictive Diagnostic and Statistical Manual, 3rd edition (DSM-III), 3rd edition revised (DSM-III-R) or fourth edition (DSM-IV) or ICD-10 criteria, it is two to three times lower.

Two systematic reviews of the literature highlight considerable variation in schizophrenia rates across countries,16,17 but less variance is demonstrated than in other medical conditions such as insulin-dependent diabetes mellitus and
multiple sclerosis. Causative or protective influences in the development of schizophrenia may be hypothesized following identification of characteristics of groups with high or low rates.

**Low rates of schizophrenia**
The Hutterites in South Dakota are a close-knit Protestant community of 35,000 people originally descended from about 90 forebears. A lifetime prevalence rate for schizophrenia of 1.1 per 1000 was recorded and replicated. Several causes have been suggested:

- Genetic, due to a low frequency of psychosis-predisposing alleles
- Social/cultural, due to protective community support factors
- Social/cultural, due to a negative selection of individuals with schizoid traits unable to tolerate the communal lifestyle leaving the group.

Low rates have also been recorded in aboriginal Taiwanese people compared with mainland Chinese people who migrated to the island after the Second World War. Two studies show rates of 2.1 and 1.4 per 1000 population, respectively.

**High rates of schizophrenia**
Two to three times the national rate have been found in certain population isolates in northern Sweden and several areas of Finland. High estimated lifetime risks for schizophrenia – recorded as 2.77 per cent for males and 1.99 per cent for females – were reported from the Palau islands in Micronesia. The highest lifetime risk estimate for schizophrenia at 4.95 per cent was recorded in a community in Dagestan, in the Russian Federation. There are also data showing high rates of schizophrenia in both immigrant and subsequent minority ethnic communities (Table 22.3).

</table>

Migration stress as a direct cause has been advanced, as several studies have shown lower rates of schizophrenia in the home countries of the Caribbean. However, simple migratory stress is not the whole answer. There is an additional explanation that needs to be explored. From Odegaard’s work onwards, the rates have been higher in migrants, but after they have been in the new country for long periods rather than an immediate development of illness, indicating that migratory stress may not work in isolation. There is no evidence that these psychotic events are somehow different from the normal course of a psychotic disorder. No other links with other biological explanations – such as increased obstetric complications or increased maternal influenza rates – have been found. A further complicating factor against a pure migration stress theory is that increased rates of schizophrenia occur in siblings of second-generation Afro-Caribbean individuals with schizophrenia when compared with white British individuals with schizophrenia. Of further concern remains the distinct possibility of continuing observer bias difficulties demonstrated in one study showing significant diagnostic disagreement between a Jamaican and a British psychiatrist.

The Aetiology and Ethnicity in Schizophrenia and Other Psychoses (AESOP) study is a large, ongoing, first-presentation study based in London, Nottingham and Bristol in the UK and has revealed similar findings (Table 22.4).

Given these data, a variety of explanations have been advanced, including lack of supportive community structures, lack of stable family structures, lower social capital (the concept that social networks have value and give advantage in some way to individuals possessing them), acculturation stresses, trans-generational acculturation processes, demoralization due to racial discrimination, institutional racism, and blocked opportunity for upward social mobility.

Table 22.4 Summary of major Aetiology and Ethnicity in Schizophrenia and Other Psychoses (AESOP) study findings

- Two-fold increase in rate of psychosis in London compared with in Nottingham and Bristol, adding an extra dimension to urbanization hypotheses
- Nine-fold increase in rates of psychosis in Afro-Caribbean people and six-fold increase in black African compared with white British counterparts
- Afro-Caribbean and black African individuals are far more likely to be detained at first presentation and more likely to access care via police rather than GP
- Detection of an association between early separation, parental loss and social isolation and development of psychosis
Culture and mental disorders

Part 2: Developmental, behavioural and sociocultural psychiatry

changing culture in response to urbanization and industrialization, and it may well also indicate changing social mores, with changes in socioeconomic and educational status.

Although genetic variations may account for some of the differences, psychosocial and cultural factors have been proposed to play a role in the outcome, such as close-knit family/communities in sociocentric non-Western countries where the social expectations are from the kinship rather than from the individuals; family set-ups where less able individuals may be looked after; higher rates of marriage and resulting support in developing nations; acute onset in developing nations, with possibility of organic and infectious agents playing a part; higher individual–environment fits that minimize social isolation and withdrawal in developing nations; and lower incidences of chronic stressors associated with developed market economies.

The influence of expressed emotion (EE) as a predictor of psychotic relapse was investigated in the WHO ten country study.49 It was noted that EE was as effective at predicting a relapse in Indian as European or North American families, but that it was in itself a much rarer phenomenon in India, thus demonstrating a potentially strong candidate for a cultural precipitant.

Affective disorders

Affective disorders are common in all cultures, but their presentation is likely to be affected by cultural factors too, in that mania or depression will carry with them different cultural symbolism. The majority of this section is devoted to depression, although some evidence is also available on mania and bipolar disorders across different cultures. A contemporaneous study to the IPSS found that rates of mania occurred at similar rates across countries.50

Comparison of the content of symptoms of schizophrenia

The WHO ten-country study noted that variations in the type of the disorder occur in different cultural settings (Table 22.5).13

The pathoplastic influence of culture on specific psychotic symptoms is undoubted. However, for both delusions and hallucinations, further influences have been identified. A developing/developed nation dichotomous split is an oversimplification, with religion playing a strong cultural mediating role.

Delusions

Religious delusions and delusional guilt are common in Christian culture but less frequent in Hindu, Buddhist and Islamic societies.45 The same study demonstrated that delusions of grandeur were rarer in village communities, where it was postulated as wrong to strive for a higher level.5 In the IPSS study, persecution was the most common delusional theme, but Pakistan (the only Islamic country in the study noted above) showed far fewer religious, grandeur and guilt themes. The religious delusions centred on Djinn possession. Prophet-type delusions, common in Africa, were virtually absent from Pakistan, where they are far less culturally sanctioned.45

Hallucinations

Visual and tactile hallucinations appeared more frequently in individuals from Africa and the Middle East than in those from Europe.46 Higher rates of auditory and visual hallucinations were also recorded in non-European patients compared with English and other European patients in a study in London.47 Furthermore, Pakistanis in Pakistan reported higher rates of visual and lower rates of auditory hallucinations than British Pakistani or white British people in the UK.48

Comparison of the outcome of schizophrenia

Since the early twentieth century, it has been proposed that a less disabling course of the disorder played out in developing nations. The WHO multicentre studies appeared to confirm this, with the IPSS showing better outcomes for patients from India, Colombia and Nigeria in a range of measures.9,10 The WHO ten-country study confirmed these findings with the data shown in Table 22.6.13

However, developing nation status may simply be an artefact to some other aspect of culture. It may reflect

</table>

Comparison of rates of depression

Cross-community comparative psychiatric surveys demonstrate significant variation, from 2.6 per cent in Nagasaki to 29.5 per cent in Santiago.52 However, the conclusion that
Chileans are ten times more depressive than Japanese people is untenable. Variations are likely to measure health systems, pathways to care and attitudes to health. However, comparisons of rates between countries using the same tools have occurred, and several of these are presented in Table 22.7.\textsuperscript{51}

Several studies have also attempted to detect differences in rates between different ethnic groups within countries (Table 22.8).\textsuperscript{51}

Variations in rates of depression occur within culturally homogenous groups in relation to basic demographic factors such as age, gender and socioeconomic status, as well as more complex factors such as the pressures of urban living, all of which may be interwoven in minority ethnic communities. The presence of extreme political events such as war or genocide can often result in the diagnosis of high levels of depression, such as the Lebanon study below. To look for explanatory cultural factors on the meanings of dysphoria in such a universally miserable setting may be inappropriate. However, culturally relevant coping strategies may also play a role in understanding how distress is experienced and expressed.

Part 2: Developmental, behavioural and sociocultural psychiatry

Culture and mental disorders

Judeo-Christian tradition, were most common in Basle and Montreal and least common in Tehran, where suicidal ideation was also least common. Somatic symptoms were more common in Tehran than in Basle or Montreal.

Other studies have also highlighted further differences. Although guilt remains a ubiquitous symptom, its focus can vary. Guilt directed towards ancestors, parents and fellow workers is common in Japan compared with guilt directed towards children and God in Germany. Attempts at subdividing types of guilt into different culturally specific components have not succeeded so far. Other symptoms such as poor libido, loss of energy and hypochondriasis occur at different rates in different groups, such as one study where they were related more commonly by people with depression in southern than northern India.

In China it is more socially acceptable to receive the diagnosis of neurasthenia than depression, and neurasthenia is a commoner diagnosis there than anywhere else. However, in 100 patients with neurasthenia in Taiwan who were examined using standardized tools, 93 were found to have clinical depression and 87 major depressive disorder according to DSM-III. On being treated with tricyclic antidepressants, a majority experienced mood lift but social function deterioration. The diagnosis of neurasthenia was viewed as important in maintaining or sanctioning this higher level of functioning.

The low rates in certain populations from the studies above, such as Taiwanese people, may be explained in Kleinmanian terms. However, this is challenged when looking at levels of diagnosed depression in Chinese groups outside China when the importance of acculturation is taken into account. Australian Chinese immigrants are able to recognize and ascribe depressive symptoms more easily. Their likelihood of gaining a diagnosis of depression is increased in line with the level of acculturation. East Asian immigrants to the USA were found to have increased attention to the affective component and less to the somatic component of self with increased acculturation. In a further study, the overall level of somatic symptoms in presentation of dysphoria in Chinese-Americans was also unaffected, suggesting that acculturation regarding dysphoria in Western culture works primarily at an affective-cognitive level.

Abandonment of notions of earlier culture has been suggested to be a depressogenic factor, with Korean Americans who abandon their identity seen as likelier to become depressed. The study also found that learning the new language and increasing social contacts were protective against developing depression, although in another, larger study, bilingualism in itself was found not to be a protective factor.

Once again, migration has been suggested as a precipitating factor in depression. However, it is a complex model when considering other influences such as culture clash and general chronic stressors encountered by most immigrants, including poor housing, lower incomes and urban living. Understandably, significantly higher levels of depression have been measured in groups of refugees and asylum seekers, and clear differences in levels of depression have been measured in different Hispanic groups in the USA, with higher levels linked to illegality of presence.

Anxiety and the stress disorders

There is much less evidence on cross-cultural comparisons of anxiety disorders. Data are presented on several different disorders collected loosely as anxiety and stress disorders. It is within this milieu that the culture-bound syndromes will be addressed. Although not all are anxiety-related, they are discussed here in an attempt to normalize them as human experiences and purposefully move away from the orientalist view of them as some kind of peculiar exotic behaviour or other.

Panic disorder

The somatic experiences that hyperventilation can bring leave open many different interpretations influenced by the individual’s cultural beliefs. Ode-ori has been postulated to be a cultural variation of panic that is described in some Nigerian cultures with symptoms such as heat in the head or parasites crawling in the head at times of heightened fear.

Social phobia

Fear of scrutiny or criticism by others, together with somatic symptoms of blushing, sweating and other symptoms of anxiety, can lead to significant avoidance behaviour. Taijinkyofusho from Japan has a core symptom of a fear of offending others through inappropriate behaviour or presentation. These symptoms were found to correlate strongly with social phobia in Japanese-Americans in Hawaii, but with more symptoms specific to taijinkyofusho associated with lower levels of acculturation.

Obsessive–compulsive disorder

Religious and superstitious themes have a major impact on obsessive–compulsive disorder (OCD) symptoms, as do widely culturally differing approaches to cleanliness, contamination and purification, which often lie at the heart of ritualistic behaviour. Conflicting information exists on rates of OCD. The Cross National Collaborative Study described similar lifetime prevalence rates of approximately 2.3 per cent in many countries, with the exceptions of South Korea at 1.9 per cent and Taiwan at 0.7 per cent. Lower rates for minority ethnic populations have been recorded in the UK and for Australian Aborigines.

Dissociative disorders

Of central importance to these diagnoses is loss of integrative function between different aspects of the self – from mind or memories to body parts or bodily functions. The symptoms are classified as affecting specific body parts...
Hispanic people and amok sociative states has been described in North Africa, and available. Figure 22.3 attempts to show a probable relation on the re-evaluation of culture-bound syndromes is rather than as separate entities themselves. A wider discussion of the construct since its use describing American soldiers’ psychopathology after the Vietnam War. The cluster of syndromes is requested without reassurance. No recognizable disease pattern is described, but repeated investigation of symptoms is required without reassurance. Variations within different cultural contexts have, however, been postulated, such as ataque de nervios among Hispanic people and hwa byung in Korea.

**Somatization disorder**

Associated with some form of conversion process, somatization disorder has strict criteria according to ICD-10 and DSM-IV. Variations within different cultural contexts have, however, been postulated, such as ataque de nervios among Hispanic people and hwa byung in Korea.

**Hypochondriacal disorder**

No recognizable disease pattern is described, but repeated investigation of symptoms is requested without reassurance. Variations on the type of presentation will depend on the cultural context, but several anxiety states based on irrational fears of sexual function are common within the developing world. It is within this context that other culture-bound disorders are described, such as latah, in which echolalia in dissociative states has been described in North Africa, and amok in South-East Asia, in which these states are seen as associated with severe episodes of violence and amnesia. The danger once again with such classification is that they are seen as entities that ‘they’ are prone to and ‘we’ are not. It is more valid to view these as cultural variations on a theme of symptom complexes in response to stressors, rather than as separate entities themselves. A wider discussion on the re-evaluation of culture-bound syndromes is available. Figure 22.3 attempts to show a probable relationship between culture-bound syndromes and psychiatric disorders.

**Post-traumatic stress disorder**

Perhaps more than any other contemporary diagnosis, post-traumatic stress disorder (PTSD) has led to vociferous arguments among psychiatrists over the cross-cultural validity of the construct since its use describing American soldiers’ psychopathology after the Vietnam War. The cluster of symptoms includes a triad of flashbacks to the prior traumatic event, hypervigilance and avoidance behaviour.

All humans can experience traumatic events. There are a variety of ways that people from different cultures use to adapt to these events. There are multiple examples of studies from across the globe in which high rates of PTSD have been recorded in many different cultures with culturally validated tools. However, the use of a medicalized framework for this process has been critiqued as being imperialistic due to the etic imposition of such a framework. In the contemporary world, this has specific and growing cross-cultural relevance within the field of conflict psychiatry, reactions to war and natural disasters and refugee health. The use of ‘traumascape’ theories attempt to build consensus around the need to see the individual as part of a wider cultural and historical setting in which different ways, rituals and processes can be drawn upon in order to heighten resilience and lower vulnerability.

**Substance misuse**

Most cultures around the world have a history of use of different mind-altering substances for social or religious practices. The cultural influences in assessment of these practices tend to be complex. In the context of a substance use, misuse and dependence may be seen as a continuum. There is significant agreement between ICD-10 and DSM-IV on the classification of dependence syndromes, with both influenced by research on alcohol. There is also evidence for the validity of the dependence syndromes for alcohol,
tobacco, 76 million people suffer from alcohol use disorders. In the absence of a dependence syndrome, there is less unanimity in how to classify, due to misuse or problematic use being subjective and inextricably judged against cultural norms. There are examples throughout history of widely differing attitudes to different substance usage, which is often linked with legality. These include the criminalization of substances such as opium across time, and the medicalization of khat, which has occurred in Europe following its use within a new social and cultural context.

Despite the difficulties, some studies have tried to measure the levels of substance misuse across cultures. It has been estimated that globally 1 billion people smoke tobacco, 76 million people suffer from alcohol use disorders and 15 million people have a drug use disorder. Further studies suggest the influence of migration and acculturation processes, with evidence that substance misuse in ethnic minorities in the UK is lower than for the indigenous population. However, potentially contradictory evidence also exists – depending on levels of use in originator countries for substance misuse being higher in immigrants to the UK than in their equivalents in countries of origin.

The manner in which culture interacts with the socioeconomic consequences of poverty is also important. Making causal links between particular cultures and increased susceptibility to substance misuse may be misleading. Several studies from a number of different cultures have identified a pattern of behaviour most loosely described as a ‘poverty trap’, which encourages ongoing substance misuse. It has been argued that poverty itself gives rise to a culture that promotes and maintains substance misuse in Sri Lanka. Similar themes exist in evidence of higher rates of substance misuse in indigenous communities such as Australia and New Zealand and the USA.

### Eating disorders

The relationship between individuals and their food is heavily influenced by the culture to which they belong. Food is often used as a means of welcoming guests and is used as an important and significant symbol in relationships. Sociocultural pressures have been advanced as causative to the development of eating disorders. The 10:1 ratio of women to men may be a reflection of their higher associated target status for such notions as thinness. This is reinforced by high rates in certain subcultural groupings, such as dancers and models, in which a demand for thinness is even more marked than in society at large. In addition, higher rates have been recorded in urban settings in all societies, with explanations varying from the changes in family structure and social mobility, to easier availability of food, marked changes in meal timings, increased obesity and higher weight consciousness.

Eating disorders have been considered as a culture-bound phenomenon, due to a low prevalence rate within many non-Western cultures. However, this has been challenged with evidence including significant variation within the West, between the USA and central Europe, and between different areas of a single country, in north and south Italy. There are reports of significant increases in certain areas of the world such as in black South African girls post Apartheid, and in developing nations generally since 1990, leading to an argument that eating disorders should be seen as markers of a ‘westernization’ process or more latterly as ‘markers of cultural transition’ in general.

### Personality disorders

Disorders based on personality raise problematic cross-cultural issues due to the normative understanding of what personality means and how it fits within a wider societal framework. Classification of personality traits or types dates back to ancient Greece, but it was Pinel in the nineteenth century who first attempted to separate out psychopathological processes and behaviours that were not illnesses. The subsequent development of ICD-10 and DSM-IV has seen an evolution in the way in which these have been classified to the current ten categories.

Diagnostic reliability between psychiatrists is low even when working within a culturally homogenous setting, perhaps due to pejorative connotations or the inherent discrimination of the psychiatric profession. In addition, the notion of culturally acceptable or unacceptable behaviour arises as an important marker in diagnosis. The overlap between the legal system and people with personality disorders is therefore unsurprising, with up to 80 per cent of people on remand in UK found to have an antisocial personality disorder.

It is therefore important to consider how the concept of the self varies across cultures. It has been argued that, in the West, the self is individuated, detached, self-sufficient and separate – an egocentric position. A corollary of this is the notion of a more sociocentric individual, whose conception of self is linked inextricably with a role in which individual choice is not absent but is subsumed within wider responsibilities. The importance of early formative years and subsequent experiences are seen as highly influential in the development of personality disorders, particularly to cluster B. The very different approaches to societal structure in which individuals develop would, unsurprisingly, result in different views of the self, different personal expectations, and different measures of failure to conform to societal norms and values.

Attempts at measuring personality disorders across cultures have occurred. The International Personality Disorder Examination (IPDE) was used in a study of 716 individuals in 14 centres in 11 countries, which showed a two-fold higher rate of diagnosis of personality disorder using DSM-III as opposed to ICD-10. Antisocial personality disorder is the only type to have been studied in cross-national
community surveys of morbidity. Rates ranged from 0.14 per cent in Taiwan to 3.7 per cent in Canada. However, the cause of such differences may be a true high prevalence or a reflection on how antisocial behaviour is defined in both societies.

Disorders of childhood and adolescence

Differences in the way childhood is experienced add a level of complexity when evaluating mental health problems cross-culturally. Children are at the forefront of the mechanisms of cultural continuation and absorb the norms and values of a particular way of life readily. Two important basic epidemiological factors are important (Table 22.9).

Table 22.9 Summary of the importance of age and gender

<table>

<td>At 7, 14 or even 21 years old, different relationships with schooling, employment, marriage and psychoactive substances occur in different cultures</td>
<td>In much of the world, being female results in a different childhood experience than being male</td>
</tr>
</tbody>
</table>

A range of different international studies have estimated prevalence rates of ‘child mental health problems’ of 20–25 per cent and more specific ‘child psychiatric disorders’ of 9–12 per cent in several countries. Increased rates are associated with lower socioeconomic status and with urban living.

Data on the attention spectrum disorders do reveal some cultural differences. In the USA, rates range from 3 per cent to 7 per cent of the general population. However, use of psychostimulant medication has been found to be associated strongly with the type of insurance policy held, meaning that white children are far more likely to be treated this way.

Disorders of ageing

Although all humans age, not all experience old age in a similar way – if at all. However, in both high- and low-income countries, the elderly population is increasing. It is estimated that the number of people over age 65 years will increase from 50 million in 1990 to 1 billion by 2025. However, there is a paucity of epidemiological and clinical information on elderly people from low-income countries as well as minority ethnic populations in high-income countries.

The different roles experienced by elderly people in different cultures towards employment, family and social responsibilities all potentially mediate mental health problems. The concept of multiple disadvantages is also pertinent for elderly people, who may experience problems associated not only with ageism but also with racism, class problems and restricted access to health and social care.

Prevalence rates for dementia are influenced by several factors, including that individuals in lower-income countries have a shorter lifespan generally and that mortality rates once dementia has been diagnosed are worse in low-income countries. There are many problems with cross-cultural comparisons, including difficulties in exact age identification, associations with pre-existing physical impairment confounders such as visual and hearing difficulties, high rates of illiteracy and innumeracy, and translational artefacts. However, some comparative prevalence studies of dementia are available and reveal rates between zero and 13.2 per cent, with a median of 4 per cent. Universally the prevalence increases with age and is higher in women, with a rough rule of a doubling every 5 years after the age of 60 years. In addition, prevalence of Alzheimer’s disease is lower and of vascular dementia higher in Asian than Western countries.

Intra-country cross-cultural studies reveal significant similarities in prevalence rates across groups in the UK. However, a population-based study in the UK revealed that having an African or Caribbean origin increased the risk of dementia. This matches data on higher prevalence rates in African-American and Hispanic people in the USA. Higher rates of stroke and hypertension in African-American people have been recorded, suggesting a link with higher rates of vascular dementia.

Deliberate self-harm and suicide

Comparative studies in this field are difficult due to a number of factors, as deliberate self-harm (DSH) and suicide rates are not recorded accurately in many places. It is suggested that a recent rise in youth suicide in Ireland is explained in part by a reduction in the number of coroner’s verdicts of ‘open’ or ‘accidental’ deaths as a result of changing attitudes towards matters formerly taboo. Some attempt at comparative work is available. In general global terms, European nations record the highest rates of suicide and Central and South American countries the lowest. Most risk factor studies have occurred in high-income nations. Gender, rural communities, alcohol misuse, life events and a history of DSH increase risks globally. Being single, divorced or widowed, all of which increase risks in the West, do not appear to do so in China or India. More ‘religious’ countries appear to have lower rates of suicide. Although the meaning of self-harm and suicide varies across cultures, it appears that the attitudes to intentions when self-harming are actually consistent across many countries. Variation in method of self-harming occurs, with firearm use an obvious cause of increased mortality in the USA. The same method but different agent can also reveal marked rate differences in suicide, for example with the use of pesticides as opposed to analgesics in China and Sri Lanka compared with Europe. Accessibility to primary and secondary healthcare can also have a significant impact on survival rates.
post-incident. Some specific regional and country data are available.

**Russia and Eastern Europe**

High rates of suicide and DSH were recorded in Russia in the 1990s following the break-up of the USSR and all the social changes that came with it. Of the former 15 Soviet states, 10 experienced a rise in suicide rates post-1991. The Russian minority in Estonia were found to have higher suicide rates after that republic’s independence.

**India**

It has been estimated that 300,000 people die by suicide in India – three times the official figure. Gender ratios are more equal than other nations, making cultural factors seemingly important. There are even figures showing higher rates of young females in India to young males, with one study showing 50–75 per cent of all deaths of women aged 10–19 years in Vellore, southern India, as opposed to 25 per cent of equivalent males. These higher rates for young women were replicated in New Delhi, but by a lesser margin of 1.2 : 1. Hanging was a more common method with young women and poisoning with young males, in a reversal of most other places.

**Japan**

Traditionally this country has a high rate of suicide, with more complex cultural sanctioning of the behaviour in certain circumstances. In 2002 the rate was 23.8 per 100,000, but when broken down it is much higher in men aged 50–59 years at 71 per 100,000 and accounted for 25 per cent of all older person’s deaths. In middle-aged men, economic pressures and insekti-jisatu, or responsibility-driven suicides to demonstrate remorse for untoward events, are thought to be culpable factors.

**China**

Overall more females than males die by suicide – the only country for which such rates are available. Rural women are found to have a greater risk than urban women, in a reversal of Western risks. Organophosphate usage is the most common method used by women, with impulsivity in the presence of family conflict noted as important.

There are also data on suicide and DSH within different minority ethnic groupings.

**The UK**

Rates of DSH have been measured as 2.5 times higher in Asian women than white women and seven times higher in Asian women than in Asian men. Black men had much lower rates of DSH presentation than white men in one London study. Additionally, Asian women were found to be more likely to report they wanted to die during DSH, more likely not to regret the incident, likely to take fewer tablets and less likely to use alcohol.

Suicide data reveal further evidence of cultural differences, with high rates detected in men in general and in Indian women as a subgroup, mirroring the country data above. One study showed that Indian women were more likely to use hanging and burning as methods of suicide than white women, for whom self-poisoning was the main method.

A further study revealed the age-specific rates of suicide for 20- to 44-year-olds in London (Table 22.10) and presented evidence that coroners appear less likely to return a verdict of suicide in ethnic minority groups.

**The USA**

Data are also available on differences in DSH and suicide rates for different ethnic groupings within the USA (Table 22.11). Historically, the rate of suicide by African-Americans has been lower than by their white counterparts. The black/white split in the USA also differs in a couple of epidemiologically important ways: (i) the rate of male to female suicides is higher, and (ii) the rates increase in early adulthood, follow a mid-life plateau and then decrease in later life. With the white population, the increase continues across life. Explanations about the protective nature of better social support networks and single motherhood among African-American women have been advanced.

DSH data are more inconsistent, but several important themes have emerged, including that more DSH occurs

among women in all groups and more African-American adolescents engage in self-harm than do their white counterparts. African-American males are also more likely to require medical attention. African-American males are also more likely to require medical attention. Indigenous groups

Several additional countries with significant indigenous populations have data suggesting an overrepresentation of their populations in death by suicide, including First Nations People/Canadian Metis and Inuit, and Australian Aborigines. The impact of social marginalization, unemployment and increased alcohol and substance misuse are all advanced as causative.

Refugees

Refugees and asylum seekers show high rates of anxiety, depression and PTSD, all of which are risk factors for DSH behaviour and suicide, even though there are few studies demonstrating elevated risk for completed suicide, suggesting resilience is an important factor.

CULTURE IN ASSESSMENT AND MANAGEMENT

This section focuses on cultural factors in the assessment process and management, including medication and psychotherapies.

Conducting a culturally aware assessment

As clinicians, we all must be aware of our cultural inheritance and prejudices so that we can understand how our response to patients is seen by patients and their carers. The assessment needs to gain an accurate and relevant amount of information quickly. It is easier to gain that information with someone similar to oneself, as various verbal and non-verbal communication mechanisms are used within a context of shared knowledge and are generally understood in the context of culture. Difficulties may arise as differences grow, whether these are related to language, religious values or broader cultural factors – but communicating across these differences is an essential skill for any psychiatrist to learn.

Any of the differences in Table 22.12 may result in a lack of shared knowledge. Into that vacuum assumptions may arise, from which prejudice may spring. Building shared knowledge requires you to have an awareness of relevant issues, which, even if somewhat alien, are accepted as valid. In a culturally aware assessment process, there are three important strands, as shown in Table 22.13.

Management with medication

The influence of culture in pharmacological management has been succinctly detailed, a summary of which now follows. Culture can be thought of as influencing at three different levels, as shown in Table 22.14.

The first is a resource issue, but the latter two provide a basis for genuine variation. Many drug trial data, in particular on antidepressants, demonstrate significant placebo effects, which have a significant culturally mediated component. In addition, most trial data have also been generated from testing in the Caucasian populations of North America and Europe.

There is also evidence for the biological basis to variation. Absorption, distribution, metabolism and excretion of any given drug will vary across individuals and to some extent across ethnocultural groups. There are very few examples of full ethnocultural homogeneity, which means that stereotyping can lead to inaccuracies, but there are many examples of cross ethnocultural variances. An early study demonstrated a higher serum haloperidol level 7 h after dosing in Asian people versus Caucasian people, even taking into account body surface area. This was thought most likely due to differential hepatic first-pass rates. More widely, there are two main ways in which this variation might act – through pharmacokinetic processes (variation in the amount of the drug that is present) and pharmacodynamic processes (variation in organism response to the drug).

Pharmacokinetics

The P450 enzyme system is important in metabolism. A highly studied part of this system is CYP2D6, which is responsible for about 25 per cent of metabolism of many drugs, including tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs) and antipsychotics. Depending on a large number of allelic variants, enzyme activity has been measured and grouped according to the following types:

- UM: ultra-rapid metabolizer (gene duplication or multiplication)
- EM: extensive metabolizer (gene duplication or multiplication)
- IM: intermediate metabolizer (one defective gene or two less effective genes)
- PM: poor metabolizer (two defective genes).

A study of 100 consecutively phenotyped hospital patients revealed that the number of adverse drug effects was highest in PMs, then IMs, and then EMs or UMs.176 The cost of treating PMs and UMs was highest, and the total hospital duration was highest in PMs, which may have relevance due to the ethnocultural linkages (Table 22.15).

In addition to genetics, external factors, such as drugs and diet, and internal factors, such as hormones, may influence the activity of P450 enzymes. It has been postulated that diet as a cultural mediator is an important factor in the differential expression of CYP1A2, which may explain why significantly longer antipyrine half-life occurs in Sudanese people living in home villages compared with Sudanese people in the UK and white UK citizens.183 Additionally, in clomipramine and antipyrine trials, significantly faster rates of metabolism have been demonstrated in South Asian subjects who switched to a ‘British’ diet, comparable with white British, than South Asians who followed ‘Indian’ vegetarian diets and South Asians in South Asia.184,185

CYP3A4 is a further enzyme in the P450 series and is involved in metabolism of many antipsychotics, including clozapine and benzodiazepines. Inhibition of this enzyme results in significant accumulation of certain drugs and a prolonged period of their action. A number of different potent inhibitors are readily available that will heighten the drug availability. Increased drowsiness in people who drank grapefruit juice after taking midazolam and triazolam has been described,186,187 and black pepper from South Asia and piper cubeba from Indonesia are also both known to be potent inhibitors of CYP3A4.188,189

Pharmacodynamics

These processes, mediated by the transporters, receptors and enzyme systems, result in differential activities in response to pharmacological agents. The two most studied systems around which ethnocultural variation has been detected are
the serotonin transporter (5-HTT) gene and the catecholamine-O-methyltrasferase (COMT) gene.

A serotonin transporter gene-linked polymorphism has been studied in its effects on the psychopathology of depression and alcoholism. In addition, it has been studied for its treatment effects on antidepressants in depression and in alcoholism. Two alleles, l and s, demonstrate differential treatment responses, with l having a significantly better treatment response to SSRIs than the s variant. Results of further analysis in different groups have still revealed inconclusive findings but could be of importance because there have been ethnocultural variations in the preponderance of l alleles – people with African ancestry have the highest rates at 70 per cent, and people of East Asian origin the lowest at 17 per cent.

The COMT gene mediates one of the pathways for metabolizing catecholamines, including dopamine and noradrenaline. Variant alleles that have been studied include the H and L varieties, with the latter demonstrating a three to four times lower rate of activity.

Again, although findings have yet to be replicated robustly, there have been studies investigating the impact of such variation in panic disorder; schizophrenia and Parkinson’s disease; treatment-resistant schizophrenia; aggressive and violent behaviour, and l-dopa therapy, with H/H genotype individuals suffering more dyskinesia than L/L genotype individuals. One of the spurs to ongoing research in this area is due to the ethnocultural variations in L allele frequency that have been detected, with rates in Caucasians the highest at 50 per cent and East Asians the lowest at 18 per cent.

Management with psychotherapies

The focus of psychotherapy aims to aid an individual’s greater understanding of self, thereby eliminating or reducing the impact of psychopathological processes. Over the course of the twentieth century, many variations of talking therapies emerged from different intellectual traditions. These have been viewed as being most relevant to Western cultures. Although there are variations that focused on processes involving greater-than-self work such as family or systems therapy, the basis for much of the work is the concept of the self. Therefore, at the very core of the one-to-one psychotherapeutic alliance is the fundamentally important cross-cultural question of what it means to be an individual.

There is a dearth of empirical studies with psychotherapies, even without addressing cross-cultural complexities. Psychotherapies do not form the basis of services to people in most parts of the globe. The effective use of psychotherapies in a multicultural setting is still little studied. However, smaller proportions of individuals from ethnic minority groups take up psychotherapy than do their white counterparts in both the USA and the UK, and more patients from ethnic minority groups drop out of psychotherapy. It appears that most people prefer a therapist from the same culture.

CONCLUSION

This chapter has presented evidence on the importance of cultural concepts in many aspects of psychiatric practice, from classification and identification of disorders to assessment and management of them. It is a complex field of endeavour, and there is still much to be discovered. However, in an age of increasing globalization in which the boundaries between cultures are transcended, it is vital to be aware of how different cultural norms and values may lead to a greater understanding of mental disorders and wider psychiatric practice.

PART 3

Neuroscience
INTRODUCTION

Neuroanatomy is one of the fundamental basic neurosciences that underpin the practice of clinical psychiatry. In this chapter the following aspects are covered, with an emphasis on those aspects that are of particular importance to psychiatry: the general anatomy of the brain and spinal cord, including the lobes, the major gyri, the limbic system and the cranial nerves; the basal ganglia; the internal anatomy of the temporal lobes; the major white-matter tracts of the brain; the types of cells found in the central nervous system; and the major neurochemical pathways. In our experience, the study of neuroanatomy is made easier by dissecting the brain, or at the very least by examining specimens; the reader is strongly encouraged to do so.

THE SKULL

Bones

The skull includes the mandible, whereas the term ‘cranium’ is without it. Excluding the six auditory ossicles, a normal adult human skull is formed from 22 bones.

Single bones

These are the:
- frontal bone;
- ethmoid bone;
- sphenoid bone;
- vomer;
- occipital bone;
- mandible.

Paired bones

The paired bones of the skull (left and right) are the:
- maxilla (the maxillae);
- nasal bone;
- lacrimal bone;
- inferior nasal concha;
- palatine bone;
- temporal bone;
- zygomatic bone;
- parietal bone.

Auditory ossicles

In addition, the paired auditory ossicles within the middle cavities of the temporal bones are (left and right) the:
- incus;
- malleus;
- stapes.

Dura mater

The cranial cavity, within the upper part of the skull, which encloses the brain, is lined with a covering of double-layered dura mater, which forms:
- the falx cerebri in the midsagittal plane, separating the two cerebral hemispheres;
- the tentorium cerebelli, which forms a roof over the cerebellum, in an almost axial plane, and separates it from the posterior under-surface of the occipital lobes of the brain.

Cranial fossae

The base of the skull (floor of the cranial cavity) is divided into three areas: the anterior, middle and posterior cranial fossae. Some key important structures to note with these are given below.

Anterior cranial fossa

- The cribriform plate of the ethmoid bone through the multi-perforations of which pass olfactory (I) nerve filaments connecting to the under surface of the olfactory bulbs
- The foramen caecum, through which passes an emissary vein.

Middle cranial fossa

- The pituitary fossa (sella turcica) containing the pituitary gland, which has a posterior lobe (neurohypophysis) and an anterior lobe (adenohypophysis)
- The optic canal, through which passes the optic (II) nerve
- The superior orbital fissure transmits the ophthalmic (V1), oculomotor (III), trochlear (IV) and abducens (VI) nerves and ophthalmic veins
- The foramen spinosum transmits the middle meningeal artery
- The foramen ovale transmits the mandibular division of the trigeminal (V3) nerve
- The foramen lacerum, upper aspect, opening of the carotid canal
- The trigeminal ganglion in a recess near the apex of the petrous temporal bone.

**Posterior cranial fossa**

- The internal acoustic meatus transmits the facial (VII) and vestibulocochlear (VIII) nerves
- The jugular foramen transmits the glossopharyngeal (IX), vagus (X) and accessory (XI) nerves
- The foramen magnum, through which passes the medulla oblongata, vertebral arteries and spinal root of the accessory nerves.

**CERVICAL VERTEBRAE**

There are seven cervical vertebrae. The first is the atlas, on which the skull articulates. The second is the axis; fracture of its odontoid peg (dens) can cause spinal cord damage or severance. The third to sixth (inclusive) cervical vertebrae have bifid spinous processes. The seventh (the vertebra prominens) has a single, palpable spinous process.

All seven cervical vertebrae have a foramen in each of their transverse processes (foramen transversarium). It is important to note that on each side, the vertebral artery, ascending from the subclavian artery, passes only through the foramina transversaria of the first to sixth cervical vertebrae, entering at the sixth. The vertebral vein emerges from the sixth cervical foramen transversarium. A variable companion vein may emerge from the foramen transversarium of the seventh cervical vertebra.

**GENERAL ANATOMY OF THE BRAIN AND SPINAL CORD**

**Lobes and major gyri**

The four major lobes of the brain (the frontal lobe, parietal lobe, temporal lobe and occipital lobe) are named after the approximately adjacent skull bones.

The frontal lobe extends rostrally from the central sulcus (formerly known as the fissure of Rolando) and superiorly from the lateral fissure (formerly known as the Sylvian fissure). It contains the primary motor cortex (M1 or MI; Brodmann area 4) just anterior to the central sulcus, occu-
hemisphere, areas 44 and 45 comprise Broca’s area (see Figure 23.1), which is the motor speech area. The DLPFC has been much studied in psychiatric disorders such as schizophrenia and in psychological experiments. It appears to be involved particularly in self-ordered working memory, monitoring and the action of the central executive. The VLFFC, on the other hand, appears to be involved in mnemonic processing and rule representation. The supplementary motor cortex (SMA; M2 or MI) is on the supereolateral border and medial side of the hemisphere, rostral to M1, and appears to be involved in the assembly of central motor programming of sequential movements. The orbitofrontal cortex occupies the orbital gyri on the inferior surface of the frontal lobe and appears to be involved in processes involving the motivational or emotional value of incoming information, including the representation of primary reinforcers, the representation of learned relationships between arbitrary neutral stimuli and rewards or punishments, and the integration of this information to guide response selection, suppression and decision-making.

The parietal lobe extends between the central sulcus (fissure of Rolando) and the parieto-occipital fissure, and laterally as far as the lateral (Sylvian) fissure. It contains the primary somatosensory cortex (S1 or SI; Brodmann areas 3, 1 and 2) just posterior to the central sulcus, occupying the postcentral gyrus and the posterior wall of the central sulcus (see Figure 23.1), which receives medial lemniscal, spinothalamic and trigeminothalamic input via the thalamic ventral posteriorterior nucleus. The location of the somatosensory association cortex (Brodmann areas 5, 7a, 7b and 40) in the superior and inferior parietal lobules is also shown in Figure 23.1.

The temporal lobe lies inferior to the lateral (Sylvian) fissure and extends posteriorly to the parieto-occipital fissure. It contains the primary auditory cortex (A1 or AI; Brodmann areas 41 ± 42; see Figure 23.1), which receives auditory sensory input from the medial geniculate nucleus and has a tonotopic cochlear representation (low auditory frequencies anterior and high frequencies posterior). As shown in Figure 23.1, the dominant temporal lobe also contains Wernicke’s (sensory speech) area, which is variously designated as Brodmann area 22 ± 39 ± 40 and may include part of the parietal cortex. The middle temporal cortex, Brodmann area 21 (see Figure 23.1), has connections with different sensory modality pathways, including those related to vision, somatosensory input and auditory input. In contrast, the inferior temporal cortex, Brodmann area 20 (see Figure 23.1), is particularly related to the higher processing of visual stimuli. The internal anatomy of the temporal lobes is considered later in this chapter.

The occipital lobe lies behind the parieto-occipital fissure and contains Brodmann areas 17, 18 and 19. Brodmann area 17 is the primary visual cortex (V1 or VI; see Figure 23.1), also known as the striate cortex, and receives visual sensory input from the lateral geniculate nucleus by means of the branches (lower and upper fields) of the optic radiation, as shown in Figure 23.2. The calcarine sulcus is shown in Figure 23.3; the part of V1 above this sulcus receives a retinotopic visual input (macular to a large posterior part of V1 and peripheral to anterior V1) from the contralateral inferior visual hemifields (superior retinal quadrants), while the part of V1 below the sulcus receives a similar retinotopic input from the contralateral superior visual hemifields (inferior retinal quadrants). V2, the second visual area, is found in much of Brodmann area 18 (see Figure 23.1), just concentric to area 17, and also contains a retinotopic mapping of the contralateral visual hemifield. V3, the third visual area, is also mainly found in Brodmann area 18 and is divided into dorsal (V3d or V3), ventral (V3v or VP) and anterior (V3a) parts. V4, the fourth visual area, is found in much of Brodmann area 18 (see Figure 23.1), just posterior to the central sulcus. Cells in V2 and V3 tend to be orientation-selective but not selective for stimulus colour or direction or movement, whereas V4 appears to be particularly involved in the discrimination of colour, orientation, form and movement.

The major gyri are shown in Figures 23.3–5.

Figure 23.6 summarizes some of the key linguistic and visual parts of the cerebral cortex of the left hemisphere, together with some of the disorders that occur when there is damage to these areas.

### Limbic system

Papez put forward the notion of a neural network theory of emotion, suggesting that

The central emotive process of cortical origin may ... be conceived as being built up in the hippocampal formation and as being transferred to the mammillary body and thence through the anterior thalamic nuclei to the cortex of the gyrus cinguli. The cortex of the [cingulate] gyrus may be looked on as the receptive region for the experiencing of emotion... Radiation of the emotive process from the gyrus cinguli to other regions in the cerebral cortex would add emotional colouring to psychic processes.

Papez also included parts of the brain involved in olfaction in his circuit. Many of these regions are shown as the shaded limbic lobe in Figure 23.1b. Papez argued that lesions directly involving or impinging on this anatomical circuit (the Papez circuit) caused symptoms largely confined to the person’s affective behaviour. Thus, in rabies affecting the hippocampus and cerebellum, Papez noted that patients display symptoms of anxiety, apprehension and paroxysms of rage and terror. He pointed out that intact neural pathways from the mamillary bodies to the cingulate gyrus, via the anterior nuclei of the thalamus, appeared to be required for a state of vigilance and wakefulness, from which he deduced that this circuit was concerned with affective behaviour. In respect of the possible emotional function of the cingulate gyrus, Papez noted that corpus colossal tumours impinging on this gyrus are often associated with personality change, loss of affect, and a degree of somnolence and stupor.

The Papez circuit was further elaborated upon by MacLean, who included the following structures (in approximately this sequence) in his version of the limbic system: olfactory bulb, olfactory tubercle, lateral olfactory stria, amygdala, stria terminalis, septal nuclei, stria medullaris, interpeduncular nucleus, medial forebrain bundle and mamillary body; and also a pathway from the septal nuclei via the supracallosal striae, dentate gyrus, hippocampus and fornix back to the mamillary body. Other components of this version of the limbic system included the anterior nuclear group of the thalamus, the diagonal band of Broca and the habenula (part of the epithalamus).

There is no consistent agreed set of components of the limbic system. Most modern definitions tend to include the cingulate gyrus, the rest of the hypothalamus and, at least partly, the basal ganglia (described later in this chapter). The cingulate gyrus is shown in Figure 23.3; the anterior cingulate cortex in particular appears to be implicated in a number of psychiatric disorders.

It has been argued that attributing emotional functions primarily to the limbic system may be inherently incorrect. For example, Pessoa stated:

In attempting to localize affect in the brain, an appealing approach has been to separate the ‘emotional brain’ from the ‘cognitive brain’ ... parceling the brain into cognitive and affective regions is inherently problematic, and ultimately untenable for at least three reasons: first, brain regions viewed as ‘affect-
tive' are also involved in cognition; second, brain regions viewed as 'cognitive' are also involved in emotion; and critically, third, cognition and emotion are integrated in the brain.¹⁴

Cranial nerves

At the base of the brain the cranial nerves are attached to the brainstem.

The fibres of cranial nerve I, the olfactory nerve, which subserves the function of olfaction, originate from the olfactory mucosa and pass to the olfactory bulb. The fibres of cranial nerve II, the optic nerve, which subserves the function of vision, originate from the retinal ganglion layer. The blind spot is caused by the lack of photoreceptors in the part of the retina from which this cranial nerve exits the eye. The optic nerve is ensheathed in the three meningeal layers of, from internal to external, the pia mater, arachnoid mater and dura mater. It passes backwards to form the optic chiasma with the optic nerve from the other eye.

Cranial nerve III, the oculomotor nerve, which subserves the function of eye movement and also carries a parasympathetic innervation to the ciliary ganglion, emerges between the cerebral peduncles in the brainstem. The superior division of the nerve supplies the superior rectus and levator palpebrae superioris muscles, while the inferior division supplies the inferior oblique, inferior rectus and medial rectus, and carries the parasympathetic innervation.

Cranial nerve IV, the trochlear nerve, which subserves the function of eye movement, emerges from the midbrain (mesencephalon) and supplies the superior oblique.

Cranial nerve V, the trigeminal nerve, which subserves the functions of general sensory input from the head and motor output to the muscles of mastication, originates from the pons. The sensory (larger) and motor roots that leave the brainstem at the middle cerebellar peduncle eventually reach the trigeminal ganglion from which the following three divisions take form: the ophthalmic division, the maxillary division and the mandibular division. Their main branches are given in Table 23.1; the only motor branches are those to the muscles of mastication and the mylohyoid branch of the inferior alveolar nerve to the mylohyoid muscle and the anterior belly of the digastric muscle.

Cranial nerve VI, the abducens (abducent) nerve, which subserves the function of eye movement, emerges from between the pons and the medulla oblongata and supplies the lateral rectus.

Cranial nerve VII, the facial nerve, which subserves the functions of facial movement, taste and lacrimal and salivary gland parasympathetic innervation, has the following major branches: greater petrosal nerve (secretomotor to the pterygopalatine ganglion); the nerve to the stapedius; chorda tympani (taste from anterior two-thirds of the tongue and parasympathetic supply to the submandibular ganglion); posterior auricular nerve (to the occipital belly of occipitofrontalis and auricular muscles); nerves to the posterior belly of the digastric and stylohyoid; and five terminal motor branches from the parotid plexus (pes anserinus), namely the temporal, zygomatic, buccal, mandibular and cervical branches, which supply the muscles of facial expression and the platysma and buccinator muscles.

Cranial nerve VIII, the vestibulocochlear nerve, has two components: the vestibular nerve, which subserves sensory functions related to balance and posture; and the cochlear nerve, which is concerned with the sensation of hearing. This cranial nerve emerges from the pontocerebellar angle and eventually, upon entry into the petrous temporal bone (through the internal acoustic meatus), it splits into its two main components. The spiral organ of the cochlea is supplied by the cochlear nerve.

Cranial nerve IX, the glossopharyngeal nerve, has several functions: taste; pharyngeal sensory and motor innervation; a parasympathetic supply to the parotid gland; carotid body and sinus innervation; and a motor supply to the stylopharyngeus muscle. This cranial nerve leaves the skull through the jugular foramen. Its main branches include the carotid, carrying afferents from carotid body chemoreceptors and carotid sinus baroreceptors; the lingual branch to the pharyngeal (posterior) part of the tongue and to the circumvallate papillae of the oral (presulcal) part of the tongue; the muscular branch, which supplies the stylopharyngeus muscle; pharyngeal branches supplying pharyngeal sensory mucosal fibres; tonsillar branches, which, with the lesser palatine nerves, form the circulus tonsillaris from which occurs innervation of the palatine tonsil region, soft palate and oropharyngeal isthmus; and the tympanic nerve.

Cranial nerve X, the vagus nerve, has widespread functions that include sensory and motor innervation of the pharynx, larynx, palate and oesophagus; a parasympathetic supply to the viscera of the thorax and the alimentary tract as far as the splenic fissure; and sensory innervation of thoracic and abdominal viscera and the external acoustic meatus and tympanic membrane. The vagus nerve leaves the skull through the jugular foramen. Its branches in the neck include meningeal branches to the posterior cranial fossa dura mater; the auricular branch, which, after supplying a branch to the facial nerve, ultimately ends in two branches, one of which combines with the posterior auricular nerve and the other of which supplies the external acoustic meatus and part of the skin of the external ear; the pharyngeal branch, which supplies motor innervation to the pharynx; branches to the carotid body; the superior laryngeal nerve, which gives rise to the internal and external laryngeal nerves; and the recurrent laryngeal nerve.

Cranial nerve XI, the accessory nerve, which enables the head and shoulders to move and supplies muscles of the pharynx and larynx, comprises a smaller cranial root and a spinal root. The cranial root emerges from the skull through the jugular foramen whence it is joined briefly with the larger spinal root. After separating from the latter, the cranial root joins the tenth cranial nerve and supplies the pharyngeal and laryngeal muscles (with the exception of tensor

veli palatine). The spinal root supplies the sternocleidomastoid and trapezius muscles.

Cranial nerve XII, the hypoglossal nerve, enables tongue movement. It supplies all the muscles of the tongue, with the exception of palatoglossus.

**Spinal cord**

Housed in the vertebral canal, the spinal cord is continuous with the brain, extending caudally from the medulla oblongata of the brain, just inferior to the foramen magnum of the skull, to the conus medullaris, which has a bony anchoring connection via the filum terminale to the dorsal aspect of the sacrococcygeal region. It has meningeal coverings that are continuous with those of the brain. There is a small central canal in the central grey matter of the spinal cord, which contains cerebrospinal fluid; this is continuous with the cerebrospinal fluid of the fourth ventricle of the brain.

Figure 23.7 shows the ascending sensory pathways that lie in the white matter of the spinal cord and include the following:

- The posterior or dorsal columns or fasciculi – the fasciculus cuneatus and the more medial fasciculus gracilis, which carry proprioceptive, vibratory and exteroceptive (i.e. relating to touch and pressure) information to higher levels of the central nervous system
- The lateral spinothalamic tract, which carries pain and temperature sensations to the somatosensory part of the thalamus
- The posterior (dorsal) and anterior (ventral) spinocerebellar tracts, which carry proprioceptive and cutaneous sensations to the cerebellum
- The spinoreticular pathway, within the spinothalamic tracts, which appear to carry cutaneous and deep pain sensations to the pontomedullary reticular formation
- The spino- and cuneothalamic pathway, which carries sensations of pressure, pinching, hair movement and temperature to the contralateral thalamus via the lateral cervical nucleus and medial lemniscus.

Descending spinal cord pathways also lie in spinal cord white matter and have important motor control functions relating to movement, muscle tone and posture. They also influence spinal reflexes. Descending pathways include the following:

- The lateral and anterior (ventral) corticospinal tracts: fibres originate mainly in the cerebral cortex (with the corticobulbar tracts), including the motor cortex (Brodmann area 4) and premotor cortex (Brodmann area 6). The course of the corticospinal tracts is shown in Figure 23.8
- The rubrospinal tract: fibres originate in the magnocellular part of the red nucleus
- The tectospinal tract: fibres originate in the superior colliculus
- The lateral and medial reticulospinal tracts: fibres originate in the reticular formation
- The interstitiospinal tract: fibres originate in the interstitial nucleus of Cajal
- The lateral and medial vestibulospinal tracts: fibres originate in the vestibular nuclear complex (in the floor of the fourth ventricle)
- The solitariospinal tract: fibres originate in the nucleus solitarius
- Spinal pathways using monoamines for neurotransmission: these originate from brain regions that are part of these neurochemical pathways (vide infra). For example, noradrenergic coeruleospinal spinal pathways project from the locus coeruleus.

The grey matter forms a central butterfly-shaped core of the spinal cord and contains multipolar neurons. The grey
matter is related to the spinal nerves. Primary afferents from spinal nerve sensory dorsal rootlets terminate in the dorsal horn of grey matter (Figure 23.9). Efferents from the ventral horn of grey matter give rise to ventral motor rootlets, which join to form a ventral motor root. Figure 23.9 also shows the formation of the mixed spinal nerve, its division into dorsal and ventral primary rami, and the connection to the latter of sympathetic ganglia via white (myelinated) afferent rami communicantes and grey (unmyelinated) efferent rami communicantes.

**BASAL GANGLIA**

The basal ganglia have important functions in respect of the control of movement and posture.

**Components**

The basal ganglia refer to deep subcortical paired nuclear masses that lie close to the internal capsule. A modern definition of the basal ganglia is shown in Box 23.1. Note that, although the putamen and globus pallidus have traditionally been grouped together as the lentiform nucleus, in practice it is the caudate nucleus rather than the globus pallidus with which the putamen should be paired, based on cytoarchitectural and connectivity similarities; this pairing of the caudate nucleus with the putamen is relatively recent in phylogenetic terms and is known as the striatum (or neostriatum), in contrast to the older palaeostriatum consisting of the globus pallidus.
Box 23.1 Components of the basal ganglia

- Corpus striatum:
  - (Neostriatum
    - Caudate nucleus
    - Putamen

- Amygdala ± claustrum.

Anatomical relationships

A three-dimensional diagram showing the striatum (caudate nucleus and putamen) and its relationship to nearby structures is shown in Figure 23.10.

Connections

The basal ganglia interact with the cerebral cortex through a complex series of loop circuits; there is a functional division into connections with different parts of the cerebral cortex (such as motor and associative areas) and the limbic system. In particular, functionally defined regions of the frontal cortex (the orbital and medial prefrontal cortex (OMPFC), involved in emotions and motivation; the DLPFC, involved in higher cognitive processes or executive functions; the premotor and motor areas, involved in motor planning and the execution of those plans) project topographically through the basal ganglia, to the thalamus, and back to the cortex. The concept of the ventral striatum refers to a ventral extension of the striatum that includes the nucleus accumbens, the medial and ventral portions of the caudate nucleus and putamen, and the striatal cells of the olfactory tubercle. Using this definition, projections from frontal cortex may be considered to form a functional gradient of inputs from the ventromedial sector through the olfactory tubercle. These connections are illustrated in Figure 23.11. The cortical functional topography maintained through cortical connections to the striatum is likely to be continued from the striatum to the pallidum (relating predominantly to the globus pallidus) and pars reticulata of the substantia nigra, from these output structures to the thalamus, and finally, back to cortex.

Alexander and colleagues put forward a model of five functionally segregated circuits linking the basal ganglia with the cortex in a parallel organization. Evidence supporting this model has been forthcoming from non-human primate studies, such as that of Middleton and Strick. The five circuits are designated the motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal and anterior cingulate cortex terminating in the dorsolateral region; furthermore, afferents from interconnected and functionally associated thalamic and cortical regions terminate in the same striatal area, resulting in a tight, anatomical and functional organization to the striatum. These connections are illustrated in Figure 23.11. The cortical functional topography maintained through cortical connections to the striatum is likely to be continued from the striatum to the pallidum (relating predominantly to the globus pallidus) and pars reticulata of the substantia nigra, from these output structures to the thalamus, and finally, back to cortex.

The five circuits are designated the motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal and anterior cingulate cortex terminating in the dorsolateral region; furthermore, afferents from interconnected and functionally associated thalamic and cortical regions terminate in the same striatal area, resulting in a tight, anatomical and functional organization to the striatum. These connections are illustrated in Figure 23.11. The cortical functional topography maintained through cortical connections to the striatum is likely to be continued from the striatum to the pallidum (relating predominantly to the globus pallidus) and pars reticulata of the substantia nigra, from these output structures to the thalamus, and finally, back to cortex.

Alexander and colleagues put forward a model of five functionally segregated circuits linking the basal ganglia with the cortex in a parallel organization. Evidence supporting this model has been forthcoming from non-human primate studies, such as that of Middleton and Strick. The five circuits are designated the motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal and anterior cingulate cortex terminating in the dorsolateral region; furthermore, afferents from interconnected and functionally associated thalamic and cortical regions terminate in the same striatal area, resulting in a tight, anatomical and functional organization to the striatum. These connections are illustrated in Figure 23.11. circuits; each is centred on a different part of the frontal lobe, as shown in Figure 23.12. The circuits consist of partially overlapping corticostriate inputs, which are progressively funnelled via the pallidum (globus pallidus) and substantia nigra to the thalamus and thence back to the cortex, as shown in Figure 23.13. Details of the five proposed circuits are shown in Figure 23.14.

Figure 23.15 depicts the organization of thalamocorticothalamic projections that relate to the basal ganglia; nuclei appear to mediate information flow from higher cortical association areas of the prefrontal cortex to rostral motor areas involved in cognitive or integrative aspects of motor control to primary motor areas that direct movement execution.16

Within each area of connected corticobasal ganglia structures, there are reciprocal connections linking up regions associated with similar functions (maintaining parallel networks); in addition, there exist non-reciprocal connections linking up regions that are associated with different cortical–basal ganglia circuits.16

### INTERNAL ANATOMY OF THE TEMPORAL LOBES

**Components**

In this section, particular consideration is given to the anatomy of the hippocampal formation and the amygdala. There are essentially three components to the medial temporal lobe: the hippocampal formation, the amygdala and

the parahippocampal cortices that cover them; the hippocampal formation refers to a constellation of structures including the subicular cortices (parasubiculum, presubiculum and subiculum proper), the hippocampus (CA1–CA3 pyramids) and the dentate gyrus (including its hilar neurons or CA4 sector). Figure 23.16 illustrates the components of the hippocampal formation.

The nuclei of the amygdala are described below.

**Surface landmarks and anatomical relationships**

Figure 23.17 is a coronal section through the brain of a human female, showing the relationship of the hippocampi to nearby structures in addition to the parahippocampal gyrus and the fimbria of the hippocampus.
The following sulci may be seen on the surface of the medial temporal lobe: the rhinal sulcus, which passes anteriorly and laterally and is often more prominent in great apes than in humans; the collateral sulcus, which passes posteriorly and laterally; the uncal sulcus, which separates the uncus (uncal hippocampal formation) from the parahippocampal gyrus; the hippocampal sulcus or fissure, which separates the rolled up main body of the hippocampal formation from the posterior parahippocampal gyrus; and the sulcus semianularis, which separates the entorhinal cortex from the cortical nuclei of the amygdala.\(^{21}\) The position of the amygdala is shown in Figure 23.10. Interestingly, the surface of the entorhinal cortex often has a corrugated appearance, which is probably the result of the presence of cytochrome oxidase-reactive islands (in layer II).\(^ {21,22}\)

**Connections**

In Figure 23.18 the disposition of the cell fields CA1–CA4 in the hippocampal formation, and its different strata, are illustrated. Different cell fields are probably involved in different connections. For example, CA2 pyramidal cells appear to receive the hypothalamic input (from the supramamillary region of the hypothalamus). Cortical and subcortical connections of the hippocampal formation are shown in Figure 23.19, with further details being given in the legend.
To understand the connections of the amygdala (or amygdaloid complex), it is useful first to have an overview of its many nuclei. These are shown in Figure 23.20 for the rat amygdala. These nuclei may be divided into groups (in Figure 23.20 by different colours): the deep or basolateral group, which includes the lateral nucleus (LA), the basal nucleus (B) and the accessory basal nucleus (AB); the superficial or cortical-like group, which includes the nucleus of the lateral olfactory tract (NLOT), the bed nucleus of the accessory olfactory tract (BAOT), the anterior and posterior cortical nucleus (CoA and CoP, respectively) and the peri-amygdaloid cortex (PAC); the centromedial group composed of the central (CeA) and medial (M) nuclei and the amygdaloid part of the bed nucleus of stria terminalis (BNST); and a separate set of nuclei that do not easily fall into any of these three previous groups and include the intercalated cell...
masses and the amygdalohippocampal area. The CeA has four divisions: the capsular subdivision (CeC), lateral subdivision (CeL), intermediate subdivision (CeI) and medial subdivision (CeM). Figure 23.21 summarizes the main afferents to the nuclei of the amygdala, while Figure 23.22 summarizes the main efferents from the nuclei. Intra-amygdaloid connections are summarized in Figure 23.23.

**MAJOR WHITE-MATTER PATHWAYS**

In this section, two major white-matter pathways of relevance to psychiatry are considered, namely the corpus callosum and the fornix. Papez’ circuit and its relationship to the limbic system were described earlier in this chapter.

**Corpus callosum**

This constitutes the largest white-matter pathway in the brain and is a set of commissural fibres providing both...
Figure 23.20 Nuclei of the rat amygdaloid complex. Coronal sections are drawn from rostral (a) to caudal (d). The different nuclei are divided into three groups, as described in text. Areas in blue form part of the basolateral group, areas in yellow are the cortical group, and areas in green form the centromedial group:

- ABmc, accessory basal magnocellular subdivision
- ABpc, accessory basal parvicellular subdivision
- Bpc, basal nucleus magnocellular subdivision
- e.c., external capsule
- Ladl, lateral amygdala medial subdivision
- Lam, lateral amygdala medial subdivision
- Levl, lateral amygdala ventrolateral subdivision
- Mcd, medial amygdala dorsal subdivision
- Mov, medial amygdala ventral subdivision
- Mr, medial amygdala rostral subdivision
- Pir, piriform cortex
- s.t., stria terminalis

homotopic and heterotopic connections between the right and left cerebral hemispheres. The corpus callosum in the sectional anatomy views of Figures 23.3 and 23.18, from which it can be seen that it extends rostrally from the splenium, via its body, to the genu, just inferior to the callosal sulcus (see Figure 23.3). Its relationship to close structures is evident from these three figures. A summary of the destinations of fibres that pass through different parts of the corpus callosum is given in Table 23.2.

**Fornix**

The course of the fornix is shown in Figure 23.3. As the fornix passes ventrally towards the anterior commissure (labelled 14 in Figure 23.3), it divides into two parts, the precommissural part and the post-commissural part. As can be seen from Figure 23.19, fibres of the fornix connect the hippocampal formation with the hypothalamus, septal nuclei of the basal forebrain and anterior thalamic nuclei.

**TYPES OF CELL FOUND WITHIN THE CENTRAL NERVOUS SYSTEM**

**Neurons**

Neurons, or nerve cells, have a variety of different sizes and shapes, but all have one axon emerging from the axon hillock and at least one dendrite; some neurons possess many dozens of dendrites. The axon can vary in length, from a few millimetres to almost a metre. In larger neurons, it can be seen that the nucleus is round and centrally placed and contains a prominent nucleolus, in which ribosomal RNA (rRNA) is transcribed (by RNA pol I), while the cytoplasm of the neuronal soma contains large numbers of basophilic granular Nissl bodies extending into the dendrites (although typically not in the axon hillock), which are the site of protein biosynthesis, consisting of rough endoplasmic reticulum and polyribosomes. Neuronal cytoplasm also contains mitochondria, which are the sites of oxidative phosphorylation; Golgi apparatus, which carries out glycosylation and phosphorylation, synthesizes proteoglycans and carbohydrates, transports lipids and creates lysosomes (from endosomes by the addition of hydrolytic

enzymes); and lipofuscin granules, which are membrane-bound yellow–brown organelles containing non-metabolizable remnants of lysosomal digestion.

Synaptic vesicles are the organelles of the boutons terminaux, which store neurotransmitters. Details of synaptic function are given in Chapter 24.

The dark tyrosine-derived pigment neuromelanin is normally found in granules in the neuronal cytoplasm of the central nervous system in the following locations: substantia nigra; pars compacta; locus coeruleus, from which arises the ascending noradrenergic pathway (see below); dorsal motor nucleus of the vagus nerve; and the pontine median raphe nucleus.

**Macroglia**

**Astrocytes**

Astrocytes, or astroglia, are classified as being either protoplasmic or fibrous/fibrillary. Protoplasmic astrocytes are found mainly in grey matter and tend to have short processes with numerous branches. In contrast, fibrous or fibrillary astrocytes are found mainly in white matter and tend to have long processes; they form a thick feltwork beneath the pia mater. Their cytoplasm tends to contain glial fibrillary acidic protein (GFAP), an intermediate filament protein.

Variants of astrocytes include Bergmann glia in the granule layer of the cerebellar cortex; and the round laminate PAS-positive corpora amylacea found in subpial and periventricular white matter and in the spinal cord, particularly in subjects of advanced age.

Astrocytes have numerous functions, which may include structural functions: central nervous system repair, astrocytes having been considered to be functionally homologous to fibroblasts in the central nervous system and helping to form scar tissue (astrocytic gliosis); the nourishment of neurons; their end-feet may play a role in the formation of the blood–brain barrier; aiding in neurotransmission; vasomodulation; ion-concentration regulation; and promoting myelination by oligodendrocytes.

**Oligodendrocytes**

Oligodendrocytes, or oligodendroglia, possess few cell processes (hence their name) and do not have cytoplasmic filaments. Those in grey matter tend to cluster around neuronal cell bodies and are known as perineuronal satellite cells. They probably play an important role in sustaining these neurons. Those in white matter are arranged in rows between myelinated fibres and are known as interfascicular glia. These white-matter oligodendrocytes are responsible for the formation of the myelin sheaths.

**Ependymal cells**

Ependymal cells, ependyma, are ciliated cuboidal cells that usually form a continuous lining of the ventricular system of the brain (including its foramina and the cerebral aqueduct) and the central canal of the spinal cord (with which the ventricles are continuous). Ependymal cells may play a role in fluid homeostasis (between cerebrospinal fluid and brain parenchyma) and in cerebrospinal fluid circulation.

**Choroid plexus cells**

The cuboidal cells that cover the fibrovascular cores of the choroid plexi of the ventricles are non-ciliated. The choroid plexi are mainly responsible for the production of cerebrospinal fluid.

**Microglia**

Microglia are now known to be resident central nervous system immune cells that provide surveillance in the normal brain and spinal cord and become activated following tissue insult to perform a number of functions, including proliferation, migration, phagocytosis, and secretion of cytokines, chemokines, trophic factors, nitric oxide and other bioactive molecules and reactive species. Detailed mechanisms by which they detect and respond to their environment are not fully understood, but it is known that microglia express a number of surface receptors and ion channels, including voltage-gated sodium channels, that participate in transduction of external stimuli to intracellular responses. When activated, microglia usually become rod-shaped.

**Stem cells**

Stem cells are multipotent cells that can give rise to a differentiated progeny and self-renewed progeny; the balanced coordination of these two stem cell fates is essential for embryonic development and tissue homeostasis in the adult. Stem cells are aided by their environment, which provides support and regulatory signals; this microenvironment is the stem cell niche and is the sum of all factors, cellular and molecular, that interact with and regulate the stem cell. At the time of writing, the following two stem cell niches have been established as existing in the adult mammalian brain: the subventricular zone (SVZ) of the lateral wall of the lateral ventricle, and the subgranular zone (SGZ) of the dentate gyrus of the hippocampal formation. Progenitor cells of the SVZ continually migrate rostrally to the olfactory bulb and differentiate into interneurons, which integrate into the granule cell layer and olfactory glomerular layer and serve important olfactory functions. Postnatal neurogenesis in the dentate gyrus plays a critical role in normal cognitive development, specifically in learning and memory functions associated with the hippocampus.

**MAJOR NEUROCHEMICAL PATHWAYS**

**Dopaminergic pathways**

Major dopaminergic pathways of the human brain are detailed in Figure 23.24. Note that the nigrostriatal dopamin-
ergic pathway has its origin in the pars compacta of the substantia nigra of the mesencephalon (midbrain) and projects to the corpus striatum of the basal ganglia; the pars compacta is part of dopaminergic cell group A9. The nigrostriatal pathway is sometimes referred to as the mesostriatal pathway. The origin of the mesolimbic and mesocortical dopaminergic pathways is also in the mesencephalon, in the ventral tegmental area (dopaminergic cell group A10). In addition to the prefrontal cortex, the mesocortical pathway probably also projects to the cingulate and entorhinal cortices.

**Noradrenergic pathways**

Major ascending noradrenergic (norepinephrinergic) projections from the locus coeruleus of the pons are detailed in Figure 23.25. Most of these tracts ascend in the medial forebrain bundle, an exception being the tract supplying the cerebellum, which does so via the superior cerebellar peduncle. The major descending noradrenergic projection to the spinal cord (coeruleospinal pathway) is also illustrated in Figure 23.25.

**Cholinergic pathways**

Two major brain cholinergic (acetylcholine) pathways are of importance in psychiatry. One is the brainstem cholinergic pathway, which takes its origin in the brainstem and is detailed in Figure 23.26. The second is the basal forebrain cholinergic pathway, which originates in the basal forebrain and projects widely to the prefrontal cortex, amygdala and hippocampus, as illustrated in Figure 23.27.
**Corticofugal glutamate system**

Corticofugal fibres project from the cerebral cortex to subcortical structures, including the basal ganglia and thalamus. These fibres form a fan-shaped arrangement of white matter known as the corona radiata (Figure 23.28a). Since the corona radiata appears as a curved linear area of low attenuation on computed tomography (CT) scans of the brain, it can be easily identified on a CT scan (Figure 23.28d).

---

**Figure 23.27** Basal forebrain cholinergic pathway. Cholinergic neurons originating in the basal forebrain project to the prefrontal cortex, hippocampus and amygdala; they are believed to be involved in memory.

A, amygdala; BF, basal forebrain; C, cerebellum; H, hippocampus; Hy, hypothalamus; NA, nucleus accumbens; NT, brainstem neurotransmitter centres; PFC, prefrontal cortex; S, striatum; SC, spinal cord; T, thalamus.

---

brain (Figure 23.28d), it is also known as the centrum semi-ovale, particularly in the field of structural neuroimaging. As mentioned in the section on the basal ganglia (vide supra), cortical-striatal-thalamic-cortical loops are likely to subserve many important functions (see Figures 23.13–15). These and similar loops of importance in psychiatry include the DLPFC-striatal-thalamic-DLPFC loop for executive functions, the anterior cingulate cortex-striatal-thalamic-anterior cingulate cortex loop for attention, the orbitofrontal cortex-caudate-thalamic-orbitofrontal cortex loop for impulsivity, and possibly an anterior cingulate cortex-nucleus accumbens-thalamic-anterior cingulate cortex loop for some aspects of emotion. The output from the cortical pyramidal neurons that begin and end these loops is illustrated in Figure 23.29. As the neurotransmitter output is the amino acid glutamate, this whole arrangement is referred to as the corticofugal glutamate system.

### Serotonergic pathways

Major ascending and descending serotonergic projections from the brainstem are detailed in Figure 23.30. The origins are from three groups of midline brainstem raphe nuclei: the medullary raphe group, comprising the nucleus raphe pallidus, nucleus raphe obscurus and nucleus raphe magnus, from which project the descending bulbospinal tract into the spinal cord and the propriobulbar tract to the inferior olivary complex; the mesencephalic raphe group, comprising the nucleus raphe dorsalis, from which project ascending tracts; and the pontine raphe group, comprising the nucleus raphe pontis and nucleus centralis superior, from which project ascending tracts, the pontocerebellar tract to the cerebellum, and propriobulbar tracts to the locus coeruleus and reticular formation.

![Output from cortical pyramidal neurons](image)

**Figure 23.29** Output from cortical pyramidal neurons. Corticostriatal-thalamic-cortical loops begin and end with a pyramidal neuron in the cortex. These pyramidal cells are located in various laminae of the cortex, which influence the direction in which they send their outputs. Cortical pyramidal neurons located in laminae 2 and 3 send output to other cortical areas; those located in lamina 5 send output to the striatum and brainstem; and those in lamina 6 send output to the thalamus. The neurotransmitter output of all cortical pyramidal neurons is glutamate (glu).

**Figure 23.30** Major serotonergic projections. Like noradrenaline, serotonin has both ascending and descending projections. Ascending serotonergic projections originate in the brainstem and extend to many of the same regions as noradrenergic projections, with additional projections to the striatum and nucleus accumbens. These ascending projections may regulate mood, anxiety, sleep and other functions. Descending serotonergic projections extend down the brainstem and through the spinal cord; they may regulate pain A, amygdala; BF, basal forebrain; C, cerebellum; H, hippocampus; Hy, hypothalamus; NA, nucleus accumbens; NT, brainstem neurotransmitter centres; PFC, prefrontal cortex; S, striatum; SC, spinal cord; T, thalamus.

**KEY POINTS**

- The frontal cortex contains M1, PMd, PMv, FEF, DLPFC, VLPFC, SMA and the orbitofrontal cortex; the parietal cortex contains S1 and S2; the temporal cortex contains A1 and, on the dominant side, Wernicke’s area; the occipital cortex contains V1, V2, V3d, V3v, V3a and V4.

- The limbic system is based on the Papez circuit, which was further elaborated upon by MacLean to include the following structures: olfactory bulb, olfactory tubercle, lateral olfactory stria, amygdala, stria terminalis, septal nuclei, stria medullaris, interpeduncular nucleus, medial forebrain bundle and mammillary body; and also a pathway from the septal nuclei via the supracallosal striae, dentate gyrus, hippocampus and fornix back to the mammillary body. Other components of this version included the anterior nuclear group of the thalamus, the diagonal band of Broca and the habenula (part of the epithalamus).

- The cranial nerves are I olfactory (smell), II optic (vision), III oculomotor (motor/parasympathetic), IV trochlear (motor), V trigeminal (sensory/motor), VI abducent (motor), VII facial (motor/sensory/parasympathetic), VIII vestibulocochlear (motor/sensory), IX glossopharyngeal (sensory/parasympathetic), X vagus (motor/sensory/parasympathetic), XI accessory (motor) and XII hypoglossal (motor).
Each of the basal ganglia consists of the corpus striatum and amygdala and interacts with the cerebral cortex through a complex series of loop circuits; there is a functional division into connections with different parts of the cerebral cortex (such as motor and associative areas) and the limbic system.

There are essentially three components to the medial temporal lobe: the hippocampal formation, the amygdala and the parahippocampal cortices that cover them; the hippocampal formation refers to a constellation of structures including the subicular cortices (parasubiculum, presubiculum and subiculum proper), the hippocampus (CA1–CA3 pyramids) and the dentate gyrus (including its hilar neurons or CA4 sector).

The corpus callosum constitutes the largest white-matter pathway in the brain and is a set of commissural fibres providing both homotopic and heterotopic connections between the right and left cerebral hemispheres.

Fibres of another important white-matter pathway, the fornix, connect the hippocampal formation with the hypothalamus, septal nuclei of the basal forebrain and anterior thalamic nuclei.

Types of cell found within the central nervous system include neurons, macroglia (astrocytes and oligodendrocytes), ependymal cells, choroid plexus cells, microglia and stem cells.

Major neurochemical pathways in the brain include the nigrostriatal, mesolimbic and mesocortical dopaminergic pathways; the ascending noradrenergic (norepinephrinergic) projections from the locus coeruleus; the coeruleospinal pathway; the brainstem cholinergic pathway; the basal forebrain cholinergic pathway; the corticofugal glutamate system; and major ascending and descending serotonergic projections from the brainstem.

INTRODUCTION

This chapter covers the basic concepts in neurophysiology: ion flux and channels, membrane potential, graded potential, action potential, synapses, and neurotransmission (neurotransmitter synthesis, release and reuptake).

It is estimated that the human brain contains of the order of 100 billion \((10^{11})\) nerve cells, or neurons. Neurons are excitable cells that are capable of converting various stimuli into electrical impulses. A typical neuron is composed of a cell body and a number of elongated projections. One of these projections (an axon) joins the cell body at an elongated cylindrical point called the axon hillock and forms the output pathway for the neuron, and a network of other projections (dendrites) forms the input pathway to the neuron (Figure 24.1). There are exceptions to this somewhat simplified morphological description, with some neurons having no dendrites and other neurons using dendrites as the output in addition to the input pathway. Neurons can be classified on the basis of their structural characteristics (Figure 24.2). A neuron may make connections with as many as 1000–2000 other neurons by way of synapses, specialized junctions between neurons. Communication between neurons takes place using chemical transmitters, which are released at the presynaptic terminal of the axon, cross the synaptic cleft and bind to receptors on the postsynaptic membrane. The electrical signals of the neurons are action potentials; these can cover quite considerable dis-
stances along the length of an axon (up to 1 m in humans). Some larger axons are surrounded by layers of myelin, a lipid substance that improves the speed with which axons can conduct action potentials. The generation of action potentials by the neuron relies on two features of the cell membrane: the resting potential and the presence of channels through which ions can flow. The resting potential is the separation of electrical charge across the membrane, with the outside being more positive by approximately 70 mV. This potential difference is altered by the opening and closing of ion channels located in the membrane itself and the flow of ions from the outside of the cell through the membrane to the inside, and vice versa. When the potential difference reaches a threshold level, an action potential is produced. The action potential is propagated along the length of the axon until it reaches the presynaptic terminal, where it causes the release of a chemical transmitter. This diffuses across the synaptic cleft and binds to receptors located on the postsynaptic membrane. The result is an increase in the likelihood of the postsynaptic neuron being brought to threshold and continuing with the propagation of the action potential (excitation), or a decrease in the likelihood of the postsynaptic neuron being brought to threshold and continuing with the propagation of the action potential (inhibition).

ION FLUX AND CHANNELS

The basis for the generation of action potentials is the movement of ions across the plasma membrane through ion channels, altering the separation of electrical charge that exists under resting conditions. The molecules contained within a liquid move continuously, and equilibrium is reached when they are distributed uniformly throughout. If there is an initial region of higher concentration, then the molecules will move away from this area towards the area of lower concentration, down their concentration gradient, until equilibrium is reached. If two compartments containing equal volumes of a solution of differing concentrations are separated by a barrier permeable to the molecules in that solution, then there will be diffusion across this membrane from the compartment containing the solution of higher concentration to that containing the lower concentration. At the same time, there will be random movement of molecules in the opposite direction. The movement of substance across a surface in a unit of time is called flux, and the net flux is the difference between two one-way fluxes. Eventually the concentrations become equal and the net flux is zero.

Charged particles (ions) such as sodium (Na\(^+\)), potassium (K\(^+\)), chloride (Cl\(^-\)) and calcium (Ca\(^{2+}\)) move across the plasma membrane due not only to concentration gradients but also, since they are charged, electrical gradients. Positively charged ions (cations) move towards negatively charged areas, and negatively charged ions (anions) move towards areas of positive charge. Since an electrical gradient exists across the plasma membrane of neurons (the membrane potential; see below), which exerts a driving force on the ions present on either side of the membrane, there are two driving forces at work across the neuronal membrane. These two driving forces (chemical and electrical) are collectively known as the electrochemical gradient.

Ions traverse the plasma membrane from the extracellular fluid to the intracellular fluid, and vice versa, by way of ion channels, protein structures within the plasma membrane that selectively allow ions to pass through. The channels are closed by the movement of a part of the protein called a gate and are opened when this gate moves out of the way. The opening and closing of ion channels is a process called gating, a rapid process that can occur many times per second. The channels open and close in response to a range of stimuli and are described as ‘leakage’, ‘voltage-gated’, ‘ligand-gated’ and ‘mechanically gated’. Leakage channels open and close randomly and allow ions to pass through. There are more leakage channels for potassium in the plasma membrane than for sodium, and as a result the plasma membrane is more permeable to potassium than it is for sodium. Voltage-gated channels open in response to a change in the membrane potential (see below); movement of sodium and potassium ions through these channels is critical for the generation and propagation of action potentials, and movement of calcium ions through these plays a role in the release of neurotransmitters at the presynaptic terminal. A ligand-gated channel opens or closes in response to a chemical stimulus, such as a neurotransmitter. This type of channel can be opened or closed in one of two ways: the chemical can bind directly to a portion of the protein of the channel itself (as in the case of the neurotransmitter acetylcholine) or it can activate a specialized protein (G-protein) in the membrane, which activates an additional second-messenger protein in the intracellular fluid, which in turn operates the channel’s gate. A mechanically gated channel opens or closes in response to a mechanical stimulus, such as vibration, which physically distorts the membrane and as a result alters the physical properties of the channel in order to activate its gate. An example of this type of gate is found in the inner ear. The structure of the voltage-gated sodium channels and potassium channels is shown in Figure 24.3. It can be seen that sodium channels can be closed, open or inactivated whereas potassium channels can be closed or open.

In addition to these ion channels, the plasma membrane contains sodium/potassium pumps that move sodium and potassium ions across the membrane. These pumps move sodium ions out of the cell into the extracellular fluid and potassium ions into the intracellular fluid against their electrochemical gradients; this active transport process requires a constant input of energy. Three sodium ions are moved out through the membrane and two potassium ions are moved in. This process contributes to the maintenance of the membrane potential by maintaining a separation of
The separation of charge is due to the differential distribution of various ions outside and inside the cell.

**RESTING MEMBRANE POTENTIAL**

Under resting conditions, the plasma membrane of a neuron has a separation of charge across it and is therefore polarized. This charge separation is a form of potential energy and is measured in millivolts (mV), or thousandths of volts. Conventionally, the extracellular fluid is designated as zero voltage, such that when it is measured using an intracellular electrode and an extracellular electrode as the reference, if the potential difference across the membrane is measured to be 70 mV, then the resting membrane potential is said to be −70 mV. This potential ranges from −40 mV to −75 mV in different neurons and is steady unless electrical current changes occur across the membrane. When alterations occur to this separation of charge due to the movement of ions across the cell membrane (see above), the membrane is said to hyperpolarize if the inside becomes more negative with respect to the outside (e.g., the potential changes from −70 mV to −80 mV) and to depolarize if the potential reduces (e.g., the potential changes from −70 mV to −60 mV). As will be discussed later, hyperpolarization of the membrane decreases the neuron’s ability to generate an action potential and is therefore inhibitory, while depolarization increases the neuron’s ability to generate an action potential and is therefore excitatory.

The separation of charge is due to the differential distribution of various ions outside and inside the cell.

**GRADED POTENTIALS AND ACTION POTENTIALS**

Changes in the membrane potentials of neurons underlie the basis of neuronal processing and transmission of electrical impulses. These alterations in membrane potential can take one of two forms: graded potentials and action potentials. Graded potentials arise when a stimulus causes activation of...
ligand-gated or mechanically gated channels. This potential is a small deviation of the membrane potential; its size is related to the intensity of the stimulus (hence the term ‘graded’) and its polarity is related to the nature of the stimulus. If the stimulus induces a reduction in the membrane potential (i.e. a decrease in the difference in charge between the inside and the outside of the cell), then it is called a ‘depolarizing graded potential’. Conversely, if the stimulus induces an increase in the membrane potential (i.e. an increase in the difference in charge between the inside and the outside of the cell), then it is called a ‘hyperpolarizing graded potential’. If the stimulus is small, only a few channels will be activated and a small graded potential will occur. These potentials are usually confined to small regions of the membrane and usually occur in the dendrites and the cell body of the neuron; they are named in relation to the location or their function, for example ‘synaptic potential’ or ‘receptor potential’. They also decrease in size within a short distance from the site from which they were initiated and are therefore useful as signal generators over a short distance. Many stimuli arriving in quick succession, however, can cause graded potentials to summate, and this has importance in the initiation of larger potentials, called action potentials.

An action potential is a large brief alteration in the membrane potential that occurs mainly in the axon plasma membrane and the axon terminals. The alteration may be as large as 100 mV, taking the membrane potential from its resting value of −70 mV to +30 mV (thus depolarizing it), and last up to 4 ms. The action potential is comprised of two phases, a depolarizing phase in which the membrane potential becomes less negative, followed by a repolarizing phase in which the potential is restored to its resting level of −70 mV. An action potential is initiated by a depolarizing stimulus (e.g. a neurotransmitter binding to a receptor), and this causes voltage-gated sodium channels to open. Sodium ions move rapidly across the membrane, down their concentration and electrical gradients, into the intracellular fluid. This influx causes depolarization of the membrane potential; when the membrane potential reaches a critical level, the threshold potential (about −55 mV in many neurons, or approximately 15 mV less negative than the resting membrane potential for that cell), depolarization becomes a positive-feedback loop. Influx of sodium causes further depolarization, which in turn causes opening of more sodium channels and further depolarization. When the membrane potential reaches a peak at about +30 mV (the inside now being more positive than the outside), sodium influx declines rapidly as sodium channels are inactivated by closure of the inactivation gate (this is in contrast to the gate being closed; see Figure 24.3). At this peak, voltage-gated potassium channels open, permeability to potassium increases, and potassium moves down its concentration and electrical gradients from the intracellular fluid to the extracellular fluid; depolarization halts and repolarization of the membrane potential starts to occur. Potassium channels are slower to close than sodium channels; as a result, there is a brief period following repolarization in which the membrane is transiently more permeable to potassium than it is in the resting state, and the membrane potential drops below that seen at rest (Figure 24.4). This is the hyperpolarization phase, when the membrane potential becomes more negative than the resting potential, at about −90 mV. During this period, another stimulus (however large) cannot produce further action potentials; this is due to sodium channels being open already or having been inactivated. This period is known as the absolute refractory period. Following this refractory period, and after some of the sodium channels have returned to their resting state and some of the potassium channels are still open, it is possible for a second stimulus to evoke another action potential, but only if this is of a sufficient size. This period of up to 15 ms coincides with the hyperpolarization period and is known as the ‘relative refractory period’.

If a stimulus is not of a sufficiently high intensity to cause the membrane potential to depolarize to the critical

Figure 24.4 Action potential (AP) or impulse. When a stimulus depolarizes the membrane to threshold −55 mV, an AP is generated. The AP arises at the trigger zone (at the junction of the axon hillock and the initial segment) and then propagates along the axon to the axon terminals. Redrawn with permission from Tortora and Derrickson (2006) Principles of Anatomy and Physiology 11th edn. Oxford: Wiley Blackwell.
threshold, then an action potential will not be produced. Such potentials are termed ‘subthreshold potentials’. An action potential is therefore an all-or-none phenomenon – there cannot be fractions of action potentials.

For an action potential to have an effect distant from its origin, it needs to be transmitted along the length of the axon, sometimes a considerable distance. This requires the membrane potential at each segment of the axon along the way to be brought to the threshold potential. Local currents are produced in adjacent segments of the axon distal to the point of the action potential, but the refractoriness of the membrane in the trailing segment of axon means that the action potential is propagated in one direction only (an exception to this is following artificial stimulation in the middle of an axon). Since the generation of an action potential is dependent upon the positive feedback cycle of voltage-gated sodium channels further along the axon, the size of the action potential is not diminished in size at the axon terminals. This type of propagation of action potentials due to depolarization and repolarization of adjacent segments occurs in unmyelinated axons and in muscle fibres; since it is continuous along the length of the cell, it is known as ‘continuous conduction’. In myelinated axons, action potentials can be transmitted at much greater speeds. The myelin sheath (see Chapter 23) is a multilayered sheath of lipid wrapped around the axon. This highly resistant sheath effectively insulates the axon and prevents electrical conduction. This sheath, however, is not wrapped in a continuous fashion along the entirety of the axon but is periodically interrupted at the nodes of Ranvier (approximately 1 μm in length, or 1 × 10⁻⁶ m). At these nodes there is no covering of myelin sheath, and it is here that there are large numbers of voltage-gated channels (in contrast to the few voltage-gated channels found in the membrane covered by myelin). The flow of local currents that occurs across the plasma membrane occurs mainly at these nodes. The nerve impulses carried along the myelinated axon effectively jump from one node to the next as current is carried in the intracellular fluid between the nodes and across the plasma membrane at the nodes. This type of nerve conduction is known as ‘saltatory conduction’ (from the Latin saltare, meaning ‘to leap’). The propagation of action potentials by saltatory conduction in myelinated axons is much faster than the continuous conduction of unmyelinated axons. In addition to the speed of nerve conduction in myelinated axons being faster, this type of conduction is also more energy-effective, since fewer sodium/potassium pumps are required to restore the resting membrane potential due to the presence of the nodes.

The diameter of an axon also affects the speed with which it conducts axon potentials, since a larger-diameter axon offers less resistance to the production of local currents. Conduction velocities range from 0.5 m/s for small-diameter unmyelinated axons up to approximately 100 m/s for large-diameter myelinated axons.

All cell membranes are capable of transmitting graded potentials, but only excitable cells such as nerve and muscle cells can propagate action potentials; this forms the basis for communication over large distances.

**SYNAPSES**

Neurons within the central nervous system are driven by communication with other neurons via specialized regions called synapses (named by Sherrington, from the Greek – syn, meaning ‘with’, and –aptein, meaning ‘to join’), of which there are, according to latest estimates, approximately 100 trillion (10¹⁴) within the central nervous system. Their presence is therefore fundamental to the functioning of the nervous system. The neuron from which the impulses are being transmitted is termed the ‘presynaptic neuron’ and the neuron that receives the impulses is known as the ‘postsynaptic neuron’. The majority of synapses occur between axon and dendrite (axodendritic), between axon and cell body (axosomatic) and between axon and axon (axoaxonic). Based on their morphology, two classes of synapse exist: those in which the cytoplasms of the pre- and postsynaptic cells are bridged by tubular structures called connexons, and those in which they are not, with the cells being separated by a synaptic cleft measuring 20–50 nm (10⁻⁸ m). These morphological differences account for the functional differences of these synapses, with the bridged (gap) junctions mediating electrical transmission and the unbridged junctions mediating chemical transmission. Electrical synapses are found in cardiac muscle and in the visceral smooth muscle but are present in much lower numbers in the human nervous system (in the cerebral and cerebellar cortices) compared with chemical synapses.

The activity of the postsynaptic neuron can be increased by the membrane potential being brought closer to its firing threshold (i.e. depolarizing it); this is an excitatory synapse. Alternatively, the activity of the postsynaptic neuron can be decreased by moving the membrane potential further way from its threshold (i.e. hyperpolarizing it); this is an inhibitory synapse. At an excitatory chemical synapse, the action potential arriving at the presynaptic terminal causes a sequence of events (see above) that result in the release of an excitatory transmitter (such as glutamate), which crosses the synaptic cleft and induces an excitatory postsynaptic potential (EPSP). One EPSP alone (of the order of 0.5 mV) may not be enough to bring the postsynaptic neuron to its firing threshold, and no action potential is generated. However, for a brief period, the postsynaptic membrane is more receptive to subsequent EPSPs, and the likelihood of it generating an action potential is increased; this is known as ‘facilitation’. If a presynaptic cell is stimulated in quick succession, it may induce EPSPs in a postsynaptic cell before the previous EPSPs have died away; this is known as ‘temporal summation’ (EPSPs generated at about the same time). If many presynaptic cells induce EPSPs in the postsynaptic cell, spatial summation may occur (Figure 24.5).
At an inhibitory chemical synapse, the action potential arriving at the presynaptic terminal causes release of an inhibitory transmitter, such as γ-aminobutyric acid (GABA), which induces an inhibitory postsynaptic potential (IPSP) in the postsynaptic cell. This IPSP is generated by the opening of chloride or potassium channels. Once open, these channels allow Cl⁻ ions into the cell and K⁺ ions out of the cell, causing the inside of the cell to become more negative (i.e. hyperpolarized). An additional type of inhibition is presynaptic inhibition, in which small presynaptic cells terminate on other presynaptic cells; these latter cells normally produce EPSPs. However, the functioning of the inhibitory presynaptic cells is to reduce the size of these EPSPs, and in this way the postsynaptic cell is less likely to be brought to firing threshold. Many thousands of presynaptic neurons can exert influence over a single postsynaptic cell (convergence), or many branches of a single presynaptic neuron can influence many postsynaptic neurons (divergence).

**NEUROTRANSMISSION**

At chemical synapses, neurotransmitters are the signal carrier by which action potentials are propagated from one neuron to another. These transmitters can be broadly classified by their size into small-molecule transmitters and larger neuropeptides. Small-molecule transmitters are synthesized from precursor molecules located in the nerve terminals using enzymes that have been synthesized in the soma of the neuron. These transmitters are transported down the axon using a slow axonal transport (0.5–5 mm/day) to the nerve terminal. Larger peptide transmitters (neuropeptides) are synthesized in the neuronal cell body and transported down the length of the axon via a cytoplasmic scaffold of microtubules at a much faster rate of up to 400 mm/day (fast axonal transport). In each case, the transmitters are packaged into vesicles before release. Thousands of neurotransmitter molecules are stored in these vesicles, which are either anchored to the presynaptic membrane at active zones or freely located within the terminal. When an action potential arrives at the presynaptic terminal, it causes calcium channels to open in the membrane, leading to calcium influx into the presynaptic terminal. This influx of calcium into the cell causes the vesicles containing the neurotransmitter to fuse with the plasma membrane, releasing the neurotransmitter into the synaptic cleft. A small fraction of the neurotransmitter released into the synaptic cleft binds to receptors located in the plasma membrane of the postsynaptic cell. Even under conditions of no stimulation (i.e. no action potential has arrived at the presynaptic terminal), these vesicles can release their contents into the synaptic cleft spontaneously and at a very low rate; this in turn causes small membrane potential changes in the postsynaptic neuron. These potentials have been studied extensively in the neuromuscular junction, where they are called ‘miniature end-plate potentials’ (mEPPs). The size of these mEPPs is not altered by altering degrees of depolarization, which implies that the release of neurotransmitter from the vesicle is an all-or-none phenomenon with a fixed amount, or quantum, of neurotransmitter released.

In order for the neurotransmitter to propagate the action potentials to the postsynaptic cell, it has to activate receptors. These can have a central opening that allows the movement of ions across the membrane (ionotropic), or they may activate other ion channels through a second-messenger system (metabotropic).

It is important to note that the term ‘receptor’ has two distinct meanings in neurophysiology. One relates to the type of sensory receptor that is a transducer (converts different forms of stimuli into electrical signals) for various sensory stimuli. These receptors can be classified as mechanoreceptors (detect physical pressure or deformation), thermoreceptors (detect changes in temperature), photoreceptors (detect changes in light levels), nociceptors (detect noxious or painful stimuli) and chemoreceptors (detect various chemical stimuli). However, the type of receptor referred to in this chapter is a protein embedded in the plasma membrane that binds a neurotransmitter and propagates action potentials.
Once the neurotransmitter has exerted its effect at the receptors, it needs to be removed from the synaptic cleft. This removal is essential for the normal functioning of the synapse. There are three main ways by which this is achieved. One is by simple diffusion of the transmitter away from the synaptic cleft and therefore away from the receptors so it can no longer exert its effect. The second is by breakdown by enzymes; an example of this is the neurotransmitter released at the neuromuscular junction, acetylcholine. This is degraded by acetylcholinesterase into choline and acetate. The third way by which neurotransmitters are removed is by reuptake. This can be back into the neurons that released it (for repackaging into new vesicles, ready for release) or into adjacent cells such as glia. An important action of many pharmacological agents is to prolong the activity of the neurotransmitter by blocking its breakdown by the enzyme or by preventing its reuptake.

KEY POINTS

- A membrane potential exists due to the separation of charged particles across the neuronal membrane.
- At rest, the inside of the neuron is negative with respect to the outside. The flow of ions can change this membrane potential in either direction – hyperpolarize it or depolarize it.
- If the threshold is reached, an action potential is generated, which is propagated to the synaptic terminal.
- The speed of propagation of the action potential is increased by a larger-diameter axon and the presence of a myelin sheath.
- Calcium influx at the presynaptic terminal causes neurotransmitter release, binding of the neurotransmitter to a postsynaptic receptor and a postsynaptic potential (excitatory – EPSP, or inhibitory – IPSP).
- The neurotransmitter is broken down or taken up by nerve terminals, and its action terminated.

Neurophysiology of integrated behaviour

Basant K Puri

INTRODUCTION

This chapter covers the physiology and anatomical pathways of the neural and endocrine systems involved in integrated behaviour, including perception, pain, memory, motor function and drives. The pathways concerned with arousal are described in Chapter 28. Motivation and emotions are described in Chapters 15 and 12, respectively.

PERCEPTION

Visual pathway

The visual pathway from the retina to V1, with the projection of retinal ganglion cell axons to the lateral geniculate nucleus (LGN) (via the optic nerve, the optic chiasma and the optic tract) and the projection from here to V1 (via the optic radiation), is shown in Figure 25.1. This figure also illustrates the visual field defects that can result from lesions at different parts of this pathway. From the details on the right-hand side of Figure 25.2, it can be seen that in V1 the LGN axons terminate primarily in layer 4 and form ocular dominance columns, with the termination site depending on the layer in which the LGN neuron is found: parvocellular cells project mainly to layer 4Cb, magnocellular cells to layer 4Cα and koniocellular cells to layer 4A and lower layer 3.1

The construction of visual experiences is dependent on attention. According to a comprehensive review by Kanwisher and Wojciulik, attention affects processing at the first stage of cortical information processing, in V1; attention not only modulates the gain on incoming visual information but can also add a pure top-down signal that increases baseline activity in striate and extrastriate cortex; attention can, under different conditions, select locations, features, objects or a combination thereof; and large regions within the frontoparietal network, which apparently provide the source of top-down bias signals in visual areas, support a very heterogeneous set of attention tasks.2 In other words: We are not passive recipients of the information that impinges on our retinae, but active participants in our own perceptual processes. Visual experience depends critically on attention. We

Figure 25.1 Visual pathway, showing the spatial arrangement of neurons and their fibres in relation to the quadrants of the retinae and visual fields. The proportions at various levels are not exactly to scale. In particular, the macula is exaggerated in size in the visual fields and retinae. In each quadrant of the visual field, and in the parts of the visual pathway subserving it, two shades of each respective colour are used: the paler shade denotes the peripheral field and the darker shade the macular part of the quadrant. From the optic tract onwards, these two shades are both made more saturated to denote intermixture of neurons from both retinae, the palest shade being reserved for parts of the visual pathway concerned with monocular vision

select particular aspects of a visual scene for detailed analysis and control of subsequent behaviour, but ignore other aspects so completely that moments after they disappear from view we cannot report anything about them.\(^2\)

Further aspects of the psychology of vision are covered in Chapter 16.

**Auditory pathway**

The anatomical pathways of the ascending auditory pathway, from the cochlear nerve to the auditory cortex, are shown in Figure 25.3a. Figure 25.3b illustrates the key stations in this pathway, from the cochlear hair cells to the inferior colliculus and thence to the primary auditory cortex via the medial geniculate body; there is also an output from the inferior colliculus to the superior colliculus, thereby allowing auditory stimuli to have an input into ocular movements (including reflex movements).

Griffiths and Warren have argued that it is meaningful to consider auditory objects as fundamental elements of the auditory world; operationally, an auditory object might be defined as an acoustic experience that produces a two-dimensional image with frequency and time dimensions.\(^3\) Figure 25.4 illustrates their consideration of models of auditory-object analysis, presented schematically as a hierarchy of operational processing stages, together with plausible neuroanatomical substrates for these operations.\(^3\)

**PAIN**

Chapter 52 details psychological and psychiatric aspects of pain. Here, neurophysiological aspects of pain are considered.

**Peripheral pain mechanisms**

**Nociceptors**

Nociceptors (pain receptors) may be dichotomized into C-polymodal nociceptors (C-PMNs) and A-mechanoheat
Figure 25.3 Main features of the human ascending auditory pathway. (a) Series of sections showing that ipsilateral and commisural connections occur at most levels in this system. The major connections are shown by the red and blue arrows; other arrows denote less heavy projections. (b) Main stations of the auditory pathway.

Figure 25.4 Models of auditory-object analysis presented schematically as a hierarchy of operational processing stages (left). Plausible neuroanatomical substrates for these operations are shown (right); however, these require further experimental validation. The putative flow of auditory information is indicated (blue arrows); the exchange of information with higher-order cortices and other sensory modalities is probably reciprocal (bidirectional arrows). The precise order of processing stages (e.g. cross-modal analysis and schema analysis) probably depends on task demands.

(AMH) nociceptors. As their names imply, AMN receptors respond primarily to mechanical and thermal stimuli. C-PNs respond not only to mechanical and thermal stimuli but also to chemical stimuli.

Peripheral inflammation
Tissue damage leads to direct stimulation of nociceptors and also the release of inflammatory mediators, including eicosanoids, cytokines, neurotransmitters, neuropeptides and adenosine triphosphate (ATP), which in turn reduce the nociceptor stimulation threshold and sensitize and stimulate the nociceptors further. Further details of the events that occur during peripheral activation and sensitization, as part of the inflammatory response, and spread of this sensitization, are shown in Figure 25.5. Peripheral inflammation leads to the production of opioid receptors by the dorsal root ganglion and their transport towards the peripheral terminal (Figure 25.6), which also depicts the fact that these peripheral opioid receptors may be activated by endogenous opioid peptides released by monocytes, T-cells, B-cells and macrophages.

Peripheral trauma
Figure 25.7 summarizes the neural mechanisms underlying the generation of pain and other symptoms associated with complex regional pain syndromes following peripheral trauma.

Dorsal horn mechanisms
Endogenous ligands that act in the dorsal horn of the spinal cord in respect of nociception include glutamate, which is an
excitatory amino acid, and substance P (Figure 25.8). The cascade of intracellular events activated by \( N\)-methyl-\( d\)-aspartate (NMDA) receptor activation is shown in Figure 25.9, while Figure 25.10 illustrates postsynaptic events following release of glutamate from central terminals of primary afferents in the spinal cord, including the role of nitric oxide.

**Spinal cord and brain pathways**

Figure 25.11 illustrates the main ascending nociceptive pathway in the spinal cord and descending modulatory pathways arising from the mesencephalon and medulla oblongata. Further details of the ascending pathways and their destination in the brain are given in Chapter 23.

**MEMORY**

The neuroanatomy of the limbic system and the medial temporal lobe is considered in Chapter 23. Figure 25.12 is a

**Figure 25.5** Events leading to activation, sensitization and spread of sensitization of primary afferent nociceptor terminals. (a) Direct activation by intense pressure and consequent cell damage, leading to release of \( K^+ \) and biosynthesis of prostaglandins (PGs) and bradykinin (BK). PGs increase the sensitivity of the terminal to BK and other pain-producing substances. (b) Secondary activation. Impulses generated in the stimulated terminal propagate not only to the spinal cord but also into other terminal branches, where they induce the release of peptides such as substance P (SP), which in turn causes vasodilation and neurogenic oedema, with further accumulation of BK and also the release of histamine (H) from mast cells and serotonin (5-HT) from platelets. (c) Histamine and serotonin levels rise in the extracellular space, secondarily sensitizing nearby nociceptors, leading to a gradual spread of hyperalgesia and/or tenderness

**Figure 25.6** Peripheral inflammation leads to the production of opioid receptors by the dorsal root ganglion. These opioid receptors are transported towards the peripheral terminal. Peripheral opioid receptors may be activated by endogenous opioid peptides released by monocytes, T-cells, B-cells and macrophages, and by exogenous application of morphine

Figure 25.7 General hypothesis about the neural mechanisms underlying the generation of pain and other symptoms associated with complex regional pain syndromes following peripheral trauma with and without nerve lesions

Figure 25.8 Release of glutamate (Glu) and substance P (SP) from the terminals of nociceptive primary afferents activates α-amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA) and neurokinin-1 (NK-1) receptors, respectively, on the postsynaptic membrane. Activation of these receptors leads to Na\(^+\) influx at the AMPA receptor and activation of second messengers. These processes prime the N-methyl-D-aspartate (NMDA) receptor with removal of the Mg\(^{2+}\) plug and Na\(^+\) and Ca\(^{2+}\) influx

Figure 25.9 Neurotransmitter release from the central terminal of peripheral afferents leads to activation of postsynaptic membrane receptor sites. Activation of phospholipase C (PLC) and adenylyl cyclase leads to the biosynthesis of the second messengers cyclic adenosine monophosphate (cAMP) and diacylglycerol (DAG), mobilization of which may result in decreased K\(^{+}\) efflux and elevated intracellular Ca\(^{2+}\). The latter results in induction of the proto-oncogene c-fos, production of Fos protein and a presumed action on target genes to alter cellular long-term responses to further stimuli
**Figure 25.10** Diagram illustrating postsynaptic events following release of glutamate from central terminals of primary afferents in the spinal cord. Following priming of the N-methyl-D-aspartate (NMDA) receptor, glutamate release results in NMDA receptor activation with subsequent Ca$^{2+}$ influx. Intracellular Ca$^{2+}$ then acts on a calmodulin-sensitive site to activate nitric oxide synthase (NOS). In the presence of the cofactor nicotinamide adenine dinucleotide phosphate (reduced) (NADPH), NOS uses arginine as a substrate to produce nitric oxide and citrulline. Nitric oxide has a role in normal cellular function, but increased production may be involved in hyperalgesia and may lead to neurotoxicity. Reproduced with permission from Power and Kam, Principles of Physiology for the Anaesthetist. Hodder, London. (2007).

**Figure 25.11** Simplified schema of afferent sensory pathways and descending modulatory pathways arising from the midbrain and medulla. Note the various sites for enhancement or reduction in pain signalling. Release of chemicals from peripheral terminals of primary afferents results in peripheral sensitization. The main ascending nociceptive pathway travels primarily via the anterolateral funiculus and terminates in the thalamus (spinopetal and reticular formation (spinoreticular). Incoming signals from the periphery are then modulated at the spinal dorsal horn by intrinsic interneurons and descending influences from the brainstem. These descending influences travel primarily via the dorsolateral funiculus and arise from several regions, including the periaqueductal grey matter, locus coeruleus and nucleus raphe magnus. Neurotransmitters released from the terminals of these descending pathways then act to inhibit incoming peripheral nociceptive input. Reproduced with permission from Power and Kam, Principles of Physiology for the Anaesthetist. Hodder, London. (2007).

**Figure 25.12** Schematic representation of anatomical connections between the neocortex, parahippocampal region and hippocampus. According to Eichenbaum and Lipton: Information flows between areas of the cerebral cortex and components of the parahippocampal region and between the parahippocampal region and areas of the hippocampus through two partially distinct channels. The perirhinal cortex receives inputs from areas that identify the nonspatial identity of stimuli. In contrast, parahippocampal/postrhinal cortex receives inputs from many areas that appear to be involved in processing the spatial content of sensory information. Thus, in the monkey, whereas the perirhinal cortex receives more inputs from areas along the ventral visual pathway considered important for object recognition, the parahippocampal cortex receives more inputs from areas along the dorsal visual stream considered important for spatial attention and visuospatially guided actions.5

Further details of the neurophysiology of memory appear elsewhere in this book, particularly in Chapter 17.

**MOTOR FUNCTION**

The course of the corticospinal tract is shown in Figure 23.8 in Chapter 23. Further details of the various parts of the brain and spinal cord concerned with motor function appear in Chapter 23, and there are clinical details in Chapter 36.

**DRIVES**

**Sexual behaviour**

Sexual behaviour is a non-regulatory form of behaviour; that is, it is not under the control of a homeostatic mechanism.

Sex hormones are clearly of importance in sexual behaviour and have effects on both the developing brain and the adult brain. Testosterone masculinizes the brain in the male fetus, with particular effects in the preoptic area of the hypothalamus, which is much larger in males than females following testosterone exposure. Prenatal exposure to testosterone is of importance in the development of gender-related behaviour. Hines has reviewed this area:

In neural regions with appropriate receptors testosterone, or its metabolites, influences patterns of cell death and survival, neural connectivity and neurochemical characterization. Consequently, testosterone exposure during critical periods of early development produces permanent behavioural changes. In humans, affected behaviours include childhood play behaviour, sexual orientation, core gender identity and other characteristics that show sex differences (i.e. differ on average between males and females).8

Sex hormones have an activating effect on the adult brain. Higher levels of circulating testosterone are associated with increased sexual activity in both men and women.7 In the latter, testosterone activity increases at around the time of ovulation and is associated with increased sexual desire.6 In adult male primates, testosterone acts on the amygdala to stimulate the sexual drive, while its action on the hypothalamus stimulates copulatory behaviour; in adult female primates, ovarian hormones also act on the amygdala to stimulate sexual drive.

There are clearly important cognitive influences on sexual behaviour. Beauregard and colleagues studied the neural substrate underlying emotional self-regulation by measuring brain activation in ten normal male subjects while they either responded in a normal manner to erotic film excerpts (oral or vaginal intercourse, etc., between one woman and two or three men, between two women and one man, and between two or more women) or voluntarily attempted to inhibit the sexual arousal induced by viewing the erotic stimuli.9 Their results demonstrated that the sexual arousal experienced in response to the erotic film excerpts was associated with activation in the limbic and paralimbic structures, such as the right amygdala, right anterior temporal pole and hypothalamus (Figure 25.13):

In addition, the attempted inhibition of the sexual arousal generated by viewing the erotic stimuli was associated with activation of the right superior frontal gyrus and right anterior cingulate gyrus. No activation was found in limbic areas. These findings reinforce the view that emotional self-regulation is normally implemented by a neural circuit comprising various prefrontal regions and subcortical limbic structures. They also suggest that humans have the capacity to influence the electrochemical dynamics of their brains, by voluntarily changing the nature of the mind processes unfolding in the psychological space.6

The same group have also compared sexual arousal and brain activation in men and women, using erotic film segments depicting sexual interactions, including vaginal intercourse in some of the scenes, between a man and a woman, using those scenes with the lowest disgust scores among the women.10 Key differences in relation to brain activation related to the hypothalamus and thalamus:

In male subjects only, processing of the erotic film segment was also associated with significant activation in the hypothalamus and thalamus. Furthermore, a regression analysis revealed the existence of a positive correlation between the intensity of the SA [sexual arousal] experienced by male subjects and the mag-

---

**Figure 25.13** Statistical activation maps for limbic-paralimbic structures defined a priori. Images are coronal sections for the data averaged across subjects. The right hemisphere of the brain corresponds to the right side of the image. In the sexual arousal condition, greater activation during the viewing of erotic film excerpts relative to the viewing of emotionally neutral film excerpts was noted in the right amygdala (a), right anterior temporal pole (b) and hypothalamus (c). In the attempted inhibition condition, no significant loci of activation were seen in the amygdalae (d), anterior temporal polar region (e) or hypothalamus (f).

Reproduced with permission from ref. 9.
nitude of hypothalamic activation. No such correlation was noted in female subjects.\(^{10}\)

Other important aspects of sexual behaviour are detailed in Chapter 45.

**Hunger**

In terms of the neuroanatomical pathways related to the hunger drive, it is noteworthy that many descending afferent fibres from forebrain structures converge in the rostral division of the nucleus tractus solitarius (rNTS) of the medulla, including dense projections from the central nucleus of the amygdala, the lateral hypothalamus and the gustatory cortex.\(^{11}\) A neuroanatomical overview of the central taste pathways is given in Figure 25.14.

Hunger is a regulatory behaviour – that is, controlled by homeostatic mechanisms – and the endocrine system plays a very important role. According to Coll and colleagues, the hormonal control of food intake may be summarized as follows:

We now know a number of circulating peptides and steroids that are produced in the body can have significant influence on appetitive behavior through their actions on the hypothalamus, the brain stem or afferent autonomic nerves. These hormones come from at least three sites: fat cells, the gastrointestinal tract and the endocrine pancreas.\(^{12}\)

Details of the control of food intake by the hypothalamus are shown in Figure 25.15. The peptide leptin is produced in adipose tissue, and circulating levels rise with overfeeding and fall with starvation.

---

*Figure 25.14* Anatomical overview of the central taste pathways. Electrical signals from cranial nerves VII, IX and X that contain information on the chemical properties of tastants are conveyed to the rostral division of the nucleus tractus solitarius (rNTS) of the medulla, the principal visceral-sensory nucleus of the brainstem. In the rat, second-order fibres (i.e. rNTS efferents) project ipsilaterally to gustatory centres in parabrachial nuclei (PBN) of the pons, from where a first (dorsal) pathway projects to the parvicellular part of the ventroposterior medial nucleus of the thalamus (VPMpc), the taste thalamic nucleus. The second (ventral) pathway includes direct projections from the PBN to the central nucleus of the amygdala and lateral hypothalamus. In primates, however, the NTS projection fibres bypass the PBN, only to join the central tegmental tract and synapse directly into the VPMpc, whereas the PBN seems to be dedicated to convey general visceral information (mainly through vagal afferents) to specialized thalamic nuclei. In either case, thalamic afferents then project to the primary gustatory cortex, which is defined as the VPMpc cortical target. The VPMpc also sends projections to regions neighbouring the primary somatosensory cortex, adjacent to the precentral gyrus, and that overlap with cortical somatotopic sites for the face and oral cavity. The primary taste cortex also projects anteriorly to the caudolateral orbitofrontal region, called the secondary taste cortex. Taste neurons in the caudolateral orbitofrontal cortex converge with cells receiving projections from the primary olfactory cortex, which might have implications for flavour perception. The orbitofrontal cortex is also targeted by projections from the lateral hypothalamus, allowing taste responses to be modulated by satiety states. Finally, cortical taste areas send afferents to the rNTS/PBN, allowing for top-down modulation of gustatory processing at the level of the brainstem.

Figure 25.15 Control of food intake by the hypothalamus. Leptin acts as a peripheral signal of long-term energy stores to bring about changes in food intake and energy expenditure. The hypothalamus receives and integrates neural, metabolic and hormonal signals to regulate energy homeostasis. In particular, the adipocyte-derived hormone leptin and its downstream anorexigenic pathways have a critical role in the control of food intake.

Figure 25.16 details how hormonal signals derived from the gut and classical endocrine organs act in synergy to affect changes in feeding behaviour. During hunger, the smell (and then possibly also the taste) of food leads to aroma and taste signals, which impact, via olfactory and gustatory cortex, on the hypothalamus, sending signals to the dorsal motor nucleus of the vagus and, via vagal cholinergic fibres, causing secretion of insulin from B-cells of the pancreas. This cephalic phase of insulin secretion should be distinguished from the gastrointestinal phase of insulin secretion, in which further insulin secretion takes place as a result of food entering the stomach and duodenum. In due course, circulating breakdown products of food directly stimulate insulin secretion from the pancreas; this is the substrate phase of insulin secretion.

Ghrelin, a ligand for the growth hormone secretagogue receptor (GHSR), is an orexigenic octanoylated 28-amino-acid peptide produced and secreted by cells within the oxyntic glands of the stomach. Circulating ghrelin levels fluctuate over the course of the day in relation to food intake; ghrelin messenger RNA (mRNA) expression and peptide secretion are increased by weight loss, fasting and insulin-induced hypoglycaemia, while peripheral administration of ghrelin stimulates food intake and decreases fat utilization.12,13 Hence, ghrelin has been proposed to be an enteric signal involved in energy homeostasis, being unique in that it stimulates appetite rather than acting as a satiety signal.12,13

THIRST

The following two homeostatic mechanisms relate to drinking: osmotic homeostasis, related to osmotic thirst, and volume homeostasis, related to hypovolaemic thirst.

Osmotic thirst

This occurs when body fluid (e.g., plasma) solute concentrations rise too far, which may result from several causes, such as dietary sodium loading leading to increased plasma sodium ion concentration; dehydration; and high levels of sweating. The raised extracellular fluid osmolality (systemic hypertonicity) stimulates the lamina terminalis. Details of components of the lamina terminalis acted upon by this circulating factor and by other circulating factors are shown in Figure 25.17. Figure 25.18 details the subsequent neural and hormonal inputs into the brain and the central neural pathways that mediate sensory integration of signals for the generation of drinking (thirst).

A positron-emission tomography (PET) study of ten volunteers has demonstrated that the cingulate cortex is particularly activated in osmotic thirst induced by intravenous infusion of hypertonic saline. The authors of this PET study concluded that the anterior and posterior cingulate, and the anterior wall of the third ventricle, are major elements of a pattern including thalamic, hippocampal, orbitofrontal, insula, and midbrain sites that subserve the genesis of consciousness of thirst when plasma [Na⁺] increases.

Hypovolaemic thirst

The volume of extracellular fluid may become lower because of haemorrhage or sodium depletion, for example.

Drinking pure water is then not an adequate solution, as this would lead to hypo-osmolality.

The autonomic nervous system control of cardiovascular function is depicted in Figure 25.19. One homeostatic mechanism related to hypovolaemic thirst involves the cardiovascular changes detailed in Figure 25.20. The effects of these cardiovascular changes on venous return and cardiac output are shown in Figure 25.21.

Another homeostatic mechanism that comes into play as a response to hypovolaemia involves endocrine responses involving the kidneys and suprarenal or adrenal glands (Figure 25.22). Note that the renin secreted by the kidney catalyses the conversion of hepatic angiotensinogen into angiotensin I, which is itself then converted into angiotensin II (catalysed by pulmonary angiotensin-converting enzyme). In addition to causing vasoconstriction and stimulating suprarenal (adrenal) aldosterone secretion, angiotensin II also acts as a neurotransmitter in the brain (see Figure 25.18). Binding to type 2 (AT₂) receptors in the subfornical organ (SFO) leads, via the supraoptic and paraventricular nuclei, to secretion of arginine vasopressin (AVP; antidiuretic hormone, ADH) from the posterior pituitary gland, which in turn leads to stimulation of AVP V₂ renal receptors, causing increased water permeability in distal convoluted tubules and collecting ducts of nephrons and therefore increased water retention, increased urinary osmolality and reduced urinary volume. These last three changes act to reverse hypovolaemia. As shown in Figure 25.18, the central action of angiotensin II also stimulates thirst.

Figure 25.17 Diagram of the sagittal midline of the rat brain, showing circulating factors that act on the various components of the lamina terminalis to influence thirst. The two parts of the lamina terminalis that lack a normal blood–brain barrier, the subfornical organ (SFO) and organum vasculosum of the lamina terminalis (OVLT), are shaded with vertical lines, whereas the other component of the lamina terminalis, the median preoptic nucleus (MnPO), is indicated by the spotted area. The part of the lamina terminalis that is included in the anteroventral third ventricle region (AV3V) is indicated by the white bracket. The interrupted white line indicates an inhibitory influence of atrial natriuretic peptide (ANP), whereas angiotensin II, relaxin and hypertonicity have excitatory actions on the lamina terminalis. The question mark indicates that the efferent pathways from the lamina terminalis that mediate thirst are not yet known.

ac, anterior commissure; oc, optic chiasm.

Figure 25.18 Diagram depicting neural and hormonal inputs into the brain and the central neural pathways that mediate sensory integration of signals for the generation of drinking (thirst). Both inhibitory and excitatory inputs from the periphery are derived from arterial and cardiopulmonary baroreceptors and other visceral receptors (e.g., gastric, hepatic/portal, renal). Information carried in afferent nerves projects mainly to the nucleus of the solitary tract (NTS). Angiotensin (ANG) acts in the form of ANG II on ANG type 1 (AT1) receptors in the subfornical organ (SFO). Osmoreception takes place in structures along the organum vasculosum of the lamina terminalis (OVLT) (MnPO). Hormonal information to the SFO is subsequently carried in descending pathways, some of which are likely to use ANG in the mode of a neurotransmitter, to forebrain structures such as those in the anterovenal third ventricle region (AV3V). Ascending information to the forebrain is carried in projections from noradrenergic cell groups in the hindbrain, which are activated by arterial and cardiopulmonary receptor input under conditions of hypotension and/or hypovolaemia. ANG and noradrenergic inputs act synergistically in forebrain nuclei. A hindbrain inhibitory pathway originating in the area postrema (AP) and medial NTS ascends to the lateral parabrachial nucleus (LPBN). This projection uses serotonin (5-HT) as a neurotransmitter and prevents against excessive sodium and water intake to limit excess expansion of blood volume. Inhibitory input is likely to ascend the neuraxis either directly or indirectly to interact with forebrain structures.

FAC, facilitation; INH, inhibition; SNS, sympathetic nervous system.

**FURTHER READING**

INTRODUCTION

This chapter begins with a consideration of corticoneurogenesis. This is followed by evidence that neurogenesis occurs in the adult human brain. Some aspects of synaptogenesis and synaptic elimination in the human brain are then described. Finally, the evidence for cerebral plasticity in adults in infrahuman mammalian species and humans is detailed.

CORTICONEUROGENESIS

Definition

Pasko Rakic has defined corticoneurogenesis as being the process of production, allocation, migration and settling of neurons into proper areal and laminar positions within the cortical sheet.1

Historical aspects

Historically, the important finding that cortical neurons migrate from their place of origin near the cerebral ventricles (in the ventricular zone) to their final destinations in the overlying cortex was discovered towards the turn of the nineteenth century by Wilhelm His, Ramón y Cajal and others. Cajal’s original drawing of Golgi-stained neonatal human visual cortex showed transient neurons; these have been named Cajal–Retzius neurons in honour of their co-discoverers.2

This pattern of corticogenesis was confirmed in the 1960s by Angevine, Sidman, Rakic and others using the technique of tagging replicating DNA in dividing cells of developing mammalian cerebral cortex with radiolabelled thymidine (3H-TdR); only those mature neurons that derived from cells dividing at the time of the radiolabelling will contain this radioactive marker.

Main stages and zones of the cortical wall

The main stages in the formation of the layered structure of the human cerebral cortex are illustrated in Figure 26.1, which also depicts the successive zones from the ventricular zone, adjacent to the cerebral ventricle, outwards to the marginal zone, adjacent to the pia mater (see also Chapter 23). The migrating neurons stop migrating in the cortical plate, which is just deep to and adjacent to the marginal zone. Neurons migrating later end up travelling past earlier neurons (which are no longer migrating) and end up nearer the pia mater. Hence, the cortical plate has an inside-out structure.

Using the fluorescent axon tracer diodacetyl-tetramethylindocarbacyanine perchlorate (Dil) and the fluorescent DNA-binding molecular marker 4’,6-diamidino-2-phenylindole (DAPI), further details of the corticogenesis at mid-gestation in the human striate cortex (Brodmann area 17, primary visual cortex, V1) have been studied, including the occurrence of a waiting period, as shown in Figure 26.2.3

The different zones of the cortical wall described above were formalized by the Boulder Committee in 1970 and based in large measure on the work of Rakic. More recently,
in light of advances in our knowledge of corticoneurogenesis, the following revisions of the Boulder model have been proposed by Bystron and colleagues:2

- **A transient layer with a diverse population of neurons forms between the neuroepithelium and the pial surface of the dorsal telencephalon before the appearance of the cortical plate (CP).** We suggest that the term preplate, which is already widely used, should be adopted for this layer.
- **The subventricular zone appears as a distinctive proliferative layer before the emergence of the CP, earlier than previously recognized.**
There is no distinct cell-sparse layer under the pial surface before the CP forms. Thus, the term marginal zone should be used only after the appearance of the CP, to refer to the residual superficial part of the preplate, which becomes the layer 1 of the mature cortex.

- The term intermediate zone (IZ) has been used in various ways. We propose that it should be reserved for the heterogeneous compartment that lies between the proliferative layers and the postmigratory cells above. The IZ contains radially and tangentially migrating cells and a thickening layer of extrinsic axons that eventually constitutes the white matter.
- The subplate (SP) is a distinct and functionally important transient layer, located directly below the cortical plate, which was not recognized by the Boulder Committee. In rodents and carnivores most SP neurons are born before the first CP cells. In humans, preplate cells also contribute to the SP, but its substantial thickening at later stages probably involves the addition of later-born neurons.

### Time course

The above inside-out pattern of development holds for all areas of the cerebral cortex, even though the time course varies for different cortical regions. For example, the striate cortex (Brodmann area 17, primary visual cortex, V1) develops over a longer period of time than Brodmann area 24, say. Figure 26.3 shows the probable range of the time of

---

**Figure 26.3** Relationships of modes of cell division to duration of corticogenesis. 
(a) Schematic model of symmetrical cell divisions that predominate before the fortieth embryonic day (E40). At this early embryonic age, the cerebral wall consists of only the ventricular zone (VZ), where all cells proliferate, and the marginal zone (M), where some of them extend their radial processes. Symmetrical division produces two progenitors (P) during each cycle and causes rapid horizontal lateral spread. (b) Model of asymmetrical or stem division that becomes predominant in the monkey embryo after E40. During each asymmetrical division, a progenitor (P) produces one postmitotic neuron that leaves the ventricular zone and another progenitor that remains within the proliferative zone and continues to divide. Postmitotic neurons migrate rapidly across the intermediate zone (IZ) and become arranged vertically in the cortical plate (CP) in reverse order of their arrival (1–4). (c) Diagrammatic representation of the time of neuron origin in macaque monkey. Data are obtained from [3H]thymidine autoradiographic analyses. (d) Estimate of the time of neuron origin in the human neocortex based on the number of mitotic figures within the ventricular zone, supravital DNA synthesis in slice preparations of fetal tissue, and the presence of migrating neurons in the intermediate zone of the human fetal cerebrum.

Neuronal migration

Figure 26.4 is a schematic diagram of the composition of, and neuronal migration in, the developing cerebral wall. Note in particular that the radial glia appear to offer a form of scaffolding from the ventricular zone to the marginal zone of the developing cerebral cortex, along which postmitotic neuronal cells travel. A model of the cascade of molecular events that are thought to take place during this process of neuronal migration, as these cells extend leading processes that follow the contours of the radial glia, has been proposed by Rakic and colleagues and is shown in Figure 26.5.

Subplate neurons are the first cortical neurons to mature. They direct migrating cortical plate neurons and targeting of their axonal projections, and are selectively vulnerable to early hypoxic-ischaemic brain injury in animal models. Timing of subplate neuron death determines the resulting defects in thalamocortical development: very early excitotoxic subplate neuron death results in failure of thalamocortical innervation, while later subplate neuron death interferes with the refinement of thalamocortical connections into mature circuits.

Radial-unit hypothesis

According to Rakic:

The manner by which postmitotic cells migrate and become distributed is crucial for understanding how the neocortex forms as a sheet rather than as a lump. The waves of postmitotic neurons that are generated within the same site in the ventricular zone, arrive successively at the cortical plate where they pass by each other, and become arranged radially in the form of cell stacks — named ontogenetic columns. Therefore, a radial unit consists of cells in the same birthplace, but share the same birthplace, migrate along the common pathway, and settle within the same ontogenetic column.

Figure 26.6 illustrates how the developing cortical plate consists of these ontogenetic columns. The corresponding radial-unit hypothesis postulates that the size of the cerebral cortex depends on the number of contributing radial units, which in turn depends on the number of founder cells.
Figure 26.5 Model of a proposed cascade of molecular events that takes place during migration of postmitotic cells across the developing cerebral wall. Migrating cells extend a leading process (LP) that selectively follows the contours of the radial glial fibre (RF) as it spans the expanding cerebral wall. The cytoskeleton within the LP and trailing process (TP) contains prominent assemblies of microtubules (MT) and actin-like contractile proteins (AC), which are involved in elongation of the LP and translocation of the nucleus (N) and the surrounding cytoplasm. The leading process enters the cortical plate (CP) and marginal zone (MZ), but the nucleus stops at the CP/MZ interface (grey area). Various intracellular; membrane-bound and extracellular matrix molecules provide signals or are directly engaged in selection of the migratory pathway; rate of cell movement and the cessation of migration at the CP/MZ borderline.

Figure 26.6 Basic developmental events and types of cell–cell interactions that occur during the early stages of cortogenesis, before formation of the final pattern of cortical connections. This diagram emphasizes radial migration, a predominant mode of neuronal movement that, in primates, underlies the elaborate columnar organization of the neocortex. After their last division, cohorts of migrating neurons (MN) first traverse the intermediate zone (IZ) and then the subplate zone (SP), where they have an opportunity to interact with waiting afferents that arrive sequentially from the nucleus basalis (NB) and monoamine (MA) subcortical centres, from the thalamic radiation (TR), and from several ipsilateral and contralateral corticocortical bundles (CC). After newly generated neurons bypass the earlier generated ones that are situated in the deep cortical layers, they settle at the interface between the developing cortical plate (CP) and the marginal zone (MZ) and, eventually, form a radial stack of cells that share a common site of origin but are generated at different times. For example, neurons that are produced between embryonic days E40 and E100 in radial unit 3 follow the same radial glial fascicle and form ontogenetic column 3. Although some cells, presumably neurophilic in nature of their surface affinities, might detach from the cohort and move laterally, guided by an axonal bundle (e.g. horizontally oriented, red cell leaving radial unit 3), most postmitotic cells are gliophilic (e.g. have affinity for the glial surface) and obey constraints strictly that are imposed by transient radial glial scaffolding (RG). This cellular arrangement preserves relationships between the proliferative mosaic of the ventricular zone (VZ) and the corresponding protomap within the SP and CP, even though the cortical surface in primates shifts considerably during the massive cerebral growth encountered in mid-gestation.

NEUROGENESIS IN THE ADULT HUMAN BRAIN

Neurogenesis in the adult human brain was demonstrated by Eriksson and colleagues.7 They studied the dentate gyrus and the subventricular zone in humans, since these regions had been shown to generate new neurons in the postnatal and adult period in infrahuman mammalian species. Patients with squamous cell carcinomas at the base of the tongue, in the larynx or in the pharynx received bromodeoxyuridine (BrdU) dissolved in saline and given as an intravenous infusion to assess the proliferative activity of the tumour cells, expressed as BrdU-labelling index. BrdU is a synthetic form of thymidine, which has been used as a marker of neurogenesis in infrahuman species. The brains of the patients were studied postmortem. No signs of macroscopic or microscopic metastases were found in autopsy material from the cerebral in any of the patients.7 Quantitation of newly generated cells in the hippocampus in each of five patients is shown in Figure 26.7. Labelling with NeuN, a neuronal marker, and comparison with the
Figure 26.7 Quantitation of newly generated cells in the adult human hippocampus. The density of bromodeoxyuridine (BrdU) immunoperoxidase-stained cells in the subgranular zone (SGZ) (a), the granule cell layer (GCL) (b) and the hilus (c) was determined in five to seven sections per patient (mean number of BrdU-positive cells/mm² sample volume ± standard error of the mean (SEM)). The corresponding patient’s age at the time of death and interval as BrdU infusion are given for each BrdU-treated patient (n = 5). Reproduced with permission from ref. 7.

Adult rat brain demonstrated that these newly generated cells were indeed neurons.

SYNAPTODENDY SYNAPTOGENESIS AND SYNAPTIC ELIMINATION IN THE HUMAN BRAIN

Huttenlocher and de Courten published the results of a postmortem study in 1987 in which synaptic density in human striate cortex was determined at various ages, together with measurement of total volume of striate cortex, making it possible to estimate the total number of synapses. Their key findings included the following:

- Synaptogenesis in human striate cortex was found to be most rapid between the ages of 2 months and 4 months, a time that also is critical for the development of function in visual cortex of the infant.
- Synapse elimination occurred subsequently, with loss of about 40 per cent of synapses between the ages of 8 months and 11 years.
- Synapse numbers were stable in adults, except for a slightly lower value in a single brain at age 71 years.
- Analysis by individual cortical layers showed similar age-related changes in all strata of striate cortex, except for somewhat later synaptogenesis in cortical layers V and VI.
- Total volume of striate cortex reached adult size remarkably early, at about age 4 months.

These findings supported the hypothesis that exuberant synaptic connections are an anatomical substrate for plasticity in developing cerebral cortex. Subsequently, Huttenlocher and Dabholkar carried out a study in which they compared the formation of synaptic contacts in human cerebral cortex in two regions: the auditory cortex (Heschl’s gyrus) and the prefrontal cortex (middle frontal gyrus). Figure 26.8 shows the combined results of this study and the previous 1987 study of the striate cortex. It can be seen that the time course of synaptogenesis in the visual cortex resembles that in the auditory cortex, except that synapse elimination appears to begin earlier in the visual cortex.

A plot of the difference between the synaptic density in auditory cortex and that in the middle frontal gyrus against conceptual age gave the distribution shown in Figure 26.9, suggesting earlier synaptogenesis and earlier synaptic elimination in auditory cortex compared with prefrontal cortex. As the authors concluded:

The present data show regional differences in synaptogenesis in human neocortex both in fetal brains and postnatally up to at least age 15 months (CA [conceptual age] 700 days) in cortical layers 2 to 3, and up to at least age 3 months (CA 363 days) in the lower cortical layers. A rapid burst in synaptogenesis occurs postnatally in visual and auditory cortex. Prefrontal cortex appears to acquire synaptic junctions more slowly. By age 3.5 years, prefrontal cortex has caught up to auditory cortex. In primary visual cortex net synapse elimination appears to have started already at that age.

CEREBRAL PLASTICITY

Non-human mammalian adult brain

Reorganization of cortical representation in the adult has been demonstrated in different mammalian species. For
example, in the late 1980s, Robertson and Irvine examined the effect of restricted unilateral cochlear lesions on the orderly topographic mapping of sound frequency in the auditory cortex of adult guinea pigs. These lesions, although restricted in spatial extent, resulted in a variety of patterns of histological damage to receptor cells and nerve fibres within the cochlea. Nevertheless, all lesions resulted in permanent losses of sensitivity of the cochlear neural output across a limited frequency range; 35–81 days after such damage to the organ of Corti, the area of contralateral auditory cortex in which the lesioned frequency range would normally have been represented was partly occupied by an expanded representation of sound frequencies adjacent to the frequency range damaged by the lesion.

In the early 1990s, a demonstration of plasticity in the frequency representation of primary auditory cortex in the adult brain of owl monkeys was published by Recanzone and colleagues, who reported increased cortical area of
representation of a restricted frequency range in primary auditory cortex that was correlated with performance at a frequency-discrimination task. Monkeys trained for several weeks to discriminate small differences in the frequency of sequentially presented tonal stimuli revealed a progressive improvement in performance with training; at the end of the training period, the tonotopic organization of AI was defined by recording multiple-unit responses at 70–258 cortical locations, and these responses were compared with those derived from three normal monkeys and from two monkeys that received the same auditory stimuli but that were engaged in a tactile discrimination task. The cortical representation, sharpness of tuning and latency of the response were greater for the behaviourally relevant frequencies of trained monkeys when compared with the same frequencies of the control monkeys; the cortical area of representation was the only studied parameter that was correlated with behavioural performance. This experiment showed that natural stimulation can modify the tonotopic organization of AI in the adult primate and that this alteration is correlated with changes in perceptual acuity.

To determine the relative contributions of intrinsic and extrinsic factors to the functional specification of different cortical regions, von Melchner and colleagues studied ferrets, for which it was known that, when retinal projections are redirected neonatally to the auditory thalamus, they have visually responsive cells in auditory thalamus and cortex, form a retinotopic map in auditory cortex and have visual receptive field properties in auditory cortex that are typical of cells in visual cortex. They found that this cross-modal projection and its representation in auditory cortex can mediate visual behaviour; when light stimuli were presented in the portion of the visual field that was seen only by this projection, ‘rewired’ ferrets (Figure 26.10) responded as if they perceived the stimuli to be visual rather than auditory (Figure 26.11). The authors of this study deduced that the perceptual modality of a neocortical region is instructed to a significant extent by its extrinsic inputs. In addition gratings of different spatial frequencies could be discriminated by the rewired pathway, although the grating acuity was lower than that of the normal visual pathway.

**Adult human brain**

Plasticity has now been demonstrated in the living human cerebral cortex, using techniques such as functional magnetic resonance imaging (fMRI), positron-emission tomography (PET) and magnetic source imaging (MSI), the last of which involves combining structural magnetic resonance imaging (MRI) with magnetoencephalography (MEG). Some examples are now given.

Flor and colleagues showed that, following upper limb amputation, phantom-limb pain is a perceptual correlate of cortical reorganization. They used MSI, as detailed in Figure 26.12, to study 12 men and 1 woman who had had an arm amputated (either post-traumatically or because of osteosarcoma). As shown in Figure 26.13, there was a large significant positive correlation between the amount of cortical reorganization and the degree of phantom-limb pain (but not non-painful phenomena). Phantom-limb pain was found to explain 83 per cent of the variance in cortical reorganization. These results indicated that phantom-limb pain is related to, and may be a consequence of, plastic changes in primary somatosensory cortex. From Figure

---

**Figure 26.10** Behavioural role of retinal projections routed to the auditory pathway. (a) Pathway from the retina to the visual thalamus, including the lateral geniculate nucleus (LGN) and the lateral posterior nucleus (LP), and to the superior colliculus (SC) in the control hemisphere (right); and to the LGN/LP and medial geniculate nucleus (MGN) in the rewired hemisphere (left). The SC and adjacent brachium (b) of the inferior colliculus (IC) were ablated neonatally in the left hemisphere. Visual projections in each hemisphere represent the contralateral visual field. (b) Apparatus for experiment. Dashed lines denote the borders of the left and right monocular fields and the direction of central gaze. Animals were rewarded at the right spout after a light in the left monocular field, and at the left spout after a sound from a central speaker. Subsequently, their responses to light in the centre or the right monocular field were tested. Animals initiated trials by standing in the start box with their muzzle between an infrared light-emitting diode (LED) and a photodiode detector. Reproduced with permission from ref. 12.
26.13 it can be seen that five of the subjects were relatively free of phantom-limb pain. The mean shift in the focus of cortical responsiveness to facial stimulation was 0.43 cm for these five pain-free subjects but almost five times higher, at 2.05 cm, for the eight remaining subjects who suffered phantom-limb pain.

When learning to play a stringed musical instrument, it is the digits of the left hand, apart from the thumb, that are used to find notes on the strings. (The right hand is used for bowing or plucking the strings.) The same group showed that the somatosensory cortical representation of the left hand of string-players is expanded compared with controls; the effect was smallest for the left thumb, and no such differences were seen for the representations of the right-hand digits. The amount of cortical reorganization in the representation of the fingering digits was correlated with the age at which the person had begun to play. These results suggest that the representation of different parts of the body in the primary somatosensory cortex of humans depends on

![Figure 26.11](image.png)

Figure 26.11 Responses of rewired and normal ferrets to sound and light stimuli. (a–c) Responses of rewired ferrets to the various stimuli under three separate conditions: after training with sound and left light stimuli, before the left lateral geniculate nucleus (LGN)/lateral posterior nucleus (LP) lesion (dark blue bars); after the left LGN/LP lesion (white bar; only the response to the right light is shown); and after the left A1 lesion (violet bars). Response bars (mean ± standard deviation) depict performance in the final 10–19 days in the pre-LGN/LP lesion condition, and in the first 10–18 days in the post-LGN/LP lesion and post-A1 lesion conditions. (d) Responses of normal ferret N1 to the stimuli before a lesion of the left LGN/LP and superior colliculus (SC) (blue bars) and after (red bars). Response bars depict performance in the final 9 days in the pre-LGN/LP + SC lesion condition, and in the first 12 days in the post-LGN/LP + SC lesion condition. Reproduced with permission from ref. 12.

![Figure 26.12](image.png)

Figure 26.12 Illustration of the method used to determine the degree of cortical reorganization. The centres of the magnetic responses to stimulation on the face and digits are superimposed on to a magnetic resonance imaging (MRI) scan of an individual subject. Using a neuromagnetometer, magnetic fields were recorded from 37 locations over a circular concave area (14.4 cm diameter) above the parietotemporal cortex contralateral to the site of stimulation (first or fifth digit of the intact hand, chin, or lower lip). Magnetoencephalography (MEG) was sampled at 520.5 Hz. For each magnetic field distribution, a single equivalent current dipole (ECD) model was fitted. The ECD locations were mapped on to the cortical surface of Brodmann area 3b, which was reconstructed from an MRI scan. Distances between locations along the curved surface of the somatosensory map can be represented by the distance in the three cortical dimensions (black rods). The arrows connecting the cortical representation of the lip and (i) the midpoint between digits 1 (D1) and 5 (D5) on the intact side (lower arrow) and (ii) the midpoint between the mirror images of the first and fifth digit and the lip on the amputated side (upper arrow) represent the cortical-distance measure used. Reproduced with permission from ref. 13.
use and changes to conform to the current needs and experiences of the individual.\(^{14}\)

Liepert and colleagues spatially mapped the motor cortex using focal transcranial magnetic stimulation (TMS) before and after 2 weeks of treatment with constraint-induced movement therapy following stroke.\(^{15}\) Motor-output areas of the abductor pollicis brevis muscle, motor-evoked potential (MEP) amplitudes and the location of the centre of gravity of motor cortex output were studied. Changes observed after constraint-induced movement therapy included an improvement in motor performance substantially in all patients; an increase of motor output area size and MEP amplitudes; indicating enhanced neuronal excitability in the damaged hemisphere for the target muscles; and a considerable shift in the mean centre of gravity of the motor output maps, indicating the recruitment of motor areas adjacent to the original location. The authors concluded that, even in chronic stroke patients, reduced motor cortex representations of an affected body part can be enlarged and increased in level of excitability by an effective rehabilitation procedure. Furthermore, the cortical regions that produce abnormal slow waves, indicating dysfunctional cortex, become reduced after such rehabilitative therapy.\(^{16}\)

From these and other studies demonstrating cerebral plasticity in adult humans, Elbert and Rockstroh have advanced the following general principles of cortical reorganization:\(^{16}\)

- The abolition of sensory input or deafferentation, as produced by amputation or segregation of a sensory nerve, results in the invasion of adjacent cortical representations of intact parts of the sensorium into the cortical representation zone of the affected sensory part.
- Increased use of a receptor pool leads to an expansion of the respective cortical representation zone.
- Training of extremity use after central nervous system injury that affected the cortical tissue representing that body part results in improved extremity function and reorganization in brain activity.
- Cortical reorganization emerges in response to massed practice of behavioural relevant tasks. This generally implies an intense training schedule of several hours a day for several successive days. The absolute amount of training seems less important than the priority of training in daily activity.
- Reorganization through synchronicity of input leads to disarrangement of representational zones.

**KEY POINTS**

- Corticoneurogenesis is the process of production, allocation, migration and settling of neurons into proper areal and laminar positions within the cortical sheet. During this process, the cortical plate has an inside-out structure and radial glia offer a form of scaffolding from the ventricular zone to the marginal zone, along which postmitotic neuronal cells travel.
- The inside-out pattern of development holds for all areas of the cerebral cortex, even though the time course varies for different cortical regions.
- According to the radial-unit hypothesis, the size of the cerebral cortex depends on the number of contributing radial units, which in turn depends on the number of founder cells.
- Neurogenesis has been demonstrated in the adult human brain.
- Exuberant synaptic connections are an anatomical substrate for plasticity in the developing cerebral cortex.
INTRODUCTION

Neuroendocrinology is the study of the endocrine role of neuronal cells and the neural regulation of the endocrine system. Many psychiatric disorders are associated with disturbances in neuroendocrine axis function, which thus implicates abnormalities of this axis as being of possible aetiological significance to the development of the psychiatric disorder. Furthermore, understanding fully the biological sequelae of stress is important in determining why some individuals seem resilient to developing psychiatric illness in the face of significant stress while others seem especially vulnerable.

In general terms, the discipline of neuroendocrinology involves the study of the neural regulation of the hypothalamic, pituitary and peripheral end-organ hormone secretions and the study of the effects of each of the endocrine axes on the central nervous system (CNS). It is now recognized that the brain is the principal endocrine gland of the body, not only due to its seminal role in orchestrating the various axes but also because of the multiple target sites within it for hormonal action.

THE HYPOTHALAMIC–PITUITARY HORMONAL AXIS

The primary endocrine regulatory regions are the hypothalamus and pituitary (Figure 27.1).

The hypothalamus is a poorly defined anatomical area situated at the floor of the third ventricle. It consists of several discrete nuclei, which are grouped according to their anatomical location as follows:

- Anterior: supraoptic and preoptic nuclei
- Central: paraventricular, dorsomedial, ventromedial and arcuate nuclei
- Posterior: posterior and mamillary.

The hypothalamus functions as a command centre. It integrates information about the state of the brain and body by way of extensive neuronal projections throughout the CNS and intrinsic chemosensitive neurons that respond to circulating levels of various hormones. The hypothalamus thus plays a seminal role in the maintenance of homeostasis by coordinating the actions of the pituitary gland to respond appropriately to any changes that it detects in the body and environment.

The hypothalamus is the site of synthesis and secretion of a variety of releasing factors, which are released into the portal vasculature at the median eminence, where they pass down the portal veins to the sinusoids surrounding cells of the anterior pituitary and regulate the synthesis and release of various hormones (Table 27.1). In addition to their principal actions as release or release-inhibiting factors for pituitary hormones, the hypothalamic peptides also function in extra-hypothalamic brain regions as neurotransmitter substances, yielding direct brain effects independent of their pituitary actions.

The hypothalamic–pituitary–adrenal (HPA) axis is the core endocrine stress system in humans. It plays a pivotal role in regulating metabolic and immune function and exerts profound effects on the brain (e.g. neurogenesis, neuronal survival, influencing the size of limbic structures, functional effects on memory and contextual emotional appraisal).

Following any threat to homeostasis, corticotropin-releasing hormone (CRH) release is triggered from the parvocellular neurons of the paraventricular nucleus (PVN) in the hypothalamus. Under basal conditions, CRH is the dominant regulator of the axis; in situations of chronic stress, many parvocellular neurons co-express arginine vasopressin (AVP), which plays an important role in sustaining HPA activation (see below). CRH and AVP act synergistically on the anterior pituitary corticotrophs to bring about the release of adrenocorticotropic hormone (ACTH), which in turn stimulates increased glucocorticoid (cortisol in humans) secretion from the adrenal glands. The glucocorticoids control homeostasis and play a central role in the ability to cope with the threat or challenge. Glucocorticoids play an important role in both the onset and the termination of the stress response; their secretion is tightly controlled and limited by their own negative feedback effects at both pituitary and brain sites (Figure 27.2). This negative feedback on CRH and ACTH secretion can occur within minutes after the onset of the stress response and thus prevents oversecretion of glucocorticoids and contributes to the reining in of the acute activation of the axis when the threat or stress has passed.

In humans, the circadian rhythm in ACTH and cortisol secretion is entrained to the wake–sleep cycle and is pulsatile in nature, with a frequency of approximately one pulse per hour. The greatest amplitudes occur in the early morning, thus resulting in peak cortisol levels at this time, with a trough in secretion occurring in the evening and early night.

The principal mechanism of action of cortisol throughout the body is through activation of intracellular receptors, which subsequently translocate to the nucleus and bind to specific DNA sequences, thus modulating gene transcription. There are two major receptors for cortisol: type 1 (or mineralocorticoid receptor, MR) and type 2 (or glucocorti-
coid receptor, GR). Centrally the MR is mainly expressed either alone or together with the GR in hippocampal neurons, while the GR receptor has a more ubiquitous distribution within brain neurons. The MR has a ten-fold higher affinity for cortisol than the GR does, and thus the MR monitors basal diurnal fluctuation in cortisol while the GR becomes progressively occupied only at peaks of cortisol secretion and after a stressful stimulus.\(^{7,8}\) The GR is therefore believed to be more important in the regulation of the stress response when endogenous cortisol levels are high, such as in major depression (see below).

In addition to receiving negative feedback from cortisol, the hypothalamus is influenced by neuronal input from cortical pathways, including those derived from the hippocampus and the amygdala. Whether feedback on to the PVN is excitatory or inhibitory depends on the location and type of the activated receptor. For example, activation of the MR at the hippocampus and amygdala exerts negative feedback inhibition on CRH, while GR stimulation in the amygdala results in an increase in CRH in response to stress.\(^{9,10}\) A wide variety of neurotransmitters also influence the hypothalamic PVN regulation of the HPA. These transmitters include serotonin, noradrenaline, acetylcholine and the opioids. Furthermore, the pro-inflammatory cytokines tumour necrosis factor alpha (TNF-\(\alpha\)), interleukin 1 (IL-1) and interleukin 6 (IL-6) are primary HPA-stimulating cytokines that act directly on the hypothalamic paraventricular neurons to stimulate CRH production.\(^{11}\)

It has become increasingly recognized that prolonged activation of the HPA axis exposes the brain and body to the deleterious effects of excessive glucocorticoid secretion, with pathological consequences, including hypertension, diabetes, formation of atherosclerotic plaques and impaired immune function. Centrally, the hippocampus suffers from atrophy of its neuronal dendrites and impaired neurogenesis, which is thought to mediate the disruption to long-term potentiation and impaired memory performance observed in states of chronic glucocorticoid excess.\(^{12}\) Furthermore, chronic stress has been shown to increase dendritic arborization in the amygdala, which may in part be why individuals can have difficulty forgetting traumatic events.

**HPA axis functioning in major depression**

Multiple disturbances at different levels of the HPA axis have been described in patients with major depression, with hyperactivity of the axis in a significant subgroup of people with depression (50–70%) being one of the most consistent and important findings in biological psychiatry. This increase in cortisol levels has been explained by both increased forward drive in the axis and decreased negative feedback.

The following disturbances in HPA axis functioning (indicating an overactive axis) are documented in major depression.

- Elevated cortisol levels
- Dexamethasone non-suppression of cortisol
- Enhanced adrenal gland volume as measured by computed tomography (CT) or magnetic resonance imaging (MRI)
- Blunted ACTH release in response to CRH (CRH stimulation test)
- Enhanced ACTH release in response to CRH when pre-treated with dexamethasone (DEX-CRH test)
- Elevated CRH in the cerebrospinal fluid
- Enhanced cortisol response to synacthen (ACTH stimulation test).

The dexamethasone suppression test (DST) was popularized in psychiatry by Bernard Carroll as a means of investigating the functional integrity of negative feedback control of the HPA axis.\(^{13,14}\) Dexamethasone is a potent synthetic glucocorticoid that binds primarily to GRs in the anterior pituitary and thus suppresses ACTH and cortisol secretion via a negative feedback mechanism. The most common form of the test involves the administration of 1 mg dexamethasone at 11 p.m., with subsequent cortisol measurements at intervals over the following 24 h, thus testing the functional integrity of the GRs (i.e. GR responsiveness) in mediating inhibition on the axis. Low-dose DSTs (0.5 mg and 0.25 mg) have also been used, in particular to investigate disorders characterized by enhanced suppression (e.g. post-traumatic stress disorder, PTSD; see below). There are several hundred published studies reporting on DST in depression, all reporting that approximately 50 per cent of people with major depression fail to adequately suppress cortisol levels after administration of 1 mg dexamethasone.\(^{15}\) The test lacks adequate specificity, however, and positive results are also seen in other disorders, including dementia, eating disorders and schizophrenia. The DST has also been used to follow the course of treatment in patients who had a positive DST while depressed. Those patients whose HPA axis recovers to normality after successful treatment for depression tend to remain in remission for longer than those who still have an abnormal DST.\(^{16}\)

In addition to impaired negative feedback control of HPA in major depression, there is an increased forward drive promoting the hypercortisolism.\(^{17}\) ACTH responses to exogenous CRH are often blunted in patients with depression, as demonstrated by the CRH stimulation test, in which 100 \(\mu\)g CRH is given intravenously with subsequent measurement of ACTH and cortisol response. This blunting is thought to reflect a down-regulation of CRH receptors on the corticotrophs of the anterior pituitary and a restricted secretory response of ACTH to CRH caused by elevated basal cortisol levels. Despite a blunted ACTH response to CRH, a normal cortisol response is maintained due to an overactive HPA axis inducing a hyperplastic adrenal cortex that is thus hypersensitive to ACTH stimulation. Furthermore, CRH neuronal hyperactivity is generally reduced by antidepressant therapy, and persistent alteration in HPA axis function
Despite compliance with antidepressant medication is a marker for a poor response to such treatment.

The CRH test has also been combined with pretreatment with dexamethasone (DEX-CRH test), which results in enhanced rather than blunted ACTH and cortisol responses in patients with depression compared with healthy controls. A multicentre study by Kunugi and colleagues demonstrated significantly enhanced pituitary–adrenocortical responses to the DEX-CRH test in in-patients with depression. Furthermore, restoration of normal HPA axis response occurred with clinical responses to treatment of depression, particularly in patients who underwent electroconvulsive therapy (ECT). Interestingly, a further DEX-CRH study by a different Japanese group demonstrated that the normalization of HPA axis dysfunction subsequent to successful treatment of depression correlated with a restoration of normal cerebral glucose metabolism in prefrontal cortical and limbic brain areas.

We have previously focused on the role of vasopressin in the increased HPA forward drive seen in depression. We examined a cohort of subjects with depression on two separate occasions, with CRH alone, and with the combination of CRH and desmopressin (ddAVP), an analogue of AVP. Consistent with previous findings, a significant blunting of ACTH output to CRH alone was noted. However, when ddAVP was combined with CRH in our study, the release of ACTH in patients with depression and in healthy volunteers became indistinguishable, thus indicating that, although CRH1 receptors are down-regulated in depression, a concomitant up-regulation of the V3 (also known as V1b) receptor takes place. In a further study assessing ACTH and cortisol responses to ddAVP in major depression, we observed increased responses in the patients with depression compared with the healthy controls, providing further support for up-regulation of the anterior pituitary V3 receptor in this disorder. Interestingly, plasma AVP levels have been found to be correlated positively with cortisol in patients with depression, and a single-nucleotide polymorphism (SNP) for the V3 receptor has been found to be protective against depression.

A fact that distinguishes the hypercortisolaemia seen in major depression from that of Cushing’s disease/syndrome (characterized by excessive glucocorticoid secretion secondary to a pituitary or adrenal tumour) is that in major depression the amplitude and timing of the circadian rhythm appear to remain intact, although the peak and nadir in circulating cortisol concentrations are elevated. In patients with Cushing’s disease/syndrome, however, the ACTH and cortisol circadian rhythms are generally lost due to the constant production of either one or both of these hormones by the pituitary adenoma or adrenal tumour. This may be why hypercortisolaemic patients with depression do not develop the physical changes that are characteristic in Cushing’s disease/syndrome. In addition, there is evidence that, in at least some tissues of the body, the GR is desensitized in patients with depression. In relation to this, we demonstrated a marked impairment in the normal cutaneous blanching response to topical corticosteroid administration in patients with major depression compared with healthy controls, thus implicating impaired GR function in mediating cutaneous vasoconstriction in this group.

CRH derived from parvocellular neurons of the hypothalamus is the primary stimulus to ACTH secretion. CRH receptors are not limited to the pituitary corticotrophs, however, but are distributed widely throughout the cerebral cortex and limbic system. CRH has thus been shown to modulate diverse neurotransmitter systems, including glutamate, dopamine, serotonin and noradrenaline. Reciprocal excitatory interactions exist between the CRHergic pathways and the brainstem sympathetic locus coeruleus–noradrenergic system. CRH activates the locus coeruleus and thus increases noradrenaline release from it; in turn, noradrenaline activates both hypothalamic CRH and the amygdala. It is thought that such reciprocal stimulation may contribute to the sleep disturbance and anxiety symptoms seen in major depression.

### HPA axis functioning in other psychiatric disorders

The HPA axis has been studied in a number of anxiety disorders, most notably PTSD. The findings in other anxiety disorders have been modest – cortisol secretion has not been associated with panic attacks per se, and dexamethasone non-suppression occurs in only approximately 17 per cent of patients with panic disorder. CRH challenge studies have been inconsistent, with some demonstrating a decreased ACTH response when compared with healthy controls but others finding a normal response. Overall, studies of anxiety disorders other than PTSD would suggest either a normal or a modestly increased HPA axis function in these disorders.

With regard to PTSD, the majority of studies demonstrate reduced baseline cortisol levels in PTSD in addition to enhanced cortisol suppression to low-dose dexamethasone administration. Furthermore, somewhat counterintuitively given the hypocortisolism above, there is considerable evidence that CRH levels are increased in PTSD. There has been growing evidence that cortisol-related alterations in PTSD may reflect an underlying vulnerability to the development of the disorder following trauma exposure. In longitudinal studies, lower cortisol levels observed soon after the experience of trauma have been found to be associated with the future development of PTSD, and relative hypocortisolism has also been associated with prior trauma exposure (a risk factor for PTSD). Genetic susceptibility may also be an important factor, and low cortisol levels have been shown to be related inversely to PTSD symptom severity in a subgroup of combat veterans displaying a particular glucocorticoid receptor polymorphism (the Bcl1 GC genotype) that results in increased glucocorticoid sensitivity.

Dysfunction of the HPA axis characterized by hypocortisolism has also been consistently observed in chronic fatigue syndrome (CFS). A case–control study, which recruited from a general population sample, compared
childhood trauma rates and awakening salivary cortisol responses in patients with CFS and healthy controls. The study demonstrated that a decreased cortisol response was associated with childhood trauma in CFS.41 Indeed, decreased cortisol responses to awakening were observed only in those subjects with CFS who reported exposure to childhood trauma and not in individuals with CFS but without such exposure. The authors suggested that hypocortisolism may reflect a marker for developmental risk for CFS rather than a correlate of the CFS itself. The role of childhood trauma in rendering an individual susceptible to future psychiatric disorder is discussed further below.

It has been suggested that the HPA axis may have some involvement in the development of psychotic disorders by increasing brain dopaminergic activity.42-44 Generally, in relation to schizophrenia, similar abnormalities to those seen in depression are described in the literature, although with less consistency and to a lesser degree. Although there have been inconsistent reports of elevated cortisol levels in subjects with psychotic disorders,45,46 the DST has been more consistent, with most studies demonstrating impaired negative feedback of the axis (i.e. higher levels of non-suppression) in subjects with schizophrenia compared with healthy controls.47,48 Some studies have observed a greater degree of suppression in patients with a higher symptom load.49,50 While antipsychotic medications can affect HPA activation in a general dampening manner, studies on drug-naïve patients with schizophrenia have consistently observed HPA dysfunction characterized by overactivation of the axis.51,52 The hippocampus has important inhibitory regulatory actions on the HPA axis as described above and, in relation to psychotic disorders, studies have demonstrated reduced hippocampal glucocorticoid receptor numbers in addition to a smaller hippocampal volume.53,54 Furthermore, the pituitary gland has been found consistently to be larger in at least the early stages of psychotic disorders, a finding that is independent of treatment with antipsychotic medications, thus ruling out enlargement secondary to effects on prolactin (see below), but it is thought to be mediated by an increase in the size and number of the pituitary’s ACTH-producing cells.55 Research has observed that individuals at ultra-high risk of developing psychosis who go on to develop a psychotic disorder already have an enlarged pituitary gland in the months before psychosis onset compared with high-risk individuals who do not go on to develop psychosis.56 Taking all of the above together, these lines of research suggest that HPA axis dysfunction may have an important role in the development of psychosis and is an interesting area of future research.

**THE HYPOTHALAMIC–PITUITARY–THYROID AXIS**

Thyroid hormones are fundamental to normal brain development and regulate neuronal growth and synaptogenesis. They are involved in maintaining optimal metabolism in multiple organ systems and play a vital role in temperature regulation.

The functioning of the hypothalamic–pituitary–thyroid (HPT) axis has been studied extensively in psychiatric illnesses, particularly in depressive disorders, due to the long-standing observation that patients with hypothyroidism and euthyroid patients with depression share many clinical features, including cognitive impairment, lethargy and low mood.57 Indeed, it is recognized that 30 per cent of patients with mood disorders have some form of thyroid dysfunction.58

The HPT axis is driven centrally by secretion of thyrotropin-releasing hormone (TRH) from the paraventricular region of the PVN of the hypothalamus (Figure 27.3). TRH is released into the portal circulation and thereafter binds to receptors on thyrotroph cells of the anterior pituitary, where it stimulates the synthesis and release of thyroid-stimulating hormone (TSH). In addition to TRH, the hypothalamus also releases an inhibitory hormone of TSH called somatostatin. TSH stimulates the synthesis and secretion of two thyroid hormones from the thyroid gland—tri-iodothyronine (T3) and tetra-iodothyronine (T4). T3 is the more biologically active form. T4 is the predominant form released from the thyroid, and subsequent de-iodination to form T3 is performed by the target organs, including the brain. TRH synthesis and release are regulated primarily by T3 through a negative feedback mechanism. TRH release is inhibited by serotonergic input to the hypothalamic nucleus, while dopamine has a net stimulatory effect.

Centrally thyroid nuclear receptors are particularly abundant in the hippocampus, but they are expressed throughout the brain. There is extensive intraneuronal...
co-localization of TRH with other neuroactive substances, including 5-hydroxytryptamine (5-HT), substance P and dopamine.59

There has been extensive investigation of the HPT axis in major depressive disorder. About 15 per cent of patients with depression have evidence of autoimmune thyroiditis.60 It has long been established that approximately a quarter of patients with major depression have an impaired TSH response to TRH administration, which has been suggested to indicate hypersecretion of TRH in this disorder (with subsequent down-regulation of anterior pituitary TRH receptors).61 Furthermore, the normal nocturnal rise of TSH that occurs in the hours after midnight can be lost in patients with depression,62 but sleep deprivation restores it.63 Subclinical (or grade II) hypothyroidism, characterized by normal thyroid hormone concentrations but elevated basal TSH levels and an exaggerated TSH response to TRH, is also overrepresented in major depression and is a known risk factor for treatment resistance.64

Clinical studies have shown that exogenous thyroid hormone can augment treatment-resistant depression.65,66 The evidence base has been improved by publication of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) programme, which was a pragmatic effectiveness study that used remission of symptoms as its main outcome measure. At stage 3 of this trial, 24.7 per cent of patients with treatment-resistant depression remitted with T3 augmentation (v. 15.9% of patients who received lithium augmentation), and T3 was found to be significantly better tolerated than lithium.67 Sokolov and colleagues found that responders to T3 augmentation had lower circulating TSH and higher circulating T4 before antidepressant treatment compared with non-responders.68 There have been inconsistent reports from small studies of concomitant T3 administration accelerating the response to antidepressant therapy when initiating treatment for depression.69,70

The mechanism of action of thyroid hormone augmentation has yet to be determined fully, but it may act through increasing serotoninergic and noradrenergic neurotransmission (possibly by acting as a co-transmitter in the case of noradrenaline).71 Another possible mechanism of action is via restoration of central thyroid hormone homeostasis, which may be disturbed in severe depression due to cortisol-induced inhibition of the enzyme 5-deiodinase. This enzyme converts T4 to T3 within the CNS, and therefore elevated cortisol levels seen in depression may impair optimum thyroid hormone functioning within the brain.72 Finally, T3 augmentation may modulate cerebral blood flow. Functional imaging research has indicated that hypothyroid subjects display a significant reduction in brain activity and cerebral blood flow compared with euthyroid controls. In relation to mood disorders, Marangell and colleagues demonstrated an inverse relationship between TSH and cerebral blood flow in unmedicated patients with mood disorders who were free from overt thyroid disease, and found the greatest reduction in blood flow to be in those areas of the brain that have been implicated in depression: the left dorsolateral prefrontal cortex (PFC) and the medial PFC.73

The HPT dysregulation seen in mood disorders may be related to underlying HPA axis abnormalities. The blunted response of TSH to TRH administration in depression has been shown to be strongly correlated with the ACTH response to CRH challenge. Glucocorticoids have been shown to inhibit TSH secretion, and in vitro studies of cultured hypothalamic neurons have demonstrated glucocorticoid-induced stimulation of TRH gene expression, an action that is inhibited by tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI).74–77

### THE PROLACTIN AXIS

Prolactin (PRL) is a polypeptide hormone that is predominantly synthesized and secreted from lactotroph cells of the anterior pituitary gland. It was discovered by Riddle and colleagues in 1933, who demonstrated its ability to elicit lactation in mammals, and has since been shown to be involved in a vast array of functions, extending from reproduction and lactation to roles in metabolism, behaviour, immunoregulation and osmoregulation.78

Hyperprolactinaemia is a potentially serious adverse outcome associated with significant morbidity such as hypogonadism, leading to osteoporosis and increased risk of hip fracture.79 A growing body of evidence has linked elevations in prolactin to a possible increased risk of certain cancers (most notably breast, but also prostate) and pituitary tumours.80–83

Secretion of PRL by pituitary lactotroph cells is predominantly under the control of dopamine, which exerts a tonic inhibitory influence on the hormone’s synthesis and release. The dopamine is derived from a neuronal population in the arcuate nucleus of the hypothalamus and reaches the anterior pituitary via transport through the long portal veins. Dopamine exerts a direct effect on the lactotrophs by binding to the dopamine type 2 receptor expressed on their cell membranes, ultimately inhibiting both synthesis and secretion of PRL.79 This tonic upstream inhibition conveys a unique characteristic to PRL secretion compared with other pituitary hormones, whose secretory tone is determined largely by stimulatory agents. This discrepancy stems from PRL’s lack of a single target organ to provide a classical negative feedback loop (e.g. in contrast to ACTH). Also, lactotrophs have much higher basal secretory activity compared with other endocrine cells and are thus more responsive to inhibition than stimulation.

With respect to psychiatry, this is of clinical relevance due to the action of antipsychotic medications on the D2 receptor. All antipsychotic medications can affect prolactin levels via binding to dopamine receptors on the lactotroph cell membrane, with those that have potent D2 receptor antagonism and poorest blood–brain barrier permeability
having the greatest and most sustained effect. Thus, the
typical antipsychotic agents have all been associated with
sustained hyperprolactinaemia; of the atypical medications,
those that cross the blood–brain barrier easily and exhibit
fast dissociation from the dopamine receptor have the least
impact on serum prolactin concentrations (e.g. clozapine,
quetiapine). All atypical antipsychotic agents result in at
least a transient rise in PRL, however, and some can display
persistent hyperprolactinaemia akin to the typical agents by
virtue of their potent D2 antagonism (e.g. risperidone,
paliperidone, amisulpride). Prevalence rates of hyperpro-
lactinaemia in patients prescribed typical antipsychotics are
high, with estimations ranging from 33 per cent to over 80
per cent. In relation to depot formulations, studies have
reported hyperprolactinaemia in approximately 35 per cent
of patients. Prevalence rates of hyperprolactinaemia in
patients prescribed atypical antipsychotic agents vary sig-
ificantly according to the individual drug, with those clas-
sified as ‘prolactin-sparing’ having rates from less than
5 per cent to 30 per cent.

Abnormally high PRL levels may be clinically silent for
many years, or the most common symptoms of hyperpro-
lactinaemia such as sexual dysfunction may be undisclos-
ed by the patient or erroneously ascribed to the underlying
disease process rather than as an adverse effect of medica-
tion. Concerns regarding the possible impact of persistent
hyperprolactinaemia have only recently come into focus as
the widespread use of atypical antipsychotics as first-line
agents has shifted attention away from the main problems
of their forerunners (extrapyramidal side effects, tardive
dyskinesia) to newer concerns regarding metabolic and
endocrine abnormalities, including hyperprolactinaemia.
There has been a growing awareness of the higher risk of
a range of physical illnesses in patients with long-term
mental illness, and consideration of the risk of physical dis-
ease complications must now be a prominent factor when
selecting treatments for mental illness, not least of these
considerations being the potential for sustained hyper-
prolactinaemia.

THE HYPOTHALAMIC–
PITUITARY–GROWTH HORMONE
AXIS

The release of GH from the anterior pituitary is under the
combined regulation of the hypothalamic pituitary peptides
growth hormone–releasing hormone (GHRH) and somato-
statin. The former has a stimulatory action and the latter an
inhibitory action. These peptides in turn are regulated by
classic neurotransmitters such as acetylcholine, noradrena-
line, dopamine and γ-aminobutyric acid (GABA).

It was first demonstrated in 1982 that stimulation of
noradrenergic alpha-2 receptors brought about the release
of GH and that such a response is blunted in major depres-
sion. This was interpreted as indicative of a subsensitivity
of the alpha-2 receptor in depression. Anseau and col-
leagues found blunted GH release following clonidine (an
alpha-2 agonist) challenge in patients with mania. Similar
responses were reported by Dinan and colleagues in
patients challenged with the noradrenergic reuptake
inhibitor desipramine. It is interesting to note that cholin-
ergic inputs also regulate GH release, and that both
depressed and manic patients challenged with the acetyl-
cholinesterase inhibitor pyridostigmine show exaggerated
release of GH. Through the use of such neuroendocrine
challenge tests, the data indicate an imbalance between
noradrenergic and cholinergic regulation in mood

RESILIENCE AND VULNERABILITY
TO STRESS

Why some individuals seem impervious or resilient to the
potential negative consequences of stressful life events
while in others the same stress precipitates psychiatric ill-
ness is an area of increasing attention and research. A pro-
posed model for understanding resilience and vulnerability
for the development of stress-related disorders is the ‘three-
hit model’ posited by de Kloet and colleagues. This pro-
poses that genetic variability in conjunction with early life
experiences primes the brain’s response to major stressful
events in later life.

Genetic variants of the MR and GR that may potentially
predispose an individual to an abnormal stress response
have therefore been the subject of much investigation. One
such type of genetic variant is the SNP, which gives rise to
differential expression of the same gene (alleles). Several
SNPs within the GR and MR genes have been tested for
functionality and have been found to change the regulation
of the HPA axis at different levels. For example, Wust and
colleagues demonstrated significantly different HPA axis
responsivity dependent on genetic GR variant status in a
male twin cohort study. Carriers of the GR polymorphism
N363S showed higher saliva and plasma cortisol responses
compared with controls to both a psychological stressor
(Trier social stress test) and following ACTH challenge,
while homozygotes for another GR polymorphism (Bc11)
demonstrated lower cortisol responses as compared with
controls. Marked sex differences also appear to exist with
respect to GR polymorphisms on stress variability, as
observed by Kumsta and colleagues, who found in their
study that women with the Bc11 G/G genotype had the
highest cortisol levels, while men with the same genotype
had the lowest cortisol levels. Characterization of patients
with stress-related psychiatric disorders according to differ-
ent GR genotypes has been carried out, with as yet incon-
sistent findings. A German study of patients with
depression found significantly elevated frequencies of the
Bc11 and ER22/23EK GR SNPs in their sample \( n = 342 \) but
failed to demonstrate a significant genotype effect when the
reactivity of the HPA axis was tested in subjects by administration of a DEX-CRH challenge.\(^\text{36}\) However, response to antidepressant treatment was improved in carriers of ER22/23EK. Brouwer and colleagues observed different treatment responses in their study that demonstrated substantially lower response rates in patients with depression who were carriers of the Bcl1 polymorphism.\(^\text{36}\)

In relation to literature on the long-lasting physiological effects of early childhood trauma, a growing body of evidence is emerging to indicate that early life events can programme abnormal activation of CRHergic pathways, including HPA axis functioning into adulthood, which may thus confer a vulnerability for the development of psychiatric illness. Animal research employing maternal deprivation paradigms in neonatal rodents and non-human primates has demonstrated that maternally deprived animals exhibit HPA axis changes that persist into adulthood and that resemble depressed adult individuals (such as hyperactivity of the HPA axis and central CRH-containing pathways).\(^\text{97,98}\) Human research has demonstrated that subjects who are abused during childhood exhibit a markedly enhanced stress response and that this remains into adulthood.\(^\text{99-101}\) It seems that if significant stress is experienced early in life within a genetic window of vulnerability, then this permanently programmes the individual’s subsequent responsiveness to future stressful events. It is also important to highlight that any such programming that may occur could apply to other closely related systems in addition to the HPA axis in a mutually permissive manner. Evidence that links childhood trauma with increased inflammatory markers in adulthood\(^\text{102-104}\) may be part of the same pathophysiological process as that of sustained HPA axis abnormalities, given that both systems are intimately connected and bidirectionally influenced. Such a model provides a plausible and dynamic biological framework for understanding the link between early stressful life events and a sustained vulnerability for a range of stress-related illnesses throughout the lifespan.

**KEY POINTS**

- Neuroendocrinology is the study of the endocrine role of neuronal cells and the neural regulation of the endocrine system.
- The core components of the neuroendocrine axis are the hypothalamus, the pituitary gland and the various end-organ sites (e.g. adrenal gland, thyroid gland).
- Regulation of the axis is largely through a combination of forward drive by hypothalamic releasing factors and negative feedback control by the various end-organ hormones. Higher brain centres, neurotransmitters and the immune system also influence the axis.
- Many psychiatric disorders are associated with disturbances in neuroendocrine axis function, which thus implicates abnormalities of this axis as being of possible aetiological significance to the development of the psychiatric disorder.
- Early childhood traumatic events may result in permanent alterations to the neuroendocrine axis.

NATURE OF SLEEP

Sleep is a state of reduced awareness and responsiveness to internal and external stimuli. The reduced awareness is selective and it is stimuli of significance to the individual that are most likely to cause arousal from sleep. Sleep is also a transient phase that alternates with wakefulness and from which, unlike coma, the subject can be aroused quickly. The transition between wakefulness and sleep, however, may last for several minutes, and it may be impossible to determine the exact moment of falling asleep. In these transitional states, some aspects of both sleep and wakefulness coexist. Similarly, physical incoordination, sometimes with confusion, is common after waking from sleep (sleep inertia), probably due to delayed activation of the prefrontal cortex at the transition from sleep to wakefulness. The hallucinations associated with delirium such as delirium tremens probably represent partial rapid eye movement (REM) sleep intrusion into wakefulness. Sleep paralysis is also intrusion of the skeletal muscle relaxation of REM sleep into wakefulness.

DURATION OF SLEEP

The mean duration of sleep in the UK is now around 7 h per night, but there is probably a normal distribution, with around 8 per cent of people sleeping for less than 5 h and 2 per cent for more than 10 h. The duration of sleep that is obtained is often different from what is needed, and it should be sufficient to lead to a feeling of being refreshed on waking and remaining alert and able to function normally throughout the day. Life expectancy is shorter in people who obtain little sleep at night and also in people with prolonged overnight sleep. Both short- and long-sleepers have approximately the same duration of the deeper stages (3 and 4) of non-REM (NREM) sleep. After sleep deprivation, the duration of these sleep stages increases on the first night of more prolonged sleep, and an increase in REM sleep is seen subsequently.

Daytime naps are normal in young children and common in elderly people, particularly between 2 p.m. and 4 p.m., when the circadian rhythms favour sleep. Stages 3 and 4 NREM sleep usually occur only if there has been significant sleep deprivation or if a nap lasts longer than around 30 min. These long naps are more likely to be followed by sleep inertia; brief ‘power naps’ of around 20 min are usually more refreshing.

PHYSIOLOGY OF SLEEP AND WAKEFULNESS

Structure of sleep

Until the discovery of REM sleep in 1953, it was generally felt that sleep was a passive homogeneous state. Since then, it has been recognized that there are four to five cycles each night of NREM and REM sleep, alternating at around 60- to 90-min intervals. NREM sleep dominates early in the night, particularly its deeper stages (3 and 4), but REM sleep becomes more prolonged later in the night.

Physiology of NREM sleep

During NREM sleep, the cerebral cortical activity is synchronized. The synchronization of cortical activity is secondary to bursts of activity in thalamocortical neurons. These effectively disconnect the cortex from the brainstem, so that motor activity is largely reflex. Functional neuroimaging has shown that the prefrontal cortex and limbic system are inactivated. There is a relative increase in parasympathetic compared with sympathetic activity, and the metabolic rate is reduced by 5–10 per cent. The core body temperature falls as NREM sleep is entered, and the reduction in alveolar ventilation leads to a slight increase in arterial Pco₂. The heart rate and blood pressure fall. Protein synthesis and other anabolic processes are increased. Cell division is most rapid during NREM sleep. It has been considered to be a restorative or a recovery phase, particularly
for the brain but probably in part for the rest of the body as well.

**Physiology of REM sleep**

REM sleep, in contrast, may have a primarily neurodevelopmental role. It is most prolonged pre- and postnatally. Both NREM and REM sleep also play a part in memory, particularly for motor tasks.

The cerebral cortex is active during REM sleep, but in a different pattern from that seen in wakefulness. The prefrontal cortex is inactivated, but several areas of the limbic system are active. This cortical activity is manifested as dreams. The cortex still reacts to sensory information from the brainstem, but there is intense skeletal muscle inhibition, which prevents the physical enactment of dream mentation. Autonomic function is very variable, with rapid fluctuations in heart rate, blood pressure and respiratory pattern.

**Control of sleep and wakefulness**

Whether the subject is awake or asleep depends on the balance of influences promoting and inhibiting each of these states. The three known processes are:

- **Sleep homeostatic drive (process S):** the drive to enter sleep increases, probably exponentially with the duration since the end of the previous NREM sleep episode. It therefore increases during prolonged wakefulness and decreases once NREM sleep has been entered at night. There is probably a similar homeostatic drive to enter REM sleep, which increases during NREM sleep but not during wakefulness.

- **Circadian rhythms:** the intrinsic circadian rhythm is usually around 24.2 h and is entrained by external time-givers to gear it to the environment. The suprachiasmatic nuclei (SCN) in the suprachiasmatic hypothalamus are the most important centres controlling the circadian rhythms. Each cell in the SCN is capable of spontaneous depolarization, and their coordination is the source of circadian rhythmicity. At least 12 genes have been identified that control the periodicity of the SCN cells. Impulses reach the SCN from the retinal ganglion cell receptors, which are distinct from the rods and cones that lead to the sensation of vision. The retinal ganglion cells are also particularly sensitive to wavelengths of around 460 nm (blue light). The output from the SCN reaches the centres controlling sleep and wakefulness, particularly the ventrolateral preoptic area (VLPO) of the anterior hypothalamus, and the centres controlling feeding, temperature, endocrine function and motor activity. Light exposure also inhibits secretion of melatonin from the pineal gland. This is usually secreted at night, with a peak level in adults at 3–5 a.m. Melatonin entrains the SCN and helps to synchronize circadian rhythms, for instance of temperature and cortisol secretion, with those of sleep.

- **Adaptive drive:** there are a variety of mechanisms that enable the sleep–wake cycle to adapt to environmental conditions. These include behavioural factors, such as motivation and attention; psychological factors, such as mental activity and relaxation; and reflex factors, such as light exposure, noise, pain, environmental temperature, physical exercise and food intake.

**NEUROANATOMY OF SLEEP AND WAKEFULNESS**

Cerebral cortical activity is critical in determining whether sleep or wakefulness occurs, but it does not generate the drive to enter sleep or wakefulness. The most important anatomical structures (Figure 28.1) that regulate this are as follows:

- **Aminergic brainstem nuclei:** these include the locus coeruleus, raphe nuclei and tuberomamillary nuclei (TMN). These are most active during wakefulness, partially suppressed in NREM sleep and totally suppressed in REM sleep. They all favour wakefulness and inhibit REM sleep. They project to the hypothalamus, thalamus and basal forebrain, and together they form the ascending reticular activating system.

- **Laterodorsal tegmental (LDT) and pedunculopontine tegmental (PPT) nuclei:** these promote REM sleep when they are most active. They are inactive in NREM sleep, but activity returns during wakefulness. They also influence the sleep-related eye movements and the loss of muscle tone that are characteristic of REM sleep.

- **Higher centres promoting wakefulness:** these include the perifornical hypothalamus whose neurons release orexin (hypocretin) and have an excitatory effect on the brainstem aminergic nuclei. The mesolimbic dopaminergic system projects to the prefrontal cortex and limbic system, cholinergic neurons in the basal forebrain and the SCN.
● **Sleep-promoting higher centres**: these include the VLPO and the anterior hypothalamus, which inhibits the aminergic nuclei and promotes NREM sleep. Accumulation of adenosine in the extracellular spaces in the basal forebrain also inhibits the wakefulness-promoting cholinergic neurons in this region and thereby promotes sleep.

● **Pathways to the cerebral cortex to enable sleep to occur**: these are mainly via the thalamus, especially during NREM sleep, and the basal forebrain and hypothalamus. These closely linked areas integrate the sleep and wakefulness drives with circadian influences.

### NEUROCHEMISTRY OF SLEEP

The neurotransmitters and neuromodulators released at synapses strongly influence sleep, but other important chemicals are more diffusely present in the brain and cerebrospinal fluid and promote sleep or wakefulness. They act as local neurohormones influencing the threshold for depolarization of the postsynaptic membranes. Some of the systemically released classical hormones act in this way. The actions of the most important neurotransmitter amines are shown in Table 28.1, but there are also a wide variety of peptides and prostaglandins, as well as cannabinoids and adenosine, which influence sleep and wakefulness.

### KEY POINTS

- The repetitive cycles of NREM and REM sleep during each night underlie the presentation of many sleep disorders.
- NREM sleep is primarily restorative and REM sleep helps to establish new neural networks.
- The anatomical and chemical substrate of sleep and wakefulness is complex and involves areas throughout the brain.

### REFERENCES

INTRODUCTION

The aim of this chapter is to introduce the basics of electroencephalographic (EEG) recording generally and outline both clinical and clinical-research practices. The use, analysis and interpretation of EEG and other neurophysiological measures require some commitment of time and resource, and it is not the aim of this chapter to train the reader to expert level. Readers in pursuit of greater in-depth knowledge are referred to Binnie and Stefan for an overall review of EEG in psychiatric settings and to specialist books such as Engel on epilepsy and Luck for further information on the event-related potential (ERP).

In essence, EEG measures the combined electrical output generated by cortical neurons and, as a consequence, clinicians should consider utilizing EEG recording if it is believed that there is an organic cause within the central nervous system (CNS) underlying the given symptoms.

This chapter gives an overall introduction to, and brief overview of, basic techniques in recording EEG. Some specific clinical uses are outlined, ranging from sensory deficit through to specific syndromes, including epilepsy and related symptomatology, which are based on visual interpretation of the electroencephalograph itself. Following this, some of the analytical methods available and how they may inform us of underlying changes in CNS function are given.

In the presentation of each section, current views and interpretations are referred to, where they are thought to offer some guidance in clinical decisions. Clinicians with expertise use such visual interpretation in diagnosis and treatment decisions. The use of mathematical analytical tools and statistical tests of difference between EEG components allows direct comparison between different research hypotheses, generated from clinical evidence.

RECORDING EEG

The basics: what does EEG measure?

Specifically, EEG measures electrical activity that is discharged by many thousands of cortical neurons as their activity synchronizes. The electrical potential of single neural cells changes, depending upon excitatory and inhibitory input from the dendrites of neighbouring presynaptic neurons; a measure of such activity using an intracellular single electrode is called the action potential. EEG can only measure activity from cells that are aligned similarly to one another and radial to the scalp. As voltage drops at distance from the source, currents from deep sources are less easy to detect than those from nearer the skull. Measures of cortical electrical activity taken at the scalp may well suffer from refractive errors due to changes at the margins between the cortical surface, cerebrospinal fluid, meningeal membranes, skull bone and scalp. These recording issues are shown diagrammatically in Figure 29.1.

EEG is more reliable when detecting neural communication differences at surface or cortical levels and less reliable for detection of deep or subcortical events.

EEG and its sister technology magnetoencephalography (MEG) have a tremendous advantage over other neurophysiological measures in terms of temporal resolution, as they can be recorded in the millisecond range. Indeed, the limiting factor underlying recording accuracy tends to be data storage capacity, as each channel (electrode) contributes a data point at each recording time over the entire period being measured, hence a sampling rate of 1000 Hz using 32 electrodes will generate 32,000 data points per second and 1.92 million data points after 1 min.

EEG is excellent at identifying when events occur. Although it can be (and is) used in assessment of location of epileptogenic focus, EEG alone is not considered sufficient
where precise spatial resolution is required but should be used when clinically necessary in cases of classification and diagnosis of suspected organically based disorder. Essential uses of EEG are highlighted in this chapter.

The temporal-sensitivity advantage makes EEG a particularly suitable tool for enabling support in the diagnosis and treatment in epileptic symptomatology, as changes in electrical activity before a seizure happen in the order of tens of seconds before its onset. As outlined below, the temporal sensitivity of EEG enables several methods of analysis that allow interpretation of underlying causality by direct interpretation of graphical output, or through indirect analysis of coherent activity and/or frequency spectra power and components, (see Spectral analysis, below; and Coherence: a mathematical measure of similarity of frequency between two cortical locations, below).

Absolute localization of current source is not possible because the electrodes at the scalp are detecting the summation of electrical voltage that may be generated in, mathematically speaking, many potential sites. The development of more sophisticated analytic tools, and the use of high-density recording electrode montages, is improving spatial resolution, but it is generally considered that, for accurate spatial resolution, other, more expensive measures should be used, in particular magnetic resonance imaging (MRI) or positron-emission tomography (PET). Exciting developments utilizing the diamagnetic properties of electrical currents are now enabling the localization of electrical source within MEG, which retains the temporal resolution of EEG not available in other scanning technologies.

**Recording EEG: a first tutorial**

Cortical electrical activity is measured using highly electro-sensitive electrodes, often, but not exclusively, utilizing a silver–silver chloride construction with electrolyte gels of varying composition. Regardless of whether these electrodes are held to the scalp by adhesive (glue) or by elastic caps, it is essential that impedance levels are reduced as much as possible in order to increase the *signal-to-noise* ratio. This entails the scalp being abraded to remove loose epidermal cells; patients and participants are asked to arrive without having used hair products previously or are asked to wash them out before recording. The advent of the elastic-based cap has enabled the process of readying the recording montage to become shorter, which in research settings has led to the development of high-density recording systems where montages of 64, 132 and even 256 electrode sites are not uncommon. In order to promote clarity and comparison between reports, there is an internationally accepted montage of electrodes, the 10–20 system (Figure 29.2). The development of dense array systems leads to reports that refer findings back to the 10–20 system for clarity in understanding. Current use of dense and very dense arrays in epilepsy is focussed on EEG *source localization* of epileptogenic focus (see Plummer et al. for a comprehensive review).

CLINICAL USE OF EEG IN PSYCHIATRY

The most basic analysis of EEG is to look at the graphed output of all the recording channels. The spike-and-wave patterns of activity associated with epileptic syndrome are usually visual and time-measured. Although described as ‘basic’, the interpretation of these patterns and of differences between channels requires care and training. More complex forms of analysis involve mathematical algorithms to transform the digital data in some way.

The printout of an EEG presents, to the uninitiated, a frighteningly complex range of waveforms. It is important, therefore, to realize that a great deal of what is seen on the EEG is, to the experienced eye, of little clinical relevance. This is the very converse of what is seen on the electrocardiogram (ECG), which is the most similar tracing likely to have been seen by most doctors. While in the ECG almost everything on the page is of considerable importance, the reading of an EEG is much more a question of pattern recognition and observing the gestalt of the whole picture. Essentially, the EEG boils down to assessing for the following abnormalities:

- Slow waves
- Paroxysmal activity
- Maturational abnormalities
- Acute organic states
- Asymmetries of normal rhythms.

Both slow waves and paroxysmal activities can be divided into those that are generalized and those that are focal (localized).

Before reading an EEG, it is important to be aware that there is a wide range of biological and technical artefacts that may be seen and can be discounted. However, a number of artefacts can be very misleading; for instance, the rolling slow-wave pattern of a sweat artefact seen only over one side of the head might be mistaken for a cortical tumour, whereas a regular sharp-wave discharge of an ECG artefact seen only on some leads might be thought to be a localized epileptic discharge.

Generalized slow waves

These may be subdivided further into synchronous and asynchronous.

Synchronous generalized slow waves appear predominantly over both left and right frontal regions. Intermittent synchronous bilateral slow waves are seen as a result of brainstem damage, representing a decrease in activity in subcortical nuclei and subsequent corticothalamic activity. Such brainstem-damage related abnormalities are referred to as frontal intermittent rhythmical delta activity (FIRDA) (Figure 29.3).

Asynchronous but generalized slow waves – that is, slow waves that occur at a different rate and at different times in the two hemispheres – are typically seen with widespread cortical dysfunction, such as an organic confusional state. Such abnormalities would typically arise with toxic or metabolic encephalopathies. Such disorders may, in the first instance, present either as confusion or occasionally as a rather atypical psychosis. It is very important that the EEG be carried out in these circumstances.

Figure 29.2 The scalp is measured from front to back (nasion to inion) and from side to side (pre-auricular points). Electrodes are placed at sites that are 10 per cent and 20 per cent respectively of these distances. Regions of the scalp are identified by lobe names and central locations: F, frontal; C, central; O, occipital; P, parietal; T, temporal. Left hemisphere sites are given odd numbers and right hemisphere sites even numbers. Electrodes placed on midline sites are given the suffix ‘Z’. As density of electrode montages increases, nomenclature has expanded by conjoining site letters; so, for instance, electrodes between central and parietal locations are given the prefix ‘CP’.

Figure 29.3 Frontal intermittent rhythmical delta activity (FIRDA)
Focal (localized) slow waves, particularly those in the delta range, are typically seen over a brain tumour but also as what is termed ‘a breach rhythm’ over a neurosurgical site, where the functioning cortex has been damaged or removed (Figure 29.4). They represent, essentially, an area of brain where the normal faster cortical activity is not occurring and, therefore, the slower rhythms from the subcortical regions can be seen.

Generalized paroxysmal activity may usefully be divided into those that show a regular three per second (3 Hz) of spike-and-wave pattern, those that show some atypical spike-and-wave pattern (Figure 29.5) and those that are generalized but not of either of the previous two types.

There is a range of generalized epilepsies that do not fall into either of the above groups and that may be associated with paroxysmal activity only during sleep.

It is essential to recognize whether an epilepsy is of a generalized nature from the outset of treatment, as certain anti-epileptic medications may make generalized epilepsies worse (phenytoin and carbamazepine on occasion), and patients with these sorts of epilepsy are unlikely to be suitable for any form of resective surgery. It is very important that the EEG be carried out in these circumstances.

Figure 29.4 Breach rhythm over left central regions, following surgery

Figure 29.5 (a) Series of spike and slow-wave complexes; (b) atypical spike and slow-wave complexes

**Paroxysmal activities**

Likewise, these may be generalized or localized. Generalized paroxysmal activities in the form of three per second (3 Hz) spike-and-wave discharges are seen in typical and true ‘absence epilepsies’, also called true ‘petit mal epilepsy’. This condition typically arises in childhood and is associated with brief absences of consciousness, often with slightly flickering eyelids and occasionally with brief jerking movements around the eyes and sometimes of the hands. During the absence, the 3-Hz spike-and-wave discharges are seen; when the discharge ceases, the individual returns to full consciousness and may not be aware of the episode at all. After a time, an individual with this sort of epilepsy will recognize that they are missing parts of the conversation. As in all generalized epilepsies, the patient has no aura or warning that the seizure is about to occur.

Generalized atypical spike-and-wave discharges tend to be slower, at 2 Hz or 2.5 Hz. They are often less regular and they often contain multiple spikes. Such discharges are seen in a range of generalized epilepsies, but particularly in the Lennox–Gastaut syndrome. This syndrome is associated with learning disabilities, multiple generalized seizure types (tonic, atonic, absence, tonic–clonic) and a poor prognosis for recovery. Lennox–Gastaut syndrome may emerge out of the early onset, in infancy, of West syndrome, with severe paroxysmal activities seen in a ‘hypsarrhythmic’ pattern and myoclonic or ‘Salaam’ attacks.
Focal paroxysmal activities are associated with partial or localization-related epilepsies. The most common form of partial epilepsy arises in one or other temporal lobe. About 80 per cent of focal epilepsies arise here. The majority of the rest arise in the frontal lobes.

In temporal lobe epilepsy, typically, fast spiking activity is seen over the affected temporal lobe at the onset of a seizure, possibly after a period of relative quietude on the EEG (electrodecremental change). Increasingly, paroxysmal activity will build up gradually, often with further spreading of the fast-spiking activity and then development of spike-and-wave discharges over the affected temporal lobe and, eventually, if the seizure becomes generalized, over the whole cortex. This is associated with the typical ‘march’ of aura, motor automatisms and secondary generalization that is characteristic of temporal lobe seizures (Figure 29.6).

Partial epilepsies arising in the frontal lobes, as observed by carers, medical staff directly or through video EEG, may often occur without any interictal paroxysmal discharge and, even during a brief and sometimes very dramatic frontal lobe seizure, clear EEG abnormalities may not be seen on the cortex. Many frontal epilepsies arise in the supplementary motor area, on the mesial surface of the frontal lobe, and may therefore not be detectable on the surface. Scalp recordings may also be obscured by movement artefacts, and so invasive recording with electrodes, at neurosurgery, over the cortex itself may be needed.

Maturational changes of the EEG

The ‘maturational’ changes of the EEG during an individual’s lifetime are of importance. The EEG of a newborn infant is completely different from that of an adult. A picture characterized by a burst of activity and then by suppression of activity will be seen in normal newborn and particularly in premature babies. As the infant grows, faster activity is seen and eventually, during late childhood and early adolescence, an alpha rhythm will begin to emerge, initially seen over central regions and gradually localizing over the occipital regions. Before the age of 5 years, it is very common to have a number of asymmetries of the EEG, with one hemisphere perhaps developing before the other. It would be expected that the normal posterior alpha rhythm, at 8–14 Hz, would be established by about the age of 15 years. It is often felt that, if this has not happened, then the EEG may be regarded as relatively ‘immature’. For further information, the reader is referred to Yordanova and Kolev.

As an individual enters old age, there tends to be a slight slowing of the alpha rhythm, although it should still remain above 8 Hz. There may be more central fast (beta) activity, and there is a tendency to a generalized increase of slower background rhythms across the whole cortex. However, if the alpha rhythm becomes markedly slow, well below 8 Hz, and there is a significant increase in slow-wave activity generally, then this may signify the development of a dementing disorder.

Acute organic states

The identification of toxic or metabolic confusional states is a major value of the EEG. In these conditions, there is usually random synchronous and asynchronous slow-wave activity of a kind not seen in an individual with a functional psychiatric condition. On occasion, specific abnormalities are seen. Lateraled triphasic complexes are associated with herpes encephalitis; bifrontal triphasic waves are typically seen at some stage in hepatic encephalopathy, although this may occur later on. Periodic high-voltage complexes are seen in subacute sclerosing panencephalitis.

In dementing conditions, there is typically a slowing of...
the alpha rhythm and a polymorphic picture of slower waves (theta and delta). The slower the development of the dementia, the less likelihood there is of marked change in the EEG. However, slow-wave activity and a slowing of the alpha rhythm is a helpful discriminator from depression.

In Alzheimer’s disease, there tends to be diffuse slowing, but there may be runs of frontal delta resulting from subcortical damage, and there is a later appearance of sharper waves and sometimes of paradoxymal activity focally. Multi-infarct dementia tends to show more localized and unilateral slow-wave activity.

The EEGs recorded in focal or lobar dementias are very frequently normal for the majority of the history.

Huntington’s dementia is associated with a particularly low-amplitude EEG, a relative flattening of the EEG.

Creutzfeld–Jakob disease is associated with an early loss of the alpha rhythm and the appearance of theta waves, but these are non-specific and may be missed. Later on in the disease, sometimes just briefly before death, the typical picture of periodic triphasic complexes is always seen. The appearance of these triphasic complexes appears to be associated with the rate of progression of the disorder, there being more abnormalities if the disease is progressing rapidly.

**Asymmetries of normal rhythms**

Asymmetries in EEG activity may be normal or pathological. A mu rhythm may show one-sided bias, which is of no diagnostic significance. A breach rhythm, on the other hand, of similar frequency and at times even similar outline to the mu, though not necessarily of the same location, indicates brain trauma and is often seen at the sites of previous surgery.

Neonates may show 50 per cent asymmetry in their various EEG activities; this is normal, but a 50 per cent disparity in amplitude between hemispheres of the adult alpha rhythm could indicate a unilateral thalamic or occipital problem.

The most significant pathological asymmetries involve slow activity within the delta and theta wavebands, except for posterior slow waves of youth, which generally present more abundantly in the right posterior quadrant than the left. As outlined above, asymmetrical slow activity, especially delta activity at the lower frequency end, is a strong indicator of pathology. Very slow undulating localized delta may indicate a focal lesion such as an acute collection or abscess. If surrounding brain tissue is distorted, it reacts functionally by slowing, so that a whole hemisphere may be affected. Conversely, generalized slow waves, if ‘flattened’ on one side, should raise the suspicion of an extradural collection.

Transient sharpened theta presenting temporally and asymmetrically may indicate temporal dysfunction or an epileptogenic site in young patients. This significance decreases with age and after the age of 50 years these transients rarely indicate new epileptogenicity.

Beta activity is present but scant in normal recordings but can increase during alcohol use or administration of benzodiazepines or barbiturates. The latter two drugs are often used in the intensive care unit (ICU) for patient sedation. Asymmetries of this induced beta activity may indicate that a brain area or side is not capable of generating faster frequencies due to underlying pathology or damage.

Thus, asymmetries have to be assessed in the context of the patient’s age and history. There is a great deal of individual variability, and hence asymmetries are really significant only if they are very obvious and generally comprise an excess of slow activity.

**ANALYTICAL TECHNIQUES IN EEG**

Research activity in both typical and atypical (medical) arenas necessitates the use of analytical techniques that enable direct and precise comparison of EEG between groups of people. In this section, an overview is given of the main types of analysis available. The time-locking of EEG waveforms to a given event allows averaging over many trials and gives a waveform known as the ERP. Other forms of analysis can enable the constituent waveforms within EEG to be measured. In this section, the ERP, spectral analysis and coherence analysis are outlined briefly.

**The event-related potential**

Recording cortically generated electrical changes to a given stimulus tells us nothing from one trial. However, if patients (or volunteers in cognitive neuroscience experiments) are given many repetitions of each stimulus trial, and the resulting EEG is averaged over all trial epochs, then the resultant mean electrical signal shows characteristic patterns or changes in positive and negative activity. Such analysis is called an evoked potential (Figure 29.7). Sensory processing in the auditory, visual and somatosensory domains is called auditory evoked potential (AEP), visual evoked potential (VEP) and somatosensory evoked potential (SEP), respectively. Some experimental paradigms requiring correct responses are known as ERPs. The positive and negative deflections at given times are known as components and are nominated N for negative deflections and P for positive deflections. These are then either counted in order of appearance (e.g. N1, P1, N2) or, where particular components are reliably found at a given time, the component is named by that time (e.g. N170, which is found over ventral posterior regions during face-processing tasks).

Where practitioners need to identify sensory processing deficits, it is possible to use evoked potentials in visual, auditory and somatosensory modalities. Very early differences in the first 100 ms represent activity related to early neural pathways between receptor and sensory cortex and are linked to attentional processes. Hemisphere differences can indicate unilateral lesions (visual modality, auditory modality, somatosensory modality).
Additionally, behavioural and cognitive links to these early and later components (100 ms onwards) may be of use in identifying underlying disorders. One such comparison is that of mismatch negativity (MMN), the result of an increase in negativity following a deviant stimulus (compared with a regular stimulus). This is thought to represent pre-attentional processes and as a consequence has been used to investigate psychiatric disorders where attentional deficits are contributory, such as Alzheimer’s disease, schizophrenia, alcohol dependency and attention deficit hyperactivity disorder (ADHD). Readers are referred to Näätänen et al.17 and Giard et al.18 for further information on auditory MMN, and Tales et al.19 for more on visual MMN.

Spectral analysis

In the previous section on the visual analysis of EEG, the frequency of spike-and-wave activity and of slow-wave rhythms as visualized on the output was outlined. In research settings where specific hypotheses are tested by measuring activity in many people, it is necessary to measure periodicity precisely. EEG can be mathematically decomposed into its component frequency bands (Table 29.1), using filtering online or mathematical forms of Fourier transform, fast Fourier transform or wavelet algorithms, the latter being most useful in ongoing or dynamic identification of spectral components. There are suggestions that independent component analysis might be a useful algorithm in frequency decomposition.20,21 In general, the slower the frequency of the EEG wave, the higher the amplitude, which enables the detection of disease or atypicality when this pattern is not found.

Direct current (DC) changes in negative or positive shift can determine the state of the nervous system metabolism;22 these change with cognitive function and load23 and correlate with blood oxygenation level-dependent (BOLD) responses measured in functional magnetic resonance imaging (fMRI).24,25

Delta-frequency waves are those measured between 0 Hz and 3 Hz and are therefore usually termed ‘slow waves’; they tend towards greatest amplitude.

Theta-frequency waves are those measured between 4 Hz and 7 Hz. Theta is seen normally in young children, and in older children and adults when drowsy. Atypical increases
and patterns of theta activation have been linked to the onset of Alzheimer’s disease\textsuperscript{26,27} and depression.\textsuperscript{28} Alpha-frequency waves are those measured between 8 Hz and 12 Hz. Predominantly measured over posterior regions in both hemispheres, alpha waves are elicited by asking participants to shut their eyes and can be seen when patients (and bored volunteers) become drowsy and over-relaxed. Likewise, the alpha rhythm usually attenuates with eye-opening or mental exertion.

Waves of similar frequency (7–11 Hz) measured over the precentral areas encompassing the sensorimotor cortex are known as mu rhythms. Characteristically, mu rhythms attenuate with contralateral limb movement,\textsuperscript{29} likewise, during the imagined movement of a limb, the contralateral mu rhythm reduces.\textsuperscript{30}

Beta-frequency waves are those measured from 12 Hz to 25–30 Hz. They are usually distributed symmetrically and frontally located, and are maximally measured in alert, eyes-open or anxious people. Some variances in beta waves are associated with effects of drugs, in particular benzodiazepines. Beta’s association with anxious thinking is reflected in reports of increased and disordered patterns of beta activity in obsessive–compulsive disorders,\textsuperscript{31} sleep disorders\textsuperscript{32} and the control of ADHD via biofeedback.\textsuperscript{33}

Gamma-frequency waves are those measured in the frequency range of approximately 26–100 Hz. Gamma rhythms are thought to represent the binding mechanism within and between different populations or networks of neurons, enabling cognitive or motor functions.\textsuperscript{34,35} In autism, increased-amplitude gamma activity has been identified and is interpreted as an attenuation of inhibitory mechanisms,\textsuperscript{36–38} in schizophrenia, disordered processing is linked to differences in gamma amplitude and coherence.\textsuperscript{39–41} Lambda waves are single sharp waves over the occipital pole, associated with scanning visual scenes or pictures. It has been suggested that they represent the start of passage of information from occipital to prefrontal areas,\textsuperscript{42} while other negative waveforms over visual areas in response to patterns may represent local processing.\textsuperscript{43}

**Coherence: a mathematical measure of similarity of frequency between two cortical locations**

Another potential source of information that can be identified through the use of spectral decomposition of the EEG signal is that of coherence, a form of analysis that compares the periodicity of a given frequency between two locations. This is thought to give information on the localization of network activity by enabling the identification of lead and lag assemblies of neurons. Current research utilizing coherence analysis is enabling the identification of malfunctioning circuits in Alzheimer’s disease\textsuperscript{44} and Parkinson’s disease\textsuperscript{45} and, by use of electrocorticograph (EcoG), potentially mapping epileptogenic circuits within temporal lobe epilepsy.\textsuperscript{46}

**CONCLUSION**

The EEG is used in psychiatric conditions in order to assist in diagnosing and excluding certain organic brain diseases. It may be helpful in distinguishing between an acute toxic confusional psychosis and an acute functional psychosis. It is of major importance in distinguishing between epilepsy and various non-epileptic seizures (psychogenic seizures). It may be of assistance in the differential diagnosis of panic disorder or focal temporal seizures. Occasionally an EEG may be a pointer to a frontal lesion rather than a depressive disorder. It is helpful in the diagnosis of a dementing disorder in a patient who appears to be depressed, or vice versa.

The technological advances over the past three decades have improved data-handling capabilities exponentially, thus enabling far greater sophistication in analytical techniques. As a consequence, many relatively new research paradigms are being utilized in endeavouring to understand, classify and define brain activity, whether normal or atypical. The vast array of different measures and analyses, combined with the many syndromes and the underlying causes of such syndromes, may appear baffling at first glance. It is the aim of this chapter to introduce some of the main issues and some of the current interpretative views as reported in the literature.

**KEY POINTS**

- EEG is useful in psychiatric conditions where organic brain disease is suspected.
- EEG is of major importance in distinguishing between epileptic and non-epileptic (psychogenic) seizures.
- EEG is essential in identifying whether an epilepsy is of a generalized nature before giving medication.
- EEG is of major importance in differential diagnosis of focal temporal seizures.
- EEG may be of assistance in making the distinction between psychosis and acute functional psychosis.
- EEG may enable differential identification between frontal lesion depressive disorder and dementia.
- In research settings, there are a number of analytical techniques available enabling the direct comparison of specific phenomena between diagnostic groups across studies.

INTRODUCTION

The brain is a highly complex and specialized organ, and this complexity can be seen in its cellular composition. The cellular specialization of the brain, and of the other components of the central nervous system (CNS) and peripheral nervous system (PNS), inevitably reflects, and is ideally suited to, its function. This cellular specificity is built on a foundation of biochemical factors, processes and mechanisms; thus, there is also a neurochemical specificity in brain function. This is primarily but not solely associated with neurons, which are differentiated by the neurotransmitters they secrete and the receptors they express. It is this neurochemistry with which this chapter is mainly concerned.

The central component of this cellular structure is the neuron. The neuron is a highly specialized cell with unique features that enable it to generate and propagate electrical impulses and to translate those impulses into a chemical signal to pass information to an adjacent cell. This process is synaptic neurotransmission, and inevitably much of this chapter will be concerned with the specialized molecules and mechanisms of neurotransmission. Synaptic control of neuronal activity provides the complex, elaborate, subtle and flexible mechanisms by which the brain is able to process information. Thus, synaptic neurotransmission is the point at which we can modify neuronal function – distorting it or normalizing it when it goes awry. The great majority of psychiatric drugs act directly or indirectly to influence neurotransmitter function at the synapse.

Glia

Astroglia (or astrocytes) are the most common cells of the CNS, where they provide many of the necessary processes absent in the highly specialized neurons. They provide the neuron with glucose and regulate the extraneuronal environment by removing the products of neuronal activity. This includes uptake of potassium ions for which they express a high density of potassium channels. They also express transporters for fast-acting neurotransmitters such as glutamate and γ-aminobutyric acid (GABA), facilitating their rapid removal from the synapse after release. They are involved in subsequent decarboxylation of glutamate to glutamine and the return of glutamine to neurons as the precursor of glutamate. Astrocytes have also been shown to express certain glutamate receptors.

The intimate relationship of astrocytes with both the blood supply (see below) and neurons demonstrates their role in mediating neuronal control of blood flow, which is usefully employed as a surrogate indicator of neuronal activity in neuroimaging studies of brain function. Proliferation of astrocytes occurs in situations following neural damage; this gliosis, or gliotic reaction, results in the CNS equivalent of scar tissue.

Microglia are the CNS equivalent of monocytes: they are relatively mobile and continually monitor the brain environment to identify damage by detecting changes in potassium ions, and act as phagocytic scavengers when activated, as can astrocytes.

The blood–brain barrier

The blood–brain barrier protects the brain from unwanted incursion by a variety of substances from bacteria and other cells to single proteins and small molecules, while permitting passage into the brain of many compounds necessary for its normal function, such as oxygen, glucose and amino acids. These protective and facilitatory processes use both passive and active mechanisms.

The blood–brain barrier is thus both a physical barrier and a series of biochemical processes associated with a dense layer of luminal epithelial cells having supportive ‘astrocytic feet’ behind them. The tight junctions between cells provide an effective physical barrier against cellular and subcellular species and plasma solutes. However, there
are also efflux transporter mechanisms that actively exclude potentially toxic small molecules, such as the p-glycoprotein transporter (MDR1 or ABCB1). Although of benefit in protecting the brain from xenobiotics, this system can compromise drug delivery by diminishing drug availability to the brain; several psychiatric drugs (e.g. risperidone, paroxetine, citalopram) are p-glycoprotein substrates.

The blood–brain barrier contains active transport mechanisms that transfer small molecules from the blood into the brain. These include a large number of transporters for glucose, amino acids and other essential nutrients, some of which may also recognize certain drugs as substrates. Important in understanding neurotransmitter biochemistry is the large neutral amino-acid transporter system (system L), of which two components are LAT-1 and LAT-2. This is responsible for the transport of several amino acids essential to brain function, including tyrosine and tryptophan, precursors of the catecholamine neurotransmitters and serotonin, respectively.

### Ion channels and ion pumps

The neuron is an excitable cell with unique physiological properties that are essential for its function in transmission of nerve impulses, the action potential, from cell body to axon terminal. There are also essential features at the axon, or neuronal, terminal that bring about release of stored neurotransmitter into the synapse in response to the arrival of the action potential. The immediate driving force behind these processes is the membrane potential across the neuronal membrane. It is maintained by an uneven distribution of ionic charge across the plasma membrane, with K⁺ more concentrated on the inside of the cell, and Na⁺ and Ca²⁺ more concentrated on the outside of the cell. These concentration gradients arise largely through the action of the energy-dependent sodium/potassium ATPase, an enzymic pump that breaks down adenosine triphosphate (ATP) in the presence of intracellular Na⁺, driving the pump that exchanges this Na⁺ for extracellular K⁺ in order to maintain ionic concentration gradients and membrane potential. It is the ion channels in the cell membrane that determine how this membrane potential is used to propagate action potentials and stimulate neurotransmitter release.

Ion channels are formed of four to six channel proteins that assemble to form a pore. Each subunit has a hydrophobic surface that readily associates with the phospholipid layer of the membrane. The composition of proteins varies between channels, and this is what provides their different properties and selectivity. Ion channels are selectively permeable for particular ions (e.g. sodium, potassium, calcium, chloride); this selectivity, specified by the pore diameter and the nature of the amino acid residues lining it, is their most important property.

Ion channels can be rested (closed, but able to be opened upon a stimulus), activated (open) or inactivated (closed and not able to be opened by a stimulus). Most ion channels remain inactivated until specific signals dictate their opening. This property of gating is governed by changes in the local environment of the membrane, such as the membrane potential, leading the channel to be termed ‘voltage-gated’, or when they respond to changes in neurotransmitter concentrations, when they are known as ‘ligand-gated’.

The voltage-gated Na⁺ and K⁺ channels control the production and propagation of the action potential. But when the action potential arrives at the neuronal terminal, voltage-gated Ca²⁺ channels are particularly important in the first stage of translating this electrical signal into chemical neurotransmission. These Ca²⁺ channels are concentrated at the synaptic cleft and open in response to the change in membrane potential associated with the arrival of an action potential. Ca²⁺ enters the cell down an electrical and chemical gradient – intracellular Ca²⁺ is held at about 10⁻⁷ M while outside the cell it is approximately 10⁻⁴ M.

The subsequent local increase in Ca²⁺ within the presynaptic cell membrane promotes fusion of vesicles containing neurotransmitter stores with the membrane, leading to exocytotic release of transmitter. This is brought about by effects on lipid metabolism and on the function of several structural and soluble proteins within the presynaptic terminal. Thus, vesicles that are attached to the cytoskeleton by synapsin I are released following a Ca²⁺-dependent phosphorylation of synapsin I, allowing them to move to the presynaptic active zone. Vesicles in the active zone are attached to, and fuse with, the plasma membrane by the action of several Ca²⁺-sensitive structural and soluble proteins.

Ca²⁺ has multiple actions on the cell and these can have toxic effects if they are not controlled carefully. Thus, there are effective mechanisms for the removal of Ca²⁺ from the cytosol following transmitter release. There are buffering systems such as Ca²⁺ binding proteins, vesicular sequestration and mitochondrial storage, and there are also two pumping mechanisms to remove Ca²⁺ from the cell, including a Ca²⁺-ATPase and a Ca²⁺/Na⁺ antiporter pump.

### CHEMICAL NEUROTRANSMISSION

Neurotransmitters are generally small molecules that are released from a neuron into a synapse in response to an action potential to have an effect on a postsynaptic cell. This implies that there is substantial cellular specialization; neurons need to have mechanisms for synthesis and storage of neurotransmitter, and postsynaptic cells will have specific receptors. Thus, there is both pre- and postsynaptic specialization. In addition, there need to be mechanisms for transmitter release (as described above) and cellular processes for removal.

Classically, there are specific criteria suggested for the identification of a specific substance as a transmitter, including its presence in the neuron, its release following
neuronal stimulation and specific removal mechanisms. In addition, the effect of the putative transmitter needs to be identical with its endogenous functional activity. However, as our understanding of the complexity of the brain has developed, increasingly more substances have been identified that meet some, but not necessarily all, of these criteria. Thus, compounds with synaptic actions may be secreted by glial cells, or stimulated release of a neuropeptide may not be associated with a rapid synaptic removal mechanism but may rely primarily on diffusion away to terminate its action.

The main classical transmitters to be discussed here are dopamine and noradrenaline, serotonin, acetylcholine, glutamate and γ-aminobutyric acid (GABA); some important neuropeptides are included in a further section. There are other compounds that also have ‘classical’ neurotransmitter activity, including histamine and glycine, and further molecules that have less conventional modes of action, such as nitric oxide (NO), adenosine and the endogenous cannabinoid anandamide. Neurotransmitters comprise a disparate group of compounds with different chemical structures and functional activities. The classical transmitters are often subdivided in a variety of ways, depending on various criteria, including chemical class (e.g. catecholamine, neuropeptide), duration of response (fast, slow) or postsynaptic effect (excitatory, inhibitory). However, it is the postsynaptic receptors that determine whether neurotransmitters are excitatory or inhibitory and that contribute to the rapidity of their response.

The classical neurotransmitters are synthesized from readily available precursors by specific and selective enzymatic processes. The ubiquity of neurotransmitter precursors is an important feature that enables the CNS to function even under conditions of extreme physiological stress. In, for example, situations of starvation, when the body may exhaust fat supplies and turn to protein breakdown for energy, the amino acids from which the monoamine neurotransmitters are produced remain available in the blood. Active transport processes across the blood–brain barrier ensure a ready availability of precursor for neurotransmitter synthesis.

The synthesis and storage processes determine the specificity of neurons for particular neurotransmitters (Table 30.1). Most of the enzymes responsible for the synthesis of transmitter molecules are found only in specific neurons. Similarly, the transporters responsible for uptake or reuptake of transmitter into the neuronal terminal and those mediating storage in vesicles are exclusive to neuronal subtypes.

### Functional anatomy of neurotransmitter systems

The specificity that neurotransmitters impart to neurons contributes to the anatomical specificity of brain function. Some neurotransmitters appear ubiquitous throughout the

**Box 30.1 The cannabinoid system**

The effects on the brain of preparations from Cannabis sativa, the hemp plant, have been known for thousands of years. Low doses of cannabis can have effects that are both euphoric and calming, as well as being analgesic and impairing cognitive and psychomotor function. It can stimulate appetite and in high doses may be psychotogenic. These actions are primarily brought about by an active component of cannabis, Δ⁹-tetrahydrocannabinol (THC), which has been shown to act as an agonist at specific cannabinoid receptors, of which CB1 is the major brain site. The naturally occurring agonists at the CB receptors, the endocannabinoids, include the derivatives of arachidonic acid, anandamide and 2-arachidonylglycerol. CB1 receptors are found primarily on presynaptic neuronal terminals, where they are thought to mediate retrograde signalling. This is a process of feedback inhibition across the synapse, whereby the endocannabinoid is synthesized in and released from postsynaptic cells in response to synaptic activity to have an inhibitory effect on further presynaptic release of transmitter.

The cannabinoid system interacts with glutamate, opioid, dopamine and other neurotransmitter systems, and these interactions are likely to be important in a variety of functions, including reward and drug dependence. Synthetic cannabinoid ligands have potential in the treatment of pain, nausea, obesity and drug dependence.

The high occurrence of cannabis abuse in people with schizophrenia is surprising considering the psychotogenic propensity of THC, although some of its other effects may be enjoyable and provide relief from symptoms. However, cannabis has other components beside THC; one of these, cannabidiol, has both CB1 antagonist effects and antipsychotic properties, indicating the potential of synthetic CB1 antagonists as antipsychotic drugs.

GABA, γ-aminobutyric acid.

brain; this is true for glutamate and GABA, respectively the major excitatory and inhibitory neurotransmitters. Thus, glutamate is associated with most neuronal interconnections from, to and between cortical areas, while GABA is the primary transmitter within the interneurons that provide inhibitory control over the activity of these and other neuronal systems. Other neurotransmitters are highly specific in both anatomical distribution and function. This is illustrated by the various pathways of dopamine: the highest concentrations of brain dopamine are found in the caudate nucleus and putamen, the terminal regions of the nigrostriatal pathway, where it is essential to the control of motor function.

The catecholamine neurotransmitters

Dopamine and the biochemically related noradrenaline (norepinephrine) are the main catecholamine neurotransmitters, so-called because of their 3,4-dihydroxyphenyl (catechol) structure. Adrenaline (epinephrine) is a further member of this group but is only a relatively scarce transmitter in the human brain, despite its major role in adrenal gland function. With serotonin (and, strictly, histamine), they comprise the monoamine neurotransmitters. They may also be referred to as ‘biogenic amines’.

Most dopamine and noradrenaline in the brain is found within neurons with their cell bodies in the brainstem: in the substantia nigra and adjacent ventral tegmental area (VTA) for dopamine, and primarily in the locus coeruleus for noradrenaline. The substantia nigra and locus coeruleus are the two melanin-pigmented nuclei of the human brain and a consequence of the high turnover of neurotransmitter in these structures; neuromelanin is a product of catecholamine oxidation.

The main dopaminergic pathways of the human brain are illustrated in Figure 30.1. The great majority of dopaminergic neurons project to the striatum, the caudate nucleus and putamen, from the substantia nigra. It is this pathway that degenerates profoundly in Parkinson’s disease. The inner-
Dopamine is synthesized from l-dopa by the additional presence of a specific noradrenaline transporter (VMAT). A further transporter for dopamine is found in the neuronal membrane, which modulates the temporal and spatial influence of dopamine, although the major removal process for released transmitter is diffusion away from the synapse.

Although neurotransmitter release from vesicles into the synapse is controlled in part by neuronal activity, the synthesis of new catecholamine transmitters is also carefully regulated by feedback mechanisms. The rate-determining TH enzyme provides the point for this control; it is subject to end-product inhibition by intracellular dopamine and noradrenaline. TH can also be regulated by receptors sensitive to extracellular transmitter (autoreceptors); there are synthesis-modulating autoreceptors sensitive to dopamine that influence the phosphorylation status of the enzyme. As the synthesis of its immediate precursor, l-dopa, is the rate-determining step in dopamine synthesis, bypassing this step by administration of l-dopa will increase the availability of dopamine, independent of the regulatory control provided by tyrosine hydroxylase. This is made use of in the treatment of Parkinson’s disease with l-dopa.

There are also release-modulating autoreceptors that provide a usually inhibitory control over neurotransmitter release; for dopamine and noradrenaline, these are D2-like and α2 receptors, respectively.

Noradrenaline neurons are biochemically differentiated from those of dopamine by the additional presence of dopamine-β-hydroxylase in the synaptic vesicles (see Figure 30.2). These neurons also employ the VMAT, but the neuronal membrane has a specific noradrenaline transporter.

Adrenaline-containing neurons such as the chromaffin cells of the adrenal medulla and some isolated brainstem nuclei contain the enzyme phenylethanolamine-N-methyltransferase, responsible for adrenaline synthesis by methylation of noradrenaline (see Figure 30.2).

5-Hydroxytryptamine

5-Hydroxytryptamine (5-HT, serotonin) also has a widespread innervation in the human brain, with most projections arising from neuronal cell bodies in the dorsal and median raphe and neighbouring nuclei of the lower brainstem. There are projections to the hippocampus, amygdala, hypothalamus, thalamus, neocortex and striatum and other basal ganglia regions, including the substantia nigra, although most structures receive some serotonergic innervation.

5-HT is synthesized from tryptophan, also a substrate for the large neutral amino-acid transporter system across the blood–brain barrier. As with the catecholamine neurotransmitters, the enzyme responsible for initial hydroxylation of precursor amino acid represents the rate-determining step in transmitter synthesis (Figure 30.3). This enzyme, tryptophan hydroxylase (TPH), has been shown to occur in two forms with separate genes; the TPH2 gene codes for the enzyme form that is found primarily in human brain. The resultant 5-hydroxytryptophan is decarboxylated by AAAD to 5-HT, which is taken up into vesicles by VMAT. Again, a specific 5-HT transporter is found in the neuronal membrane.

Although the initial tryptophan hydroxylation step is rate-determining, the TPH enzyme is not saturated and availability of tryptophan can determine the rate of 5-HT synthesis. Tryptophan is unusual among amino acids in that up to 90 per cent is bound to plasma albumin and hence unavailable for transport into the brain; this limits the tryptophan available for 5-HT synthesis. Also, in contrast to catecholamine synthesis, there is no end-product inhibition of TPH, although TPH activity may be influenced by neuronal firing, which can be modulated by autoreceptors of the 5-HT1A subtype.
Melatonin
In a specific set of cells in the pineal gland, 5-HT is converted by two enzymes to form melatonin. This hormone is released from the pineal gland under the control of, and to have feedback effects on, the suprachiasmatic nucleus of the hypothalamus, the circadian clock of the brain. Melatonin release is enhanced at night to have, among other actions, inhibitory effects on 5-HT neuronal activity.

Synaptic removal of the monoamine neurotransmitters
Once released into the synapse to have effects on postsynaptic cells by binding to receptors, 5-HT and the catecholamine neurotransmitters are removed via neuronal transporters specific to each transmitter. These important sites for pharmacotherapeutic intervention are found on the presynaptic cell membrane and permit transmitter, at least in part, to be recycled by uptake into the neuronal terminal and re-stored in vesicles.

Excess transmitter can be metabolized, and all three transmitters are substrates for monoamine oxidase (MAO), which occurs in two main forms with different genes. MAO-A is responsible for 5-HT and noradrenaline, while dopamine can also be oxidized by MAO-B. The enzymes are present throughout the body, including the gut, kidneys and liver, and found in neurons and glial cells in the CNS, although there is some selectivity of MAO subtype within brain regions. In addition to its role in metabolizing transmitter, MAO has a function in metabolizing dietary xenobiotics and thereby protecting the brain from unwanted and potentially neuroactive compounds. This is demonstrated by the ‘cheese effect’, the hypertensive crisis occurring when both MAO subtypes are inhibited by an MAO inhibitor and a source of tyramine (e.g. mature cheese, pickled herrings, some red wines) is ingested. Tyramine, normally rapidly removed by MAO before it can reach neuronal terminals, acts as a ‘false transmitter’ and directly or indirectly (by transmitter release) can bring about a substantial and occasionally life-threatening increase in blood pressure.

Although MAO-A is the only metabolic removal mechanism for 5-HT, the catecholamines are substrates for another enzyme, catechol-O-methyltransferase (COMT). This enzyme also acts on the products of MAO (and vice versa) (Figure 30.4). It exists in soluble and membrane-bound forms; its cellular and subcellular localization is not fully understood, although the soluble enzyme may be localized primarily to glia while membrane-bound COMT appears to be present on intracellular membranes of postsynaptic cells. In regions where the innervation is relatively dense (such as the striatum for dopamine), COMT has little effect on transmitter availability, since reuptake via neuronal transporters and subsequent storage or oxidative metabolism is relatively more important in regulating synaptic transmitter. However, in regions such as the cortex where neuronal terminals are relatively sparse, COMT activity appears to have a relatively greater importance and can influence concentrations of dopamine. This has attracted interest since there are common genetic variants in COMT that influence its activity and are associated with (presumably dopamine-mediated) individual differences in frontal cortical cognitive function, particularly in the context of cognitive deficits in schizophrenia.

Acetylcholine
The first identified neurotransmitter was acetylcholine, detected as the substance released from the vagus nerve to diminish heart rate. In addition to its role in the PNS as a transmitter in parasympathetic nerves and at the neuromuscular junction, it also has a role in brain function, controlling motor and cognitive functions. It has a major cell group in the basal forebrain, where, from the basal nucleus of Meynert, there are projections to the cerebral cortex and parts of the amygdala, thalamus and basal ganglia. Adjacent nuclei (of the septum and the diagonal band of Broca) project to the hippocampus. This system is implicated in Alzheimer’s disease, in which the degeneration of basal forebrain cholinergic neurons is thought to contribute to cognitive deficits.

Cholinergic neurons in the brainstem projecting rostrally are part of the reticular activating system. There are also cholinergic interneurons, notably in the striatum, where they play a major role in the control of motor function.

Acetylcholine is synthesized in neurons from readily available precursors: acetyl-coenzyme A (acetyl-CoA), deriving from glucose in intermediary metabolism, and choline, a component of membrane lipids. This enzymatic process requires choline acetyltransferase (ChAT), an enzyme specific to cholinergic neurons and present in excess in the neuronal terminal (Figure 30.5). Hence, it is the availability of precursors that normally determine rate of acetylcholine synthesis, although there appears to be some product inhibition of ChAT activity. Acetylcholine is stored in vesicles by a specific vesicular acetylcholine transporter.

Released acetylcholine is removed from the synapse by the hydrolytic enzyme acetylcholinesterase (AChE) to pro-
duce acetic acid and choline. AChE is a glycoprotein that in one form is attached to the extracellular matrix of the cell membrane at the synapse and rapidly breaks down released acetylcholine. AChE inhibition can increase brain acetylcholine and is a target for the treatment of Alzheimer’s disease. Much of the choline produced in this process is taken up into the presynaptic neuron by a high-affinity transporter specific to cholinergic cells, where it can be recycled into more acetylcholine. Release-modulating autoreceptors are present on cholinergic terminals; these are primarily of the muscarinic M2 subtype.

**Glutamate**

Glutamate (glutamic acid) is the major excitatory neurotransmitter in the brain and is involved in all aspects of brain function. It is found throughout the CNS, notably as the transmitter in the large pyramidal neurons (e.g. motor neurons) of the cortex that project to other regions of the brain or spinal cord. Aspartate (aspartic acid) is another excitatory neurotransmitter that is similarly distributed, albeit in somewhat lower concentrations; it may be a specific transmitter in certain cortical, hippocampal and cerebellar neurons. However, it is not easy to clearly differentiate aspartate and glutamate neurotransmission, since the two transmitters have common effects at several receptors and share many presynaptic mechanisms. It is thus common to refer to the effects of the two as excitatory amino acid (EAA) neurotransmission; often, discussion of glutamatergic action cannot distinguish effects of aspartate and is used to imply EAA, rather than solely glutamate, neurotransmission. This convention with be used in much of the following discussion, which will not specifically address aspartate as a transmitter.

The neuronal specificity of glutamatergic cells is provided by specific synthetic and transporter mechanisms. Glutamate is an important component of cellular metabolism, being an amino acid required for protein synthesis, and hence is found in all cells, where it is synthesized from glucose via the Krebs cycle. Neurotransmitter glutamate is formed primarily from glutamine by the enzyme glutaminase. Glutamate is then taken up into vesicles by specific transporters (vesicular glutamate transporters 1 and 2 primarily in brain) for storage before release on stimulation.

Released glutamate is removed very rapidly from the synapse by specific cell membrane transporters, the excitatory amino acid transporters (EAATs). These sodium-dependent transporters are found not only in presynaptic neurons (primarily EAAT3 in cerebral neurons) but also in postsynaptic cells (also EAAT3) and surrounding glial cells (EAAT1, EAAT2). Glia EAAT2 in particular is responsible for over 90 per cent of total glutamate uptake. These highly effective removal processes are essential not only in limiting the action of glutamate to transient effects on synaptic transmission after release but also in limiting the toxicity that comes from excessive extracellular glutamate (Box 30.2). Glutamate

---

**Box 30.2 Excitotoxicity**

It has long been known that the excitatory amino acid neurotransmitter glutamate can cause damage to neural tissue. Introduced systemically, it can cause damage to retinal cells and to regions of the hypothalamus in young animals; these effects can be blocked by antagonists of glutamate receptors. Glutamate receptor agonists such as kainic, ibotenic and quinolinic acids can also cause neuronal damage on injection into neural tissue, specifically to neuronal cell bodies and dendrites, while preserving axons passing through the area of lesion. This process demonstrates a close correlation between the excitatory receptor effects and neurotoxic potencies of these glutamate agonists, indicating a mechanism of excitatory neurotoxicity, or excitotoxicity.

Excitotoxicity is due to enhanced and excessive receptor-mediated Ca2+ entry into neurons via the glutamate/N-methyl-D-aspartate (NMDA) receptor. Neurons have mechanisms to minimize the cytosolic concentrations of Ca2+, but when these buffering and transporter capacities are overcome by an excess of Ca2+ influx following excitatory stimulation of glutamate receptors, several toxic processes may be initiated:

- Activation of proteases and phospholipases
- Loss of mitochondrial function
- Loss of nuclear function
- Further glutamate release.

The concept and process of excitotoxicity have been valuable in developing models for the understanding of neurodegenerative disease. In addition, it may well contribute to neuronal damage following ischaemic stroke and epileptic seizures, and to the neurotoxic effects of inflammatory responses within the brain. Excitotoxic damage is also postulated to contribute to the structural changes and neuronal deficits in the brain reported in schizophrenia and affective disorders.

**FURTHER READING**

release is under inhibitory control by metabotropic autoreceptors, primarily of the mGluR2 subtype.

The glutamate removed from the synapse by uptake into glia is mainly metabolized to glutamine by the enzyme glutamine synthetase, which is absent in the neuron. This glial glutamine then serves as the precursor for further neuronal glutamate after active transport from the glial cell into the neuron. Thus, there is a ‘glutamine cycle’ providing for the synthesis and recycling of neurotransmitter glutamate, differentiating this pool of amino acid from the glutamate associated with cellular metabolism (Figure 30.6).

**Figure 30.6** Pathway for glutamate synthesis and recycling

---

**γ-Aminobutyric acid**

GABA is the main inhibitory neurotransmitter in the brain. Like glutamate, GABA is ubiquitous in the CNS, where it is found in the majority of interneurons and also in some inhibitory projection neurons. For example, neurons projecting from the striatum to the pallidum and subsequently the thalamus are GABAergic; these are important in the control of motor function and selectively degenerate in Huntington’s disease. Neurons containing GABA can be subdivided in many ways: on the basis of their electrical activity (fast-/slow-firing), the neuropeptides they contain (e.g. cholecystokinin (CCK), somatostatin), their morphology (e.g. chandelier cells) or their calcium-binding proteins (e.g. parvalbumin). Parvalbumin-containing GABAergic interneurons have been found to be diminished in the cortex and hippocampus in schizophrenia.

GABA is synthesized from glutamate in neuronal terminals by the enzyme glutamic acid decarboxylase (GAD). It is stored in vesicles by the specific vesicular GABA transporter. Synaptic released GABA is removed rapidly by sodium-dependent transporters, which, as for glutamate, are found not only in presynaptic neuronal membranes but also on adjacent astrocytes. GABA release, as with other neurotransmitters, is under inhibitory feedback control through autoreceptors, primarily of the GABA_A subtype.

Metabolic breakdown of GABA occurs in both neurons and glia by the enzyme GABA-transaminase which, by transferring an amino group to α-ketoglutarate, results in the (re)formation of glutamate, the immediate synthetic precursor of GABA.

**NEUROTRANSMITTER RECEPTORS**

The various neurotransmitters and other signalling molecules in the brain bring about their effects by action at specific receptors. These receptors are proteins that respond to agonists – that is, molecules such as neurotransmitters and drugs that mimic neurotransmitter action at the receptor. Agonist action is due to binding of the molecule to a specific recognition site on the protein; this binding to the receptor initiates a process of biochemical or ionic effects that influence cellular function. Molecules including agonists that bind to receptors are called ligands; drugs and other ligands that block the binding of agonist to the receptor, or block the effects of agonist binding, are referred to as antagonists.

Receptors are generally membrane-bound, although certain hormonal receptors may be found in the cytoplasm. Although they can occur on intracellular membranes, this chapter focuses on receptors in the cell membrane and responding to extracellular neurotransmitters or hormones. There are two main groups of cell-surface receptors – the metabotropic receptors and the ionotropic receptors.

The archetypal neurotransmitter receptor is found within the synapse on the postsynaptic membrane, where it responds rapidly to released neurotransmitter to influence postsynaptic neuronal activity, typically increasing or decreasing likelihood of an action potential. However, there may be receptors on the presynaptic axon terminal that control neurotransmitter release; these respond to neurotransmitter released from that neuron (an autoreceptor) or are postsynaptic to another neurotransmitter terminal (a heteroreceptor). There may also be autoreceptors elsewhere on the neuron, such as the cell body or its surrounding dendrites, which control transmitter synthesis or neuronal activity.

**Ionotropic receptors**

Ionotropic receptors, also referred to as ligand-gated ion channels, are large proteins generally composed of five subunits that assemble in the membrane. They tend to exhibit considerable heterogeneity in their subunit composition, leading to a variation in function. These oligomeric proteins contain about 20 transmembrane segments arranged around a central aqueous channel. Ionotropic receptors open in response to the binding of a ligand (e.g. neurotransmitter) to the receptor protein. This causes a conformational change in the receptor, which generally results in the opening of an ion channel. When open, the ion channel is usually selective to one or more ions, primarily Na⁺, K⁺, Ca²⁺ or Cl⁻. Because of the close linkage between ligand
binding and ion channel opening, ionotropic receptors operate with a very short latency (a few milliseconds). Consequently, receptors of this type control fast synaptic transmission in the nervous system. However, when continuously exposed to ligand or transmitter, many ionotropic receptors exhibit rapid desensitization. This may be an adaptive response to limit postsynaptic response under conditions of high presynaptic activity.

The direct link to an ion channel, characteristic of the ionotropic receptors, is in contrast with the indirect action of metabotropic receptors, which commonly use second-messenger systems (see below). Members of the ionotropic family, including nicotinic receptors, GABA<sub>δ</sub> receptors, NMDA and non-NMDA receptors and the 5-HT3 receptor, are discussed in more detail below.

**GABA<sub>δ</sub> receptors**

GABA receptors are the major inhibitory receptor in the brain. The ionotropic GABA<sub>δ</sub> receptor is the most prevalent of the known GABA receptor subtypes and demonstrates a ubiquitous distribution throughout the brain.

The GABA<sub>δ</sub> receptor is composed of five subunits comprising an integral transmembrane ion channel. The channel is gated by the binding of two agonist (GABA) molecules. When open, the channel predominantly conducts chloride ions, resulting in hyperpolarization in the postsynaptic cell.

Several classes of subunits have been cloned. These receptor subunits have been labelled with the Greek letters α, β, γ, δ, ε, θ and ρ. GABA requires both α and β components in order to bind. GABA<sub>δ</sub> receptors are typically made up of two α and two β subunits among the five subunits, although the particular subunit composition often varies widely among brain regions and species. Furthermore, the existence of a large family of genes coding for diverse subunits (α<sub>1–6</sub>, β<sub>1–4</sub>, γ<sub>1–3</sub>, δ<sub>1–6</sub>, ε<sub>1–6</sub>, θ<sub>1–6</sub>, ρ<sub>1–3</sub>) adds to the structural diversity of the receptor. The existence of multiple GABA<sub>δ</sub> receptor subtypes differing in subunit composition, localization and functional properties underlies their role for fine-tuning of neuronal circuits.

Apart from the binding site for GABA, the receptor complex possesses sites of action for a number of clinically important drugs. These include the benzodiazepines, general anaesthetics and barbiturates. All of these drugs lack the side effects (e.g. sedation, amnesia) associated with the older drugs.

Hence, receptor-mediated transmission, an effect brought about by increasing the affinity of the receptor for glycine.
NMDA receptors play an important role in long-term potentiation (LTP), long-term depression and synaptic plasticity, all cellular mechanisms involved in learning and memory. Overactivation of the receptor can result in damage and eventually cell death through the process of excitotoxicity (see Box 30.2).

Like NMDA receptors, AMPA and kainate receptors also mediate fast excitatory transmission and are associated with channels that, when open, primarily conduct Na⁺ ions. Unlike NMDA receptors, however, these channels are not voltage-dependent, do not require the binding of a co-agonist and have a low permeability for Ca²⁺ ions.

As with NMDA receptors, the AMPA receptor assembly is also thought to be formed by a combination of four subunits termed GluR₁–₄, each transcribed by a different gene. Splicing in the extracellular N-terminal regions of the transmembrane domain of the transcript results in each of the four subunits having a ‘flip/flop’ variant. AMPA receptors are found throughout the CNS with a similar distribution to NMDA receptors. Receptor diversity is brought about in a region-dependent manner through tissue-specific subunit compositions. This receptor type undergoes dynamic insertion and removal from the neuronal membrane, an effect that is dependent on neuronal activity in the synapse. Activation of AMPA receptors is critical for depolarization and regulation of NMDA receptor signalling. The ion channel of the NMDA receptor is blocked by Mg²⁺ under resting conditions; activation of AMPA receptors results in partial depolarization of the cell membrane leading to extrusion of the Mg²⁺ ions.

In common with NMDA and AMPA receptors, kainate receptors are composed of four subunits. These receptors are comprised of combinations of GluR₁–₇ and KA₁–₂ subunits. Although classically described as having a distribution that was limited to specific regions, it is now evident that kainate receptors have a widespread distribution throughout the CNS, being located at both pre- and postsynaptic sites. Pharmacologically they are still difficult to distinguish from AMPA receptors, and very few kainate receptor-selective compounds have been identified. Key evidence is emerging to support a metabotropic-like action of some postsynaptic kainate receptors, suggesting a dual signalling mechanism for these receptors. This bimodal action is common with AMPA receptors but is completely distinct from the purely ionotropic NMDA receptors.

Nicotinic receptors
Nicotinic and muscarinic receptors, named after the selective exogenous agonists nicotine and muscarine respectively, are two types of receptor activated by the neurotransmitter acetylcholine. The muscarinic receptors are G-protein-coupled receptors and discussed below, while the nicotinic type are ionotropic receptors that mediate a fast synaptic transmission following agonist activation.

Nicotinic receptors are composed of five types of subunits (α, β, γ, δ, ε). These subunits are found in different combinations in the different types of nicotinic receptor. Muscle-type nicotinic receptors always contain two α subunits, which are critical in acetylcholine binding, and one of each of the other subunits. In contrast, neuronal nicotinic receptors contain only two types of subunit (α and β). However, the structural diversity of these receptors comes from the existence of diverse subunits – α₂–₇, β₆–10, and ε₂–₄.

The neuronal nicotinic receptors have been further divided into two main groups based on their sensitivity to the snake venom toxin α-bungarotoxin. The α-bungarotoxin-sensitive receptors are homomeric, containing the α₉ or α₁₀ subunit, and are found primarily in pre- and postsynaptic neurons and in developing muscle. The α-bungarotoxin-insensitive receptors are heteromeric, containing combinations of α₂–₇ and β₁–₄, and often modulate the release of other transmitters. The most common of the neuronal receptors is the α₂β₂ subtype, which is ubiquitously expressed and is able to bind most nicotinic agonists with high affinity. The stoichiometry of the individual receptor subtype determines its biophysical and functional properties as well as its pharmacological profile.

Nicotinic receptors are involved in a wide range of physiological processes. Muscle-type nicotinic receptors are localized at neuromuscular junctions, where an electrical impulse from a neuron to a muscle cell signals contraction and is responsible for muscle tone; as such, these receptors are targets for muscle relaxants. The many types of neuronal nicotinic receptors are located on both pre- and postsynaptic neurons in the CNS, where they are involved in complex brain function such as cognitive function, learning and memory, arousal, reward, motor control and analgesia.

5-HT₃ receptors
The 5-HT₃ receptor is unique among the currently known serotonergic receptor subtypes in that it belongs to the ionotropic family. 5-HT₃ receptors are similar in structure to other ionotropic receptors, and agonist activation opens a cation channel that results in depolarization.

They have a widespread distribution in the PNS, where the highest concentrations in the brain are found in the area postrema, entorhinal cortex, amygdala and certain brainstem nuclei.

5-HT₃ postsynaptic receptors mediate fast excitatory transmission. They are also found on presynaptic terminals, where they modulate neurotransmitter release. 5-HT₃ receptor antagonists, through blockade of receptors in the CNS and gastrointestinal tract, are currently used in the treatment of postoperative and cytotoxic drug nausea and emesis.

Metabotropic receptors
These are the most common class of receptors. Of the neurotransmitters discussed previously, all act at specific metabotropic receptors. The major subgroup of metabotropic receptors that is employed for all these neurotransmitters is
referred to as the G-protein-coupled receptors (GPCRs), short for guanine nucleotide diphosphate (GDP)-binding protein coupled receptors.

All have a characteristic structural design: seven hydrophobic (lipophilic) transmembrane regions within a single polypeptide chain, such that GPCRs wrap back and forth through the lipid cell membrane and are exposed to both the intracellular and extracellular surface of the cell. This gives rise to an alternative name for this group of receptors – the seven-transmembrane domain (7TM) receptors. The specific structure is determined by these hydrophobic polypeptide sequences alternating with hydrophilic regions that remain outside the membrane; these include a C-terminal region that resides within the intracellular cytoplasm and an N-terminal region that extends into the extracellular space. The extracellular domain of the GPCRs usually contains the neurotransmitter binding site, although some GPCRs bind ligands within the transmembrane of the receptor (Figure 30.7).

**Figure 30.7** Schematic representation of a G-protein-coupled receptor. There are seven transmembrane helices. COOH is the C-terminal (intracellular), and NH2, the X-terminal (extracellular).

G-proteins are the transduction components that are linked to GPCRs. G-proteins exist as a cluster of subunits (α and β). At rest, the α subunit is tightly bound to GDP. When a GPCR is activated (occupied by an agonist), it associates with its G-protein, initiating the exchange of GDP to guanine nucleotide triphosphate (GTP) by the α subunit, which in turn dissociates from the βγ subunit (Figure 30.8). The GTP-α and βγ subunits can then act with effector proteins, also known as secondary transduction components, inside the cell. These effectors include intracellular enzymes such as adenylyl cyclase and phospholipase C, ion channels and other classes of proteins. Termination of the signal mediated by the G-protein is usually brought about by the hydrolysis of GTP to GDP by GTPase, which the α subunit possesses intrinsically. This leads to a re-association of the α subunit with the βγ subunit and the cycle can begin again. As the action of metabotropic receptors is mediated by biochemical processes, the effect of receptor stimulation is relatively long-lasting, with a typical timescale of seconds to minutes. This is in contrast to the fast-acting ionotropic receptors discussed above.

The modulation of intracellular enzymes by G-protein activation results in the production of second messengers, signalling molecules that communicate the agonist-mediated stimulation to effector proteins within the intracellular domain of the cell. The specific Gz protein subunit that is activated often determines which effector the G-protein will influence. There are a large number of identified Gz proteins. Two of the most common are Gzq, and Gzq', which stimulate adenylyl cyclase and phospholipase C respectively, while Gzq results in adenylyl cyclase inhibition. However, these G protein subtypes can also directly influence neighbouring ion channels; thus, Gzq can open Ca2+ channels and Gzq inhibits these but opens K+ channels, with hyperpolarizing effects.

Adenylyl cyclase, when stimulated by the Gzq subunit, converts ATP to cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A (PKA), which phosphorylates intracellular proteins, many of which are enzymes of the cAMP protein kinase class.

Phospholipase C (PLC), when activated, cleaves the phospholipid phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol-1,4,5-triphosphate (IP3) and diacylglycerol (DAG). IP3 triggers the release of Ca2+ from intracellular stores, resulting in a rise in [Ca2+] within the cell and activation of
D2-like receptors in mediating dopaminergic neurotransmission and in the cerebral cortex, where it has a greater role than present in the basal ganglia and other subcortical structures. Dopamine D1-like receptors influence more neuronal systems than solely the postsynaptic site. Agonist action at presynaptic autoreceptors provides the means to regulate neurotransmitter synthesis and release; diffusion of dopamine to extrasynaptic D2-like receptors allows it to influence more neuronal systems than solely the postsynaptic cell.

Functional polymorphisms of the D2 and D3 receptor genes have been reported to be associated with aspects of antipsychotic drug effects, including response of positive symptoms and, for D3, tardive dyskinesia. Polymorphisms of the D4 receptor gene have been associated with various symptoms and, for D3, tardive dyskinesia. Polymorphisms in other regions of the brain, including the pituitary gland, where it is involved in the tonic inhibition of prolactin secretion. In the early 1990s, it was found to be one of a series of three structurally related gene products: D2, D3, and D4 receptors. The D3 receptors are also found in the striatum and notably the limbic structures. They may have a particular involvement as an autoreceptor in presynaptic control of dopamine release. D4 receptors, once thought to be overexpressed in schizophrenia and important in clozapine’s action, are no longer major targets for antipsychotic drug development. They are found in the cerebral cortex but in substantial concentrations only in the retina.

Dopamine D2-like receptors are found on postsynaptic membranes and at presynaptic sites. Agonist action at presynaptic autoreceptors provides the means to regulate further transmitter synthesis and release; diffusion of dopamine to extrasynaptic D2-like receptors allows it to influence more neuronal systems than solely the postsynaptic cell.

Functional polymorphisms of the D2 and D3 receptor genes have been reported to be associated with aspects of antipsychotic drug effects, including response of positive symptoms and, for D3, tardive dyskinesia. Polymorphisms of the D4 receptor gene have been associated with various personality traits, including novelty-seeking behaviour and obsessive–compulsive disorder.

Dopamine D1-like receptors
The dopamine D1 receptor is distributed more widely, being present in the basal ganglia and other subcortical structures and in the cerebral cortex, where it has a greater role than D2-like receptors in mediating dopaminergic neurotransmission. Thus, it is important in the action of dopamine on cognitive function in the frontal cortex. D1 receptors have a lower affinity for dopamine than D2 receptors and may be involved primarily in more classical synaptic neurotransmission; they do not contribute to presynaptic control mechanisms via autoreceptor function.

As with D2-like receptors, molecular biological studies identified heterogeneity of D1-like receptors; a second gene encoding a receptor structurally related to the D1 receptor was identified. This D5 receptor is the least understood of the five dopamine receptors; it is found to be important in the central control of blood pressure, but it is intriguing in being reported to be genetically associated with the risk of schizophrenia and attention deficit hyperactivity disorder (ADHD).

The D1 receptor has long been considered as having opposing effects to the D2 receptor, with an excitatory action primarily through stimulatory effects (via Gα1) on adenylate cyclase.

Adrenoceptors
Receptors to the neurotransmitter noradrenaline (and that also respond to adrenaline) were originally divided into α- and β-adrenergic receptor (adrenoceptor) subtypes, each of which have undergone further subdivision on the basis initially of pharmacological differences and, more recently, separate genes.

\( \alpha_1 \) Adrenoceptors
\( \alpha_1 \) Adrenoceptors within the CNS are found in high concentrations within the locus coeruleus, which contains the cell bodies for the ascending and descending noradrenergic neurons. Receptors are also found in the thalamic nuclei, amygdala and hippocampus, and cerebral cortex, corresponding to the regulation of mood and attention. The activation of \( \alpha_1 \) adrenoceptors generally results in an excitatory effect via Gα1-mediated pathways, but it is thought to reduce neuronal activity in the hippocampus. \( \alpha_1 \) Adrenoceptors may also influence brain functions via non-neuronal mechanisms, as glial cells can express \( \alpha_1 \) adrenoceptors. \( \alpha_1 \) Adrenoceptors can be subdivided into A/C, B and D subtypes, based upon their differential affinities to adrenergic compounds.

\( \alpha_2 \) Adrenoceptors
\( \alpha_2 \) Adrenoceptors are found as autoreceptors, present in noradrenergic regions of the hindbrain, and postsynaptic \( \alpha_2 \) receptors, as target receptors for noradrenergic projections, in the forebrain (cortex, limbic regions, hypothalamus) and in the spinal cord. Reflected by their widespread distribution, they are involved in many functions, including blood pressure regulation, analgesia and sedation, and temperature regulation. Furthermore, they appear to be involved in the regulation of behaviour, cognitive function and mood; the hyperactivity of brain monoaminergic neurons that occurs during stress can lead to psychopathologies such as anxiety disorders and depression. Three subtypes of the \( \alpha_2 \)
adrenoceptor have been characterized: A, B and C. Their cellular activity, typical of many auto- and heteroreceptors, is to decrease adenylate cyclase activity through coupling to G_i.

**β Adrenoceptors**

There are three classes of β adrenoceptor – 1, 2 and 3 – which have differing affinities for noradrenaline and adrenaline. The distribution of β adrenoceptor sites in the human brain has shown that β_1 receptors are found mostly in the striatum and globus pallidus, while β_2 sites are located predominating in the cerebellum and β_3 in the hippocampus, cerebral cortex and striatum. Within the CNS, noradrenergic transmission has long been implicated in stress-related changes in behaviour, and β adrenoceptor antagonists are used widely in anxiety disorders such as social phobia, post-traumatic stress disorder and panic disorder. All β adrenoceptors activate G_i to stimulate adenylate cyclase, although there is evidence of the involvement of other signalling pathways such as mitogen-activated protein kinases.

**5-Hydroxytryptamine receptors**

All but one subtype of the many 5-HT receptors are metabotropic GPCRs. Most important in the context of psychiatric disorders are the 5-HT1 and 5-HT2 receptor classes, although both 5-HT4 and 5-HT6 receptors are involved in CNS function and are potential targets for drug action.

**5-HT1 receptors**

5-HT1A receptors are found at postsynaptic sites in the hippocampus and cortex, where they mediate inhibitory effects of transmitter on adenylate cyclase. They are also present as autoreceptors on the cell bodies and dendrites of 5-HT neurons in the raphe nuclei, where they are important in regulating neuronal activity, notably in the context of antidepressant drug mechanisms. A polymorphism in the promoter region of the 5-HT1A receptor gene has been shown to influence control of gene expression by affecting the binding of a transcription factor; this functional polymorphism has been reported to be a risk factor for depression and suicide and to influence symptom response to antidepressant drugs.

5-HT1B and 1D receptors are primarily presynaptic autoreceptors providing an inhibitory control of 5-HT release, but they have been little studied in the context of psychopharmacology and mental illness.

**5-HT2A receptors**

5-HT2 receptors are excitatory postsynaptic receptors, working via stimulation of PLC. Of the two major subtypes, the 5-HT2A receptor is found in many regions of the brain, including the cortex and the basal ganglia, where, among other actions, they influence dopaminergic neurotransmission. They are thought to be involved in some of the beneficial effects of atypical antipsychotic drugs on cognitive and negative features of psychotic illness and in minimizing extrapyramidal side effects. Polymorphisms of the 5-HT2A receptor gene have been associated, albeit weakly, with a variety of psychiatric diagnoses and response to treatment, particularly relating to antidepressants and antipsychotics.

**5-HT2C receptors**

5-HT2C receptors, found in basal ganglia and limbic regions of the brain, may also contribute to effects of some of antipsychotic and antidepressant drugs. These receptors appear to inhibit dopaminergic activity, influencing motor function. They also have effects on food intake and other hormonally controlled behaviours, due to their presence in the hypothalamus. Functional polymorphisms of the 5-HT2C receptor gene are associated with several effects of psychiatric drug treatments, including the frequency of tardive dyskinesia and the severity of drug-induced weight gain.

**5-HT4 and 6 receptors**

5-HT4 and 5-HT6 receptors are excitatory receptors with effects mediated by stimulation of adenylate cyclase. 5-HT4 receptors are found in several subcortical regions, including basal ganglia and limbic systems, although pharmacological interest is mainly in their presence outside the CNS, in the gastrointestinal system in particular. Nevertheless, the receptors do appear to have effects on learning and memory and are a drug target for the treatment of cognitive and dementing disorders. 5-HT6 receptors, found in many cortical and subcortical brain regions, are closely involved in cognitive function through their ability to regulate cholinergic neurotransmission. They are also involved in anxiety, affect and control of body weight and are thus a drug target for the treatment of obesity and several neuropsychiatric indications.

**Muscarinic acetylcholine receptors**

The muscarinic acetylcholine-sensitive receptors have five subtypes, M1–M5. In terms of their activity, they can be divided into two groups: the M1, M3 and M5 subtypes with an excitatory action via stimulation of PLC, and the inhibitory M2 and M4 receptors, which act through adenylate cyclase. M1 receptors are found widely in brain tissue, where they are postsynaptic to cholinergic terminals in cortex and striatum and hence can influence cognitive and motor functions. M5 receptors are little studied, but one site at which they are found is on dopaminergic neurons and thus they can contribute to dopaminergic regulation.

The M2 and M4 subtypes function as inhibitory autoreceptors in the hippocampus and cortex (M2) and striatum (M4), where they may also have heteroreceptor effects. These muscarinic receptors are also involved in spinal cord function, notably nociception, and are also important outside the CNS. The M3 receptors are involved in stimulating secretion from various organs, including the salivary gland and the pancreatic beta cell, although they are also present in the CNS, where they can act as excitatory heteroreceptors. Several muscarinic receptor subtypes are found in smooth muscle, where they control gut motility and can
influence various aspects of genitourinary function, among other effects.

**Histamine receptors**
Of the four subtypes of the GPCR histamine receptors, H1–3 are most studied in terms of brain function. H1 and H2 are excitatory receptors found postsynaptic to histamine projections in many parts of the brain: H1 in the hypothalamus and limbic structures, and H2 in the basal ganglia and cortex. H1 receptors in particular are thought to mediate drug effects on sedation and food intake. H3 receptors are primarily presynaptic, acting as inhibitory autoreceptors and as heteroreceptors controlling the release of other transmitters, including acetylcholine.

**Metabotropic glutamate receptors**
The metabotropic glutamate receptors (mGluRs) are dimeric GPCRs comprised of eight subtypes (mGluR1–8) that fall into three main groups, based on sequence homology, signal transduction mechanism and receptor pharmacology. Group I receptors are mGluR1 and mGluR5, group II are mGluR2 and mGluR3, and group III contains mGluR4 and mGluR6–8. mGluRs are unusual in that they show no sequence homology with other GPCRs. They contain a large extracellular N-terminal tail that contains the glutamate binding site. Group I receptors stimulate Ca2+ release via IP3 formation, while group II and III receptors are negatively coupled to adenylate cyclase.

With the exception of mGluR6, which is confined to the retina, all other mGluRs are expressed in the mammalian CNS, where they are found in both neuronal and glial cells. Individual family members exhibit distinct spatial and temporal expression profiles. Neuronally expressed group I mGluRs are typically localized postsynaptically, whereas group II and III receptors are predominantly presynaptic, localized in axon terminals where they can regulate neurotransmitter release. The role played by mGluRs in glial cells is unclear.

Development of drugs with greater subtype specificity and enhanced bioavailability has identified important roles played by mGluRs in the CNS. For example, preclinical studies have provided evidence for the potential use of group II mGluR agonists in the treatment of schizophrenia. Furthermore, selective agents acting as allosteric antagonists at the mGluR6 subtype have demonstrated therapeutic potential for addiction.

**GABA\(_B\) receptors**
GABA\(_B\) receptors are metabotropic receptors that belong to the GPCR family. Although GABA\(_B\) receptors are found throughout the CNS, they are present at lower levels than the ionotropic GABA\(_A\) receptor. GABA\(_B\) receptors are located both pre- and postsynaptically. Presynaptically they inhibit the release of excitatory and inhibitory transmitters. The functional importance of postsynaptic GABA\(_B\) receptors is highlighted by segregation of GABA\(_A\) and GABA\(_B\) synapses in the mammalian brain. Two major GABA\(_B\) subunits have been identified, GABA\(_B\)\(_{1}\) and GABA\(_B\)\(_{2}\); these two subunits form heterodimers together, where GABA\(_B\)\(_{1}\) contains the ligand binding site and GABA\(_B\)\(_{2}\) mediates G-protein signalling through Go\(_i\), opening K+ channels postsynaptically and inhibiting Ca2+ channels at presynaptic sites.

Pharmacologically, GABA\(_B\) receptors can be distinguished from GABA\(_A\) receptors by their selective affinity for baclofen and the lack of affinity for muscimol and bicuculline. Baclofen is currently used as a muscle relaxant to decrease spasticity in a number of neurological disorders. Studies utilizing novel brain-penetrative GABA\(_B\) receptor antagonists also suggest a role for this receptor in the improvement of cognitive function.

**INTRODUCTORY PHARMACOLOGY OF THE MAJOR NEUROTRANSMITTER SYSTEMS**

Synaptic chemical neurotransmission is the essential process in communication between neurons and hence is a core mechanism in brain function. It is also the major point at which we can influence neuronal activity with drug treatment. Each of the presynaptic processes of transmitter synthesis, storage, release and reuptake, the metabolic removal of transmitter, and the various presynaptic and postsynaptic receptor sites is a potential, if not actual, target for neuro- and psychoactive drugs (Figure 30.9). In addition, there are other ways in which drugs may influence neuronal activity, including direct effects on ion channels, on second-messenger systems, on neuronal metabolism and on membrane structure.

One such mechanism, which is independent of a direct effect on neurotransmitter function but which has effects...
on neuronal activity, is that of the local anaesthetics. These drugs cross the neuronal cell membrane to block the voltage-gated Na⁺ channels that are so important for propagation of the nerve impulse. This mechanism is employed in some antiepileptic drugs, several of which are also effective in relieving symptoms of bipolar disorder. These anticonvulsants and mood stabilizers, including valproate, lamotrigine and carbamazepine, demonstrate a use-dependent blockade of Na⁺ channels relatively selective for rapidly firing neurons. Some anticonvulsants are also inhibitors of Ca²⁺ channels, resulting in effects associated with diminished neurotransmitter release.

**Neurotransmitter synthesis**

Neurotransmitter synthesis is the initial process open to pharmacological intervention. Although inhibition of rate-determining enzymes is an effective mechanism of diminishing transmitter in experimental pharmacology, enhancement of transmitter synthesis by supplementation with precursor compounds has been an effective and clinically valuable approach. The key example here is L-dopa. Shortly after the identification of dopamine as a neurotransmitter in the basal ganglia, a region important in the control of motor function, a profound deficit of dopamine was found in the striatum of patients dying from Parkinson’s disease. Providing L-dopa, which bypassed the rate-determining step of tyrosine hydroxylation, increased the availability of dopamine and relieved the motor symptoms. Co-administration of a peripherally acting dopa decarboxylase inhibitor was found to minimize the peripheral side effects of L-dopa at the same time as increasing its availability to the brain. This drug combination has been the mainstay of Parkinson’s disease treatment for several decades.

Supplementation of serotonin synthesis by treatment with tryptophan is another example of effective enhancement of transmitter function by a precursor compound. This takes advantage of the fact that tryptophan hydroxylase is not saturated, so the availability of tryptophan from the blood is the rate-limiting factor. Tryptophan has been found to be effective in the treatment of some patients with depression. Tryptophan depletion – administering an amino acid mixture without tryptophan but containing large neutral amino acids that compete with tryptophan at the blood–brain barrier has been a way of decreasing serotonin synthesis in humans in the study of the role of serotonin function in mood and cognition.

Pharmacological manipulation of the availability or synthesis of excitatory amino acid neurotransmitters is not easily undertaken and could potentially have effects on other aspects of cell function, given the essential role of glutamate in non-transmitter aspects of cell function. However, synthesis of acetylcholine can be influenced by pharmacological effects on its precursor; acetylcholine concentrations can increase in response to administration of quantities of choline or choline-containing lipids, an approach that has been explored in the past for the treatment of dementia.

**Neurotransmitter storage**

Depletion of vesicular stores of neurotransmitter can have a profound effect on neuronal, and hence brain, function. This is seen with reserpine, a drug used for centuries as an antihypertensive and antipsychotic by blocking the vesicular monoamine transporter. This results in depletion of vesicular stores of catecholamines and serotonin and consequently substantial reduction in the synaptic activity of these neurotransmitters. Side effects of reserpine include, not surprisingly, parkinsonism, relating to its effect on dopamine, and depression, relating primarily to its effects on serotonin. Tetrabenazine, used in the treatment of dyskinetic motor disorders such as Huntington’s disease, has similar action in inhibiting the vesicular monoamine transporter.

One of the actions of the dietary monoamine tyramine is to displace catecholamines from vesicular stores, resulting in the ‘cheese effect’ associated with MAO inhibition (see above). Amphetamines (see below) also displace endogenous transmitter from catecholamine-containing (and sometimes serotonin-containing) vesicles, with methylphenidate showing some greater selectivity for central dopaminergic terminals.

**Neurotransmitter release and reuptake**

Stimulant drugs such as cocaine and amphetamine, and amphetamine-related drugs such as methylphenidate and methylenedioxymethamphetamine (MDMA, ecstasy), also have effects on monoamine neurotransmitter release and reuptake. The effects of these and many other drugs in inducing dependence is associated with an increase in the activity of dopamine in the nucleus accumbens, a region involved in reward mechanisms. The increase in dopamine release in this and other areas by the stimulant drugs is brought about by an enhancement of dopamine release or a blockade of its reuptake.

The differences in action between these stimulant drugs reflect their differences in mechanism and neurotransmitter selectivity. Cocaine is an effective inhibitor of the neuronal dopamine transporter and, to a lesser extent, serotonin and noradrenaline transporters. Amphetamine can also interact with the dopamine and noradrenaline transporters but brings about a reversal of their transport processes, enabling cytosolic catecholamine to be transported out of the cell, in essence enhancing transmitter release.

The drug of abuse MDMA appears primarily to involve 5-HT systems in its action. Although it does appear to have amphetamine-like effects on dopamine release, MDMA enhances serotonin release, inhibition of reuptake through the serotonin transporter and depletion of stores, partly
through effects on 5-HT synthesis by inhibition of tryptophan hydroxylase.

The major drugs influencing monoamine neurotransmitter reuptake are the antidepressants. The tricyclic antidepressants (TCAs) vary in selectivity between having primarily noradrenergic effects (e.g. desipramine) and those with relatively greater effects on serotonin reuptake (e.g. amitriptyline). However, the TCAs have wide and variable effects on other systems, including serotonin, muscarinic, alpha-adrenergic and histamine receptors, many of which may contribute to unwanted side effects. The selective serotonin reuptake inhibitor (SSRI) antidepressants primarily inhibit the serotonin transporter, with generally fewer effects on other systems, resulting in an improved side-effect profile. Effects on noradrenaline reuptake have been reintroduced more recently with the selective noradrenaline reuptake inhibitor (NRI) reboxetine, and selective serotonin and noradrenaline reuptake inhibitors (SNRIs) such as venlafaxine.

Tiagabine, an antiepileptic drug that has been proposed, like several other antiepileptic drugs, to have efficacy in bipolar disorder, inhibits GABA reuptake through a neuronal transporter, resulting in increased extraneuronal concentrations of transmitter.

**Neurotransmitter metabolism**

The removal of neurotransmitters by metabolizing enzymes is a process that provides further pharmacological opportunities to influence synaptic activity – inhibition of neurotransmitter breakdown is likely to result in its increased availability for release into the synapse. MAO, being the only enzyme for metabolic removal of serotonin and important for catecholamine metabolism, is a valuable target to enhance neurotransmitter activity. Inhibition of this enzyme (or enzymes – there are two forms of the enzyme, A and B, with different substrate selectivity) is the mechanism of action of several antidepressant drugs. These MAO inhibitors include the older and non-specific ‘suicide’ (i.e. irreversible) inhibitors phenelzine and tranylcypromine, which are susceptible to the ‘cheese effect’ (see above), as well as the newer, reversible and hence safer MAO type A inhibitor moclobemide. MAO-A is thus the target for antidepressant action, since it metabolizes 5-HT and noradrenaline. MAO-B inhibition with selegiline is an adjunctive treatment for Parkinson’s disease; it enhances the efficacy of l-dopa by inhibiting dopamine breakdown.

COMT inhibition is not used routinely in psychiatry, although it has been proposed as a potential approach to alleviate cognitive deficits in, for example, schizophrenia. However, COMT inhibitors are used in the adjunctive treatment of Parkinson’s disease, where they inhibit peripheral breakdown of l-dopa.

Acetylcholine neurotransmission can be enhanced by inhibition of the enzyme responsible for its synaptic removal, AChE. This can be beneficial in the treatment of Alzheimer’s disease with drugs such as donepezil or galantamine, which are reversible inhibitors of AChE. However, the organophosphates that comprise many insecticides and the mustard nerve gases are inhibitors of AChE that can cause profound toxicity and fatality by reaction with the enzyme and subsequent uncontrolled accumulation of synaptic acetylcholine.

Many anti-epileptic drugs focus on increasing GABA function. One approach has been to inhibit GABA metabolism; vigabatrin blocks the breakdown of GABA by GABA transaminase to increase synaptic availability.

**RECEPTOR PHARMACOLOGY**

A comprehensive review of the role of neurotransmitter receptors in neuropharmacology is beyond the scope of this chapter. However, we have indicated below some relevant receptor-mediated effects of common drugs and have included some future prospects for improved treatments through novel receptor ligands.

**Dopamine receptors**

The D1-like (D1 and D5) receptors are very similar in structure and pharmacology, and few compounds can distinguish between them as yet. Ligands selective for D1-like receptors are primarily used scientifically, agonists producing an increasing behavioural responsiveness as shown by stimulatory effects on activity and finer motor movements. Conversely, D1-like receptor antagonists are potent inhibitors of these dopamine-mediated behaviours. Neither agonist nor antagonist classes of D1 receptor ligands are used clinically. The D5 receptor, in contrast to the D1 receptor, can occur directly coupled to the GABA<sub>A</sub> receptor, enabling functional interactions; however, there are as yet no selective D5 ligands.

Agonism of dopamine D2-like receptors is the major mode of action of the antipsychotic drugs, resulting in a reduction in the positive psychotic symptoms in many patients, although this mechanism appears to have no great effect on the negative and cognitive features of schizophrenia. This action at striatal D2 receptors is also responsible for the acute extrapyramidal side effects, although various other pharmacological effects of the drugs, including partial agonism in the case of aripiprazole, are used to minimize the incidence of these side effects. The second-generation atypical antipsychotics such as risperidone, olanzapine and quetiapine have effects at many other receptors but are all antagonists of D2-like receptors, albeit with different relative affinities at the D2, D3 and D4 subtypes. Thus, amisulpride and clozapine have higher affinities for D3 and D4, respectively, than for the D2 receptor subtype. Several phenothiazine antagonists for the dopamine D2 receptor, and other antipsychotics, are also
used for the prevention and treatment of iatrogenic nausea and vomiting and cytotoxic and radiation sickness.

Apopomorphine is a strong dopamine receptor agonist that, as with non-selective ergot-derived D2 agonists such as bromocriptine and cabergoline, can be used for the treatment of Parkinson’s disease, often as an adjunct to L-dopa. D2-agonists such as bromocriptine are also effective in treating the consequences of hyperprolactinaemia, such as hypogonadism and galactorrhoea.

**Adrenoceptors**

Many of the drugs interacting with the β adrenoceptor are widely used pharmaceutically for peripheral conditions: β adrenoceptor agonists including the non-selective isoprenaline and the β1-selective dobutamine treat a variety of cardiac disorders, while β2-selective agonists such as salbutamol are spasmylytics and widely used in asthma. β Adrenoceptor antagonists, β-blockers, such as propranolol (non-selective) and atenolol (β1-selective antagonist), are used for the treatment of hypertension and angina, but they have central effects on anxiety by reducing the physiological symptoms (tremor, sweating, clammy palms) of the fight/flight response. More recently, β2-specific agonists have become of interest in the potential treatment of anxiety and depression, after disappointing initial studies as potential anti-obesity drugs, which reflects their action in enhancing lipolysis.

α Adrenoceptor pharmaceuticals also have peripheral effects, focusing primarily on smooth muscle control; α1 agonists are vasoconstrictor sympathomimetics. Centrally acting α1 antagonists include phentolamine, which can affect the pain response, and prazosin, which as well as being antihypertensive and useful in urinary disturbances has been reported to reduce sleep disturbances in post-traumatic stress disorder. It is the α1 antagonism of some antidepressant and antipsychotic drugs that underlies their side effect of postural hypotension.

Clonidine is a α2-adrenergic agonist used in the treatment of hypertension and migraine; it may also be useful in controlling neuropathic pain. In addition, it has wide-ranging effects on sleep: increasing sedation, reducing insomnia and minimizing night sweats. Moreover, it is also used as adjunct therapy in Tourette’s syndrome and attention deficit disorder to control hyperactivity, impulsivity and tics. Antagonism of α1 receptors is an effect of the antidepressants mianserin and mirtazapine; by blocking these presynaptic auto- and heteroreceptors, these drugs stimulate release of noradrenaline and 5-HT. The α2 antagonist idazoxan has been investigated scientifically as adjunct therapy with antipsychotics in schizophrenia, where it improves symptom response in previously poorly responding patients. This indicates that the α2 antagonism of clozapine might contribute to its particular efficacy in this patient group. The naturally occurring α2-adrenergic antagonist yohimbine has been reported to be useful in the treatment of erectile dysfunction.

**5-HT receptors**

The pharmacology of 5-HT receptors is relevant to treatment of the majority of psychiatric disorders. Depression, anxiety, bipolar disorder and schizophrenia all have 5-HT implicated in mechanisms of therapeutic drug action, if not in their pathology. Many psychiatric drugs have effects at 5-HT receptors, and those that do not, such as the antidepressants that act on transport processes, may still bring about therapeutic effects via 5-HT receptor-mediated effects.

**5-HT1A receptors**

One therapeutic mechanism with such indirect receptor regulation involves the 5HT1A autoreceptor. The action of SSRIs in blocking 5-HT reuptake into neurons results in increased extraneuronal 5-HT around the somatodendritic sites of the regulatory 5-HT1A receptors. The agonist effect on these inhibitory autoreceptors results initially in a compensatory decrease in neuronal firing, followed by an eventual down-regulation of receptor density and a return to normal, or elevated, receptor-stimulated neuronal activity. This is thought to account for the delay in clinical response to antidepressant treatment. A polymorphism (−1019G/C) within the 5-HT1A gene influences this receptor regulation, resulting in a diminished neurochemical and hence clinical response in some individuals.

The 5-HT1A receptor is a target for some anxiolytic drugs, such as buspirone, a partial 5-HT1A receptor agonist. 5-HT1A partial agonist activity is also a component of the pharmacological profile of some antipsychotic drugs, including aripiprazole, quetiapine and clozapine, although whether this contributes to their clinical effects on, for example, depressive symptoms remains unclear.

**5-HT2 receptors**

The 5-HT2A receptor is implicated in both antidepressant effects and antipsychotic action. A consequence of most antidepressant treatments is a decrease in the numbers of postsynaptic 5-HT2A receptors, despite an increase in neuronal sensitivity to 5-HT. More direct effects on 5-HT2A receptors occur with many antipsychotics, particularly the atypical drugs. It is thought that their antagonism of 5-HT2A receptors may contribute to diminished extrapyramidal side effects, as striatal 5-HT2A antagonism results in increased dopamine release. It is also suggested that the same mechanism in the frontal cortex might underlie an improved response of negative schizophrenia symptoms to treatment with some atypical drugs, although support for this relationship between pharmacology and clinical response is unimpressive.

Several antidepressants and antipsychotics have an antagonist action at the related 5-HT2C receptor, including mirtazapine, clozapine and olanzapine. Whether this action might contribute to some beneficial effects on symptoms is unclear, although there is a theoretical basis for it providing
some protective effect against antipsychotic-induced extrapyramidal side effects. However, the role of the 5-HT2C receptor in controlling food intake is likely to be important in the substantial effects of 5-HT2C antagonists on weight gain.

**5-HT6 receptors**

Drugs acting on 5-HT6 receptors can have positive effects on learning and memory, an effect mediated through their regulation of glutamatergic and cholinergic activity. The high affinity of a wide range of psychiatric drugs, including several antipsychotics and antidepressants, for the 5-HT6 receptor, together with its almost exclusive expression in the CNS, being abundant in limbic and cortical regions, raises the possibility that such compounds could be developed as adjunct therapeutics with existing treatments to improve learning and memory deficits in Alzheimer’s disease, schizophrenia and depression. A preliminary report that the cognitive enhancing properties of a 5-HT6 receptor antagonist extends to patients with Alzheimer’s disease further highlights the therapeutic promise of this receptor subtype.

**Acetylcholine receptors**

Both muscarinic and nicotinic acetylcholine receptor families are involved in a number of physiological functions, including cognition, reward, motor activity and analgesia, and have been implicated in pathological conditions such as Alzheimer’s disease, Parkinson’s disease, some forms of epilepsy, depression, autism and schizophrenia.

Muscarinic receptors in the basal ganglia mediate action of anticholinergic drugs, including procyclidine and benzatropine, used in the treatment of iatrogenic parkinsonism and other acute extrapyramidal side effects. The side effects of these drugs limit their use, however. Muscarinic antagonists can suppress M3 receptor-mediated salivation, causing dry mouth, can decrease gut motility, causing constipation, and can inhibit cholinergic neurotransmission in the cortex and hippocampus, resulting in cognitive disturbances. Several antipsychotics, notably clozapine, have antimuscarinic effects, as do some of the older tricyclic antidepressants.

Agonist action at postsynaptic muscarinic receptors and selective antagonism at the M2 autoreceptor provide potential targets for treatment of cognitive dysfunction in Alzheimer’s disease and other disorders, including schizophrenia. Nicotinic receptors too represent a target for cognition: nicotine in cigarettes or patches reportedly improves cognition in Alzheimer’s disease. The α4β2 subtype has a selective partial agonist, varenicline, used to support smoking cessation, while drugs acting at the α7 receptor are under investigation for treating cognitive disturbances in schizophrenia.

**GABA receptors**

GABA<sub>A</sub> receptors contain a number of recognition sites for molecules other than GABA. A substantial number of centrally acting and clinically active drugs, including the benzodiazepines, barbiturates, steroids and anaesthetics, can modulate the activity of GABA<sub>A</sub> receptors and thereby affect the inhibitory neurotransmission mediated by GABA.

Reflecting the ubiquitous distribution of GABA<sub>A</sub> receptors, benzodiazepines can be muscle-relaxant, anticonvulsant, sedative and anxiolytic drugs. These drugs, and some non-benzodiazepine drugs such as zolpidem, appear to exert their effects by selectively potentiating the effects of GABA on the GABA<sub>A</sub> receptor. However, not all GABA<sub>A</sub> receptors are affected by benzodiazepines, because of the requirement of a particular α subunit.

The barbiturates exert their modulatory role on the GABA<sub>A</sub> receptor through increasing the duration of channel opening, but they have no effect on opening frequency or channel conductance.

Neuroactive steroids are potent positive allosteric modulators of GABA<sub>A</sub> receptors with sedative, anxiolytic and anticonvulsant properties. There is evidence that the δ subunit is involved in modulating the effect of neurosteroids, since their action is reduced in mice lacking the δ subunit.

GABA<sub>A</sub> receptors in particular have long been implicated in mediating at least some of the pharmacological actions of alcohol. More recently, a specific and pharmacologically relevant alcohol binding site on a subtype of GABA<sub>A</sub> receptor (α<sub>1</sub>β<sub>2</sub>δ) has been identified. A putative behavioural alcohol antagonist, Ro15–4513, at this binding site has been identified that diminishes the actions of low to moderate concentrations of alcohol in potentiating GABA-induced Cl<sup>−</sup> currents.

Picrotoxin is a pro-convulsant alkaloid that noncompetitively blocks the GABA-gated chloride flux by binding to a site located within the ion channel. The major agonists, antagonists and modulators are summarized in Table 30.2. It is clear from the above that we are only starting to understand the complexity of the GABA<sub>A</sub> receptor and considerable work is needed to further understand the role played by the different subtypes in brain function. However, the development of drugs that are more selective for various subtypes may offer much in improved clinical specificity with reduced adverse effects.

Baclofen is a GABA analogue that was originally tested as a GABA-like substance that might prove useful in controlling epilepsy and other convulsive states. It was subsequently found that baclofen showed very little postsynaptic effect in the brain and the actions of the drug were not blocked by bicuculline. This led to the discovery, in the early 1990s, of the GABA<sub>B</sub> receptor. Activation of presynaptic GABA<sub>B</sub> receptors with baclofen decreases Ca<sup>2+</sup> conductance and reduces neurotransmitter release. Baclofen has clinical efficacy as an antispasticity agent and may have analgesic properties in certain types of pain, such as trigeminal neuralgia.

The drug of abuse and anti-narcolepsy agent sodium oxybate (γ-hydroxybutyrate, GHB) is also thought to act via GABA<sub>B</sub> receptors. Brain-penetrative competitive antago-
nists at GABA<sub>B</sub> receptors have been developed in the hope of better elucidating the role played by this receptor in the brain. Studies suggest that GABA<sub>B</sub> antagonists may suppress absence epilepsy seizures, improve cognitive impairment and even act as neuroprotective agents.

**Glutamate receptors**

Due to the multiple combinations of individual subunits, a feature characteristic of many ionotropic receptors, NMDA receptors exist in many different subtypes. However, compounds that can usefully discriminate between these multiple subtypes have still to evolve. The agonist homoquinolinic acid, a conformationally constrained analogue of glutamate, shows higher affinity for NMDA receptors that contain the NR2B subunit, thus displaying some subtype selectivity.

Similar to GABA<sub>A</sub> receptors, various modulatory sites on the NMDA receptor offer several opportunities for pharmacological interaction. One example is the glycine co-agonist site, which increases the affinity of the NMDA receptor for glutamate. This potentiation of NMDA receptor function by glycine or glycine agonists (e.g. D-serine, cycloserine) has been shown in clinical trials to be a useful approach to enhancing symptom response in the treatment of schizophrenia, in which an NMDA receptor hypofunction is implicated.

Activation of the receptor can also be modulated by the binding of different polyamines. Agonists of the polyamine modulatory site, specific for the NR<sub>2B</sub> subunit, exhibit neuroprotective action in a number of biochemical models of ischaemia and trauma. The dissociative anaesthetics ketamine and phencyclidine belong to a group of NMDA receptor antagonists that act by binding to the pore of the open (activated) NMDA receptor channel and are thus non-competitive antagonists. However, none of these compounds shows subunit selectivity.

A number of AMPA receptor positive allosteric modulators, drugs that do not lead to receptor desensitization and do not activate the receptor when applied alone, have been identified. These AMPA receptor potentiators have demonstrated efficacy when explored in rodent models of cognition and are now entering clinical trials.

Initially the utility of drugs acting at the mGluRs as in vivo tools has been restricted by their limited CNS bioavailability following systemic administration. More recently, mGluRs have emerged as potential new drug targets for treatment of a range of CNS disorders. mGlu2/3 receptor agonists are reported to reduce panic anxiety in panic disorder, and animal and clinical studies also provide strong evidence that agonists at the same receptors have robust efficacy in treating positive and negative symptoms in patients with schizophrenia.

### NEUROPEPTIDES

A neuropeptide is a short neuroactive protein of generally fewer than 100 amino acids. Neuropeptide transmitters are synthesized differently from classical neurotransmitters: instead of being produced enzymatically in the neuronal terminal from common precursor compounds, peptide neurotransmitters are synthesized from precursor proteins produced from specific genes. In most cases, these gene products give rise to a prepeptide, which is then cleaved by peptidase enzymes to form the peptide neurotransmitter. This means that increases in production of neuropeptide require an increase in gene expression, a slow process that can take hours or even days. This limiting step means that an increase in neuronal demand for peptide synthesis cannot induce a rapid response.

Peptides are stored in large dense-core vesicles within neurons. These neurons very often contain both a conventional neurotransmitter and one or more neuropeptides; that is, they coexist within a neuron. Release of the large vesicles, containing the neuropeptide, and the small vesicles, containing the neurotransmitter, is regulated differentially in that peptides are typically released at a high neuronal firing frequency, while neurotransmitters are released at a low frequency.

These differences between the classical and neuropeptide transmitters have led some to argue that the neuropeptides do not always fulfill the criteria defining a neurotransmitter, and they should be better described as neuromodulators.

---

GABA, γ-aminobutyric acid.
Thus, they may not always have effects alone on postsynaptic cells but require the action of a classical transmitter, which is enhanced or, in some cases, suppressed by neuropeptide action. This modulatory action thus differs from the direct effect often shown by classical transmitters, although in complex and dynamic neuronal circuits these transmitters are often modulating other neurotransmitter effects. The semantic differences between neuromodulator and neurotransmitter are arbitrary; where neuropeptides act within synapses, we shall refer to them as neurotransmitters. However, it should be said that several neuropeptides have local or systemic hormonal activity, often in addition to neurotransmitter action. This too can be seen for classical transmitters such as noradrenaline, 5-HT and histamine, however.

Peptides bind with high specificity and high affinity to their receptors, which are generally G-protein-coupled or metabotropic receptors. Activation of the peptide receptors modulates the responsiveness of the postsynaptic membrane to the action of classical neurotransmitters, and hence many classical neurotransmitters localize with neuropeptides in the brain, for example dopamine with neotensin (NT) or CCK. Moreover, many neuropeptides may act independently as neurotransmitters.

Unlike classical neurotransmitters, synaptic inactivation of neuropeptides is generally performed by enzymes, and there is no active reuptake process. Released neuropeptide transmitter molecules diffuse away from the synapse and are cleaved by peptidases, which may be cytosolic or membrane-bound. These enzymes are not specific to a single peptide neurotransmitter but instead show specificity for certain types of amino acids pairing, the building blocks of peptide transmitters. However, this ‘inactivation’ is not always all as it seems. Certain peptide fragments derived from enzymatic activation can also be biologically active.

**Cholecystokinin**

CCK is a peptide neurotransmitter that was originally isolated from the gut but that is distributed extensively and abundantly within the central nervous system. CCK is co-localized with dopamine in a significant subset of mesencephalic neurons originating within the ventral tegmental area and terminating in the nucleus accumbens. Neurochemical and behavioural studies demonstrate that CCK has significant modulatory effects on dopamine transmission within the mesolimbic system. In addition, CCK is thought to regulate the functional activity of postsynaptic GABAergic medium-sized spiny neurons in the nucleus accumbens.

CCK binds to two different subtypes of receptors, which are both GPCRs and display approximately 50 per cent homology. The CCK, receptor is found mainly in the gut but also in several brain nuclei, such as the interpeduncular nucleus, area postrema and nucleus of the solitary tract. Conversely, the CCK1 receptor is distributed widely throughout the CNS and is found in the olfactory bulbs and tubercle, medial frontal and cingulate cortices, frontal and frontotoparial cortices, retrosplenial cortex, nucleus accumbens, striatum and hippocampus. The CCK1 receptor binds CCK-8 and the peptide gastrin at equal potency.

CCK’s actions include the induction of anxiety-related behaviour in humans and experimental animals, an action via stimulation of CCK receptors. Antagonists of this receptor display intrinsic anxiolytic properties. Conversely, CCK produces a reduction in food intake, via the hindbrain CCK1 receptors, while also inhibiting expression of orexigenic peptides in the hypothalamus.

CCK is found in various forms, dependent on the numbers of amino acids (e.g. CCK-58, sulphated CCK-8 (CCK-8S) and CCK-4, where CCK-8S is the major transmitter form), and their synthesis is reliant on post-translational modification of the CCK gene product preprocholecystokinin. The CCK-8 inactivating enzyme is a serine peptidase, tripeptidyl peptidase II.

**Neurotensin**

NT is a 13-amino-acid peptide. NT immunoreactive neurons and terminal systems and receptors are found in many parts of the brain, including the basal and anterior hypothalamus, nucleus accumbens, septum and several brainstem nuclei. Its actions include analgesia, hypothermia and release of growth hormone and prolactin. NT is present in midbrain dopaminergic neurons of the mesolimbic, mesocortical and nigrostriatal dopaminergic pathways.

There are currently three characterized receptors for NT in the CNS. NTS1 and NTS2 receptors are both GPCRs and found on neurons and glia within the CNS. NTS1 receptors have high affinity for NT, but NTS2 receptors have lower affinity and the role of NT at this receptor is unclear. The NTS3 receptor is a type I amino acid receptor single-transmembrane-spanning receptor and is found in adipocytes as well as neurons and glia.

Most studies on the role played by NT in the CNS indicate clearly that NTS1 regulates dopaminergic function in both the nucleus accumbens and dorsal striatum by reducing function of the D2 autoreceptor and the activity of postsynaptic D2 receptors located on glutamate terminals. The influence of NT on dopaminergic transmission in nigrostriatal and mesocortical pathways suggests that NT plays a role in the pathophysiology of several CNS disorders, including Parkinson’s disease, schizophrenia and addiction.

NT is synthesized as part of a 170-amino-acid precursor protein that also contains the related hexapeptide neurenomin N. It is degraded by a number of peptidases, leading to the formation of biologically inactive fragments.

**Substance P**

The 11-amino-acid polypeptide substance P (SP) coexists with the neurotransmitter serotonin in bulbospinal and
dorsal raphe neurons, and with GABA and dynorphin in the striatal medium spiny neurons. In the CNS, SP has been associated with the regulation of anxiety and stress, respiratory rhythm, nausea and vomiting, and particularly pain and nociception. Reducing levels of SP with compounds such as capsaicin produces an analgesic and anti-inflammatory effect.

SP and its GPCR, the NK₁ receptor, are believed to play an important role in the modulation of stress-related, affective and anxious behaviour. Both peptide and receptor are found in brain limbic regions such as the amygdala and hippocampus, areas associated with stress and affective response, and show significant spatial overlap with neurotransmitters such as serotonin and noradrenaline. Aversive and stressful stimuli have been shown to change SP brain tissue content and NK₁ receptor binding, while an increase in intracerebral SP concentration produces anxiogenic-like responses in various behavioural tasks. For this reason, NK₁ receptor antagonists are currently being developed for the treatment of anxiety and depressive disorders.

SP is one of the tachykinin peptides, which include neurokinin A (NKA) and neurokinin B (NKB), all synthesized from the same preprotachykinin gene. SP can be degraded by a number of peptidases, including neutral endopeptidase and angiotensin-converting enzyme (ACE).

**Opioid neuropeptides**

The opioid neuropeptides include the dynorphins, encephalins, endomorphins and nociceptin/orphanin FQ. They bind to a series of GPCRs termed the opioid receptors, which also bind opiate drugs such as morphine as ligands.

The dynorphins, dynorphin A, dynorphin B and α/β-neoendorphin, arise from the precursor protein prodynorphin. Within the CNS, they have the highest concentrations in the hypothalamus, medulla, pons, midbrain and spinal cord. Moreover, dynorphin and their G-protein-coupled κ-opioid receptor are highly expressed in dopaminergic-rich regions: the prefrontal corticostriatal loop, within the prefrontal cortex, nucleus accumbens and dorsal striatum, and the ventral tegmental area and substantia nigra pars reticulata. This localization is consistent with neurochemical data indicating that dynorphin and κ-opioid receptors regulate the activity of mesoaccumbal, mesocortical and nigrostriatal dopamine and GABAergic neurons, and regulate extracellular dopamine levels. In addition, dynorphins are important in the pain response and the maintenance of homeostatic control. The dynorphins arise from the precursor protein prodynorphin.

The encephalins, Met⁵-encephalin and Leu⁵-encephalin, are two pentapeptides whose sequences differ only in their C-terminal amino acid. Within the basal ganglia, encephalins play an important co-transmitter role in the GABAergic striatal output pathway projecting to the external segment of the globus pallidus. These striatopallidal medium spiny neurons also co-express dopamine D2 receptors. The encephalins bind to the μ and δ classes of opioid receptors. μ-Receptors are found in the thalamus, cortex and periaqueductal grey matter, where they modulate analgesia, respiratory depression and euphoria. δ-Receptors are found in the amygdala, pontine nuclei and cortical regions, where they modulate analgesia and antidepressant effects. Both receptors are also involved in drug dependence.

Exogenous opioids include the natural opiates such as morphine and codeine, and synthetic opiates such as oxycodone, diacetylmorphine (heroin), methadone and pethidine. Repeated exposure to increasing dosages of opioids can lead to opioid tolerance (the need to take higher dosages of drugs in order to achieve the same opioid effect due to receptor sensitization) and drug dependence (susceptibility to withdrawal symptoms). These effects involve the mesolimbic reward system – opioid tolerance reduces the ventral tegmental area’s release of dopamine from an important brain system underlying craving and compulsive drug use. The locus coeruleus is involved in the expression of opiate physical dependence and withdrawal involving the neurotransmitter noradrenaline.

**Corticotropin-releasing hormone**

Corticotropin-releasing hormone (CRH) is an important neuropeptide that is highly involved in the stress response. The regions of the hypothalamic paraventricular nucleus (PVN) with CRH neurons, the medial and periventricular nuclei, receive heavy projections of catecholaminergic fibres from the brainstem nuclei. In addition to containing noradrenaline, these catecholamine cell groups projecting to the PVN also express glutamate and neuropeptide Y (NPY). These catecholamines are suggested to have stimulatory effects on both the release and the production of hypophysiotrophic CRH, while co-transmitters of the catecholaminergic afferents that innervate CRH neurons, including NPY and glutamate, may also have profound regulatory roles over hypophysiotrophic neurons.

In response to stress, CRH is produced by neuroendocrine cells in the PVN of the hypothalamus and is released from these neurons into the primary capillary plexus of the hypothalamo-hypophyseal portal system, a system of blood vessels that links the hypothalamus and the anterior pituitary. At the pituitary, CRH stimulates the release of the stress hormone adrenocorticotropic hormone (ACTH). ACTH then acts on the adrenal glands to produce glucocorticoid hormones, mainly cortisol. In a negative-feedback cycle, glucocorticoids act on the hypothalamus and pituitary to suppress CRH and ACTH production. This pathway, shown in Figure 30.10, is termed the hypothalamic–pituitary–adrenal (HPA) axis and is a major neuroendocrine system that controls reactions to stress. The HPA axis regulates many body processes, including mood, digestion, the immune system, sexuality and homeostatic control such as energy storage and use.

The HPA axis seems to have many cross-links with the
Fig. 30.10 Schematic representation of the hypothalamic–pituitary–adrenal (HPA) axis. In response to stress, corticotropin-releasing hormone (CRH) is produced by neuroendocrine cells in the paraventricular nucleus of the hypothalamus and is released from these neurons into a system of blood vessels that links the hypothalamus and the anterior pituitary. Here, CRH stimulates the release of adrenocorticotropic hormone (ACTH). ACTH then acts on the adrenal glands to produce glucocorticoid hormones, mainly cortisol. In a negative-feedback cycle, glucocorticoids act back on the hypothalamus and pituitary to suppress CRH and ACTH production.

neuroendocrine pathways that homeostatically regulate food intake: CRH-containing neurons are located in the PVN of the hypothalamus, the major centre in the control of feeding behaviour; CRH inhibits feeding in rats; CRH is suggested to be an important intermediate in the anorectic effects of leptin; and the hypophagic effect of central CRH may result in part from inhibitory control of the orexigenic neural pathways involving NPY. CRH exerts an opposite effect on appetite when compared with glucocorticoids, with the orexigenic effect of glucocorticoids, following the anorectic effect of CRH at the beginning of the stress response, playing a role in the recovery stage for the replacement of the replenishment of energy required during the fight or flight response.

CRH is a 41-amino-acid peptide synthesized from procor- ticotropin-releasing hormone. CRH binds to the corticotropin-releasing hormone receptor (CRHR), a GPCR.

Hypothalamic neuropeptides

Angiotensin II (Ang II) binds to two types of GPCR, namely AT1 and AT2. Brain AT1 receptors are found largely within the circumventricular structures and in hypothalamic and brainstem nuclei. There is a strong association between brain angiotensin and catecholaminergic systems, in particular in brain regions involved in autonomic and cardiovascular control and fluid balance with noradrenergic and adrenergic neurons and the nigrostriatal system with dopamine. Ang II is involved in the regulation of blood pressure and fluid and electrolyte balance, which it regulates peripherally and within the CNS. Ang II is synthesized from the precursor angiotensinogen via the enzyme ACE. Upon degradation by various propeptidases, a number of peptide fragments of Ang II are formed, which are also thought to be biologically active – Ang II (1–7), Ang III and Ang IV – with the latter suggested to produce positive effects on memory.

Vasopressin (AVP), also known as arginine vasopressin and antidiuretic hormone, is a 9-amino-acid peptide that binds to two types of receptor (1A and 1B) within the CNS. Acting largely within the pituitary and hypothalamus, AVP homeostatically controls plasma osmolality and regulation of blood pressure and temperature. AVP has also been suggested to have higher-order functions such as regulation of male-typical social behaviours, including scent-marking, aggression and paternal care. Additionally, AVP is suggested to be fundamental for the formation or expression of social learning and memory and in emotionality.

Oxytocin (OT) is a 9-amino-acid peptide with a similar structure to AVP whose sequence differs from OT by two amino acids. OT is synthesized in the nuclei of the hypothalamus and stored mainly in the posterior pituitary. Its major role is in female reproduction – uterine contractions, breastfeeding and maternal behaviour. It also plays an important role in the regulation of male and female sexual behaviour. Brain OT has generally been described as an important regulator of the stress response, with central administration of synthetic OT found to exert an anxiolytic effect in rodents. OT also plays a major role in the regulation of complex physiological stress responses, including stress-induced neuronal activation and activity of the HPA axis by inhibiting HPA axis responses to a wide variety of
physical, emotional and pharmacological stressors, and may thus make an important contribution to the attenuated stress responsiveness found in pregnancy and during lactation.

Two related neuropeptides, orexin A and B, are produced in the lateral and posterior hypothalamus and send projections throughout the brain. A major role of the orexin system is the integration of circadian rhythm, tiredness and metabolic influences to promote wakefulness, thought to be through interaction with neurotransmitters such as dopamine, histamine and acetylcholine. Dysregulation of the orexin system causes narcolepsy.

Feeding neuropeptides

There are multiple neuropeptides involved in controlling satiety, appetite and food intake. These include neuropeptides found within the hypothalamic nuclei involved in the control of feeding (e.g. NPY, agouti-related peptide (AgRP)) and circulating peptides secreted peripherally into the blood to have effects on these areas of the hypothalamus (e.g. ghrelin, leptin, adiponectin). Some of these are described briefly here.

NPY is a 36-amino-acid peptide found in the hypothalamus and the autonomic nervous system. NPY binds to five GPCRs (Y1–Y5). Its main effect is increasing food intake; in rodents, stimulation of NPY activity increases eating, while blockade of hypothalamic NPY activity via the Y1 and Y5 receptor subtypes decreases food intake. NPY has been implicated in eating disorders: in obesity, an increase in NPY activity is thought to be brought about by high levels of glucocorticoids abolishing the negative feedback of CRH on NPY synthesis and release.

AgRP is produced in the arcuate nucleus in the hypothalamus and is co-localized with NPY in neurons. AgRP increases appetite and decreases metabolism and energy expenditure. α-Melanocyte-stimulating hormone (MSH) is an anorectic peptide also found in neurons of the arcuate nucleus in the hypothalamus and playing an inhibitory role in feeding and energy storage. Melanin-concentrating hormone is another peptide found primarily in the hypothalamus, where it is involved in the control of food intake and energy balance. Melanin-concentrating hormone knockout mice are lean and hypophagic and have increased metabolic rates.

Leptin is a protein hormone that plays a key role in regulating energy intake and energy expenditure, including appetite and metabolism. It is produced by adipose tissue; leptin secretion increases as fat is deposited and diminishes as the adipocyte stores of fat decrease. It interacts with the LepRb class of receptor, which are present in a number of hypothalamic nuclei. Leptin signals to the brain that the body has had enough to eat, by inhibiting the activity of neurons that contain NPY and AgRP and stimulating receptors containing MSH. First discovered in mutant obese mice, mutations in the leptin gene have been shown to have a role in obesity and in antipsychotic-induced weight gain. It has been shown that leptin may also be produced within the brain.

Two further circulating peptides with effects on food intake are ghrelin and adiponectin. Ghrelin is produced in the stomach and pancreas to stimulate appetite and increase adiposity and is thought to act in concert with leptin. Adiponectin has an import role in glucose regulation, fatty-acid breakdown and insulin sensitivity. Produced by adipose tissue, adiponectin has been shown to be decreased in obesity.

Neurotrophins

Neurotrophins or neurotrophic factors are a class of growth factors that stimulate the survival, growth and differentiation of cells in the CNS. Neurotrophins activate two distinct classes of transmembrane receptors, the tropomyosin-related kinase (Trk) family of receptors and the p75 receptor. The Trk family of receptor tyrosine kinases includes the TrkA, TrkB and TrkC receptors, which are activated preferentially by the neurotrophins nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT-4/5 and NT-3. Conversely, the p75 receptor binds both the mature form of the neurotrophins and their precursor peptides.

NGF mediates neuronal survival and differentiation. First characterized as a survival factor for developing sympathetic and sensory neurons, it is now clear that it plays an important role in the maintenance and regeneration of mature peripheral neurons. However, the highly restricted specificity of NGF for sympathetic and sensory neurons and striatal and basal forebrain cholinergic neurons suggests that NGF has an important selective role in the CNS. Cholinergic neurons of the nucleus basalis, medial septum and striatum are unique in that they express both NGF receptors TrkA and p75; it is thought that NGF maintains the function of cholinergic neurons in these regions. Accordingly, due to the loss of cholinergic neurons in Alzheimer’s disease, investigations have also revealed alterations in various markers for NGF and its receptors in patients with Alzheimer’s disease.

BDNF regulates synaptic plasticity, helping to support the survival of existing neurons and to encourage the growth and differentiation of new neurons and synapses, including hippocampal and cortical neurons and cholinergic, nigrostriatal dopaminergic and 5-HT neuron classes. BDNF and its receptor TrkB are also expressed widely in association with glutamatergic synapses. BDNF is synthesized, stored and released from glutamatergic neurons. It facilitates glutamate release and increases phosphorylation of the NR1 and NR2B subunits of the NMDA–receptor complex.

BDNF is involved in LTP, cAMP response element binding protein (CREB), a transcription factor consistently implicated in memory processing, is a major mediator of neuronal BDNF responses. This provides strong evidence for a
role for BDNF in memory formation and storage, particularly in hippocampus-dependent learning.

The many actions of BDNF on different types of neuron have led to the view that malfunctioning of neurotrophins may be a contributing factor in the development of psychiatric disorders. This hypothesis is supported by studies showing that neurotrophins are abnormally regulated in animal models of psychiatric illness and changed after antipsychotic or antidepressant administration. In addition, human studies have demonstrated altered BDNF levels in both blood and the CNS in schizophrenia, while in depression plasticity-related changes such as hippocampal atrophy are thought to be related to a decreased expression or function of BDNF or the TrkB receptor (Box 30.3). In addition, a functional coding region polymorphism (Val66Met) of the BDNF gene, associated with smaller hippocampal volumes and poor performance on hippocampus-dependent memory tasks, has been proposed as a risk factor (albeit a weak one) for the development of bipolar disorder and schizophrenia.

**KEY POINTS**

- Synaptic control of neuronal activity provides the complex, elaborate, subtle and flexible mechanisms by which the brain is able to process information.
- Neurons are highly specialized cells with mechanisms for synthesis and storage of neurotransmitter, mechanisms for transmitter release and processes for removal of transmitter from the synapse.
- There are many substances that may be released from neurons to have a variety of effects on neuronal activity and cellular function: the fast amino acid neurotransmitters, the slower monoamine transmitters, the modulatory neuropeptides, and less conventional compounds such as cannabinoids (Box 30.1) and NO.
- The specificity that neurotransmitters impart to neurons contributes to the anatomic specificity of brain function. Some neurotransmitters are ubiquitous throughout the brain, while others are highly specific in both anatomical distribution and function.
- Neurotransmitters and other signalling molecules bring about their effects by action at specific cell membrane receptors, of which there are two main groups: the ionotropic receptors, which are ligand-gated ion channels influencing cell membrane polarization, and the metabotropic receptors, which, via G-protein-mediated production of second messengers, can have a wide variety of biochemical effects on cell function.
- Synaptic neurotransmission is the major point at which we can influence neuronal activity in the brain. Each of the processes of neurotransmitter synthesis, storage, release, reuptake and metabolism, and the receptors at which neurotransmitters act, are targets for neuropsychiatric drugs.

**Box 30.3 Adult neurogenesis**

Many organs of the body show a capacity to regenerate. For many years, it was understood that the neurons of the adult central nervous system (CNS) were unable to do this: neurons are postmitotic cells and, when lost from the developed brain, are not replaced. More recently, research has questioned this assumption. Neurogenesis, the process by which new neurons are formed, does occur in certain discrete areas of the adult mammalian brain, including the dentate gyrus of the hippocampus.

It has been shown that there are neural progenitor cells in the subgranular zone of the rat hippocampus that divide to produce young cells that mature into fully differentiated hippocampal neurons. Animal studies have shown that this process can be down-regulated by stress and glucocorticoids, while antidepressants, increased activity and an enriched environment can enhance neurogenesis. These environmental and pharmacological effects on neurogenesis appear to have effects on, and perhaps via, brain-derived neurotrophic factor (BDNF) expression, reflecting the importance of this neurotropic factor both in neurogenesis and in maintaining neuronal survival.

It has not been demonstrated unequivocally that neurogenesis occurs in the human adult. However, disturbances of neurogenesis may occur in major psychiatric disorders. Thus, depression has been hypothesized to reflect deficits in neurogenesis, resulting in neuronal deficits and hence volume loss in the hippocampus, an effect reversed by antidepressant drug treatment.

Receptors and their pharmacology

INTRODUCTION

The aim of this chapter is to give a brief overview of the pathological changes that underlie key central nervous system (CNS) disorders that may be encountered in a clinical psychiatry setting.

PATHOLOGICAL CHANGE IN THE CENTRAL NERVOUS SYSTEM

Neurons

All of the cell types seen in the brain can be involved in the reaction to damage, but it is often the neurons that are the primary target for pathology in CNS disorders. Neurons are highly metabolically active cells, a fact that is clearly reflected in their morphology. They have a large nucleus with a prominent nucleolus, numerous mitochondria, a highly developed Golgi apparatus, and abundant rough endoplasmic reticulum (ER). It is these stacks of rough ER that form the characteristic Nissl substance, which can be stained with basophilic dyes such as cresyl violet and help to distinguish neurons from other cell types (Figure 31.1a).

Neurons can undergo a number of different morphological changes, depending on the nature of the insult. For example, in response to acute hypoxic or ischaemic changes, neurons become eosinophilic, with a shrunken cytoplasm and a hyperchromatic nucleus (Figure 31.1b). In more chronic conditions, neurons become atrophic, with pyknotic nuclei and diffusely basophilic cytoplasm.
Whereas these morphological changes are generally associated with cell death, central chromatolysis, in which the cell body swells, the Nissl substance disperses and the nucleus moves to the edge of the cell, is associated with reparative processes, particularly in large motor neurons such as those seen in the ventral horn of the spinal cord. Another key manifestation of pathology, particularly in degenerative disorders, is the presence of intraneuronal inclusions, such as Lewy bodies in Parkinson’s disease (PD) (Figure 31.1c), some of which will be discussed in more detail later in this chapter.

In addition to changes seen in the neuronal cell body, axons can also display pathological changes. Eosinophilic swellings or spheroids, composed of neurofilaments and cellular organelles, are found in axons where normal axonal transport has been interrupted as a result of trauma or hypoxia. Although these can be seen in routine haematoxylin and eosin (H&E)-stained sections, they are more easily detected using immunostaining for the β-amyloid precursor protein (Figure 31.d).

Astrocytes

Astrocytosis, observed as a proliferation and hypertrophy of astrocytes, is a reactive process initiated by damage to the CNS, irrespective of cause. These changes are accompanied by the production of large amounts of the intermediate filament protein glial acidic fibrillary protein (GFAP), immunostaining for which is used routinely to detect astrocytosis (Figure 31.1e). When astrocytes become activated, the cell processes become much more prominent and the enlarged cytoplasm becomes uniformly eosinophilic (gemistocytic). In some degenerative conditions, proteins can accumulate in astrocytes, for example tau in progressive supranuclear palsy (PSP) or corticobasal degeneration.

Microglia

Microglia are considered to be the immune sensor cells of the CNS, able to present antigen and to release a variety of cytokines and chemokines. They also have a key role in the phagocytosis of tissue debris after injury. It remains unclear whether activation of CNS microglia is a beneficial or deleterious process, although it seems likely that at least in the first instance it is a protective response; if it persists, however, it may drive the progression of longer-term degenerative processes. Microglia adopt different morphologies, depending on their activation state. Resting microglia have a highly ramified structure, whereas activated microglia have shorter thickened processes and a more obvious cell body. Activated cells can be immunostained using the MHC II marker CR3/43 (Figure 31.1f). Macrophage/microglial cells can be seen around old infarcts, where they often contain haemosiderin, and also around areas of active demyelination, where they can be seen to contain myelin debris.

Oligodendrocytes

Oligodendrocytes are the myelinating cells of the CNS. Damage to these cells is evident in demyelinating diseases such as multiple sclerosis (MS) (Figure 31.1g). However, as with astrocytes and neurons, they can also be affected by inclusions, such as the α-synuclein immunoreactive Papp–Lantos inclusions that are now considered diagnostic for multiple system atrophy (MSA) (see Movement disorders, below). Tau-positive coiled bodies are also characteristic of PSP and other tauopathies (see Movement disorders, below).

DEMENTIAS

Alzheimer’s disease

There are estimated to be 700,000 people in the UK with dementia,1 the most common form of which is Alzheimer’s disease (AD). The distinctive pathology of the disease that was to take his name was originally described by Alois Alzheimer in 1907 and initially was restricted to cases of presenile dementia, where the age of onset was below the age of 65 years. However, the term AD is now used to cover dementia patients of all ages who reach a threshold level of neuropathological change.

Macroscopic pathology

Cerebral atrophy and low brain weight are commonly observed in AD, but these features are also seen in other degenerative disorders and so are not reliable diagnostic indicators. The atrophy tends to be more marked in the frontal, parietal and medial temporal lobes. The hippocampus in particular may be atrophic, with relative enlargement of the inferior horn of the lateral ventricle, a finding often picked up by in vivo imaging.

Microscopic pathology

The microscopic lesions that define the disease are extracellular senile plaques, intracellular neurofibrillary tangles and gliosis, all of which are associated to some extent with normal ageing and therefore none of which is pathognomonic. Diagnosis is therefore made on the basis of the number and distribution of plaques and tangles with respect to age.4–6 Plaques consist of deposits of the 39– to 43-amino-acid amyloid-β (Aβ) peptide, which is derived from the processing of a longer membrane-bound protein called amyloid precursor protein (APP). The plaques have a varying morphology, ranging from diffuse, amorphous deposits to the more classical form with a condensed core surrounded by a neuritic halo (Figure 31.2a). In some cases, there may also be significant deposition of the Aβ peptide in the walls of the intraparenchymal and leptomeningeal blood vessels in the form of cerebral amyloid angiopathy (CAA) (Figure 31.2b).

Neurofibrillar tangles are composed primarily of a hyperphosphorylated form of the microtubule-associated...
protein tau. Aggregation of this protein causes disruption of the neuronal cytoskeleton and consequently impairs normal transport processes within the neurons. Tau pathology can also be seen in the neuritic clusters around classic plaques and the neuritpl threads in the brain parenchyma (Figure 31.2c). Traditionally, both plaques and tangles were stained using silver impregnation techniques, but nowadays, with antibodies available against the key pathological proteins, immunostaining is the method of choice.

Although cortical pathology predominates in AD, both tangles and plaques can also be found in subcortical areas. Most notably, neuritic pathology and severe cell loss are seen in the nucleus basalis of Meynert. The cells in this basal forebrain nucleus provide the cholinergic innervation to the entire cerebral cortex, and it is the loss of this system that is thought to underlie some of the core cognitive and memory deficits observed in AD. Consequently, it is replacement of this cholinergic deficit that forms the basis for most currently available therapies for AD.

Dementia with Lewy bodies

Dementia with Lewy bodies (DBL) is the second most common form of dementia and is one of a group of disorders (including PD) that involves alterations to the protein α-synuclein. Clinically it can be distinguished from AD on the basis of a fluctuating course and the presence of symptoms such as hallucinations. It can occur as a result of the presence of cortical Lewy bodies alone or, more commonly, in the presence of some degree of AD pathology. In fact, there is much current debate as to what is the precise pathological substrate for dementia in patients with DBL, DBL and AD, and Parkinson’s disease dementia (PDD).

Macroscopic pathology

Cerebral atrophy tends to be less severe than that seen in AD. Section of the midbrain reveals a pale substantia nigra, similar to that seen in PD, due to the loss of neuromelanin-containing dopaminergic neurons.

Microscopic pathology

Cortical Lewy bodies are smaller than those typically found in brainstem nuclei and are more irregular in shape. They are found most abundantly in the deeper layers of the cingulate, entorhinal and temporal cortices (Figure 31.3), whereas the occipital and primary sensory and motor cortices are generally spared. The substantia nigra shows variable degrees of neuronal loss and Lewy body pathology. Lewy neurites are also seen throughout the brain and within the hippocampus show a particular localization in the CA2 subfield. Both Lewy bodies and neurites can be detected using ubiquitin immunostaining, but the method of choice is now to use α-synuclein antibodies.

Frontotemporal lobar dementias

As the name suggests, the frontotemporal lobar dementias (FTLDs) are a group of non-Alzheimer neurodegenerative disorders, including Pick’s disease, in which the frontal and temporal cortex are the areas preferentially affected by pathology. They present clinically in many ways, but there are three main syndromes. The first involves behavioural changes, including social disinhibition, and subsequently language disturbances. In the other two syndromes, progressive non-fluent aphasia and semantic dementia, the language deficits are primary. In other FTLDs, parkinsonism or amyotrophic lateral sclerosis may also feature in the clinical presentation. Historically, a variety of terminologies has been used to describe these conditions, but in light of more recent genetic and biochemical findings and a greater
understanding of their molecular biology there is now an emerging consensus in terms of nomenclature.10

**Macroscopic pathology**

Selective atrophy of the frontal or temporal lobes is typically observed in FTLD brains. This may or may not be associated with gross atrophy of the basal ganglia and loss of pigmentation of the substantia nigra, depending on the type of FTLD.

**Microscopic pathology**

By using immunocytochemistry for key proteins, it is possible to identify the various subtypes of FTLD based on the pathology seen. Tau immunostaining is observed in tangle-only dementia, Pick’s disease and rare cases where there is a mutation in the gene for tau, MAPT. In tangle-only dementia, there is cortical neuronal loss, gliosis and numerous neurofibrillary tangles in the absence of any Aβ pathology (in contrast to AD). In Pick’s disease, there are tau-immunoreactive inclusions called Pick bodies in cortical neurons and in neurons of the dentate gyrus of the hippocampus.

The other major subset of FTLD is those that are tau-negative but that exhibit ubiquitin-positive inclusions (FTLD-U). It has been discovered that the ubiquitinated protein present in these inclusions is TAR DNA-binding protein 43 (TDP-43).11 Immunostaining with antibodies against TDP-43 highlights neuronal cytoplasmic inclusions, intranuclear ‘cat’s-eye’ type inclusions (Figure 31.4), dystrophic neurites and glial cell inclusions and can be used to diagnose these conditions, some of which are associated with specific gene mutations.12,13

**Vascular dementia**

Despite numerous clinical and pathological studies, the precise relationship between vascular pathology and cognitive decline remains far from clear. One key problem is that pure vascular pathologies are relatively rare, and often there are signs of coexistent degenerative pathology, most frequently AD, giving rise to the concept of ‘mixed dementia’.

However, it is generally accepted that large-vessel disease, small-vessel disease and hypoperfusion may all contribute to cognitive impairment. Based on an assessment of the extent and location of these pathological changes, criteria for the neuropathological diagnosis of six subtypes of vascular dementia have been proposed.14

**Macroscopic pathology**

Dementia is common in individuals who have had a stroke, whether as a result of a single large infarct or multiple smaller infarcts. This led Hachinski and colleagues in 1974 to coin the term ‘multi-infarct dementia’,15 a term that has now largely been superseded by the broader term of ‘vascular dementia’. Pathological and imaging studies suggest that vascular dementia is related to the volume and location of cerebral lesions.16,17 In some patients with ‘strategic infarcts’ in areas important for normal cognitive function, such as the hippocampus, this relationship breaks down and the effects can be disproportionate to the size of the lesion.

**Microscopic pathology**

Small-vessel disease, particularly arteriosclerosis (Figure 31.5), is a common feature of dementia in elderly people. This may be seen in the form of lacunes, small holes in the tissue, which arise as a result of ischaemic damage around occluded vessels and are most frequently associated with hypertension. Lacunar infarcts are most commonly seen in the basal ganglia, thalamus and cortical white matter. Depending on their precise location, they may be clinically silent and may be found incidentally only at postmortem. On magnetic resonance (MR) and computed tomography (CT) imaging, small-vessel disease in the white matter, along with its attendant myelin disruption and glial reaction, is known as leucoaraiosis. The severity of leucoaraiosis has been correlated with the extent of cognitive impairment, making imaging an important component of the clinical assessment of vascular dementia.

In addition to the common vascular conditions outlined above, a number of rarer familial vasculopathies have been...
identified. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is a disorder associated with mutations in the NOTCH3 gene, resulting in multiple infarcts in the frontal white matter and basal ganglia. There are then a string of rare conditions named according to the nationality of the families in which they were first described: hereditary cerebral haemorrhage with amyloidosis, Dutch type (HCHWA-D), which is due to a mutation in the same APP gene that is central to the pathology of AD; hereditary cerebral haemorrhage with amyloidosis, Icelandic type (HCHWA-I), which is due to a mutation in the CST3 gene that encodes for the cystatin C protein; and familial amyloidosis, Finnish type, which is due to a mutation in the GSN gene that codes for gelsolin.

**Creutzfeldt–Jakob disease**

Creutzfeldt–Jakob disease (CJD) is the most common form of human prion disease. The disease usually presents as a rapidly progressing dementia, often associated with ataxia, visual abnormalities and pyramidal and extrapyramidal features. Prion diseases, also known as transmissible spongiform encephalopathies, are unique in that they may be sporadic, inherited or acquired. The transmissible agent is defined as a prion (proteinaceous infectious particle), contains no nucleic acid and is composed entirely of a modified form of a normal cellular prion protein. The mechanisms underlying the conversion of prion protein from its normal cellular form to the disease associated form in sporadic CJD are not well understood. However, inherited forms of prion disease such as Gerstmann–Straussler–Scheinker syndrome and fatal familial insomnia are associated with mutations in the prion protein gene, PRNP. Furthermore, varying susceptibility to prion diseases is associated with polymorphisms in the PRNP gene, most notably at codon 129. Acquired forms of prion disease, which require transfer of the pathological form of the prion protein but may have very long incubation times, include kuru, a disease associated with endocannibalism in the Fore tribe of Papua New Guinea; iatrogenic CJD, which has been associated with contaminated neurosurgical instruments, cadaveric dural grafts and pituitary hormones; and variant CJD, which is thought to have arisen from infected beef entering the human food chain.

**Microscopic pathology**

Prion diseases are characterized by the presence of spongiform change in the cortex, thought to be the distension and swelling of neuronal cell processes (Figure 31.6a). There is also neuronal cell loss, prominent reactive astroglisis and deposition of the pathological form of the prion protein (Figure 31.6b).

**Dementia pugilistica**

Boxers who are subjected to repeated blows to the head during the course of their career may develop neurological signs and a progressive dementia known as ‘punch–drunk syndrome’ or dementia pugilistica in later life. Although this phenomenon was initially reported in boxers, there are now plenty of studies suggesting that longer-term cognitive impairment may also be a risk in other contact sports, such as rugby union and Australian rules football.

**Macroscopic pathology**

Rotational acceleration as a consequence of repeated glancing blows to the head can lead to focal damage of midline structures. A fenestrated cavum septum pellucidum is often seen in boxers, whereas it is rarely seen in non-boxers unless there is a history of head injury. The ataxia and parkinsonism often seen in dementia pugilistica are caused by scarring to the inferior surface of the cerebellum and the loss of pigmented cells from the substantia nigra, respectively.

**Microscopic pathology**

The main microscopic changes associated with dementia pugilistica are neurofibrillary tangles throughout the cerebral cortex, particularly the medial temporal lobe, and the brainstem. These have been found to be biochemically very similar to those seen in Alzheimer brains. In the original
boxer studies, carried out using silver staining techniques, no amyloid plaques were seen; but when the cases were revisited using immunocytochemistry for the Aβ peptide, large numbers of diffuse deposits were observed. Similarly, diffuse Aβ has been observed in a proportion of patients who die soon after a single episode of severe head injury, and this has prompted further investigations of possible links between trauma and the subsequent development of neurodegeneration. One possible mechanism for this is the initiation of neuroinflammation.

MOVEMENT DISORDERS

Parkinson’s disease

PD is the most common of the movement disorders, affecting approximately 1 per cent of the population over the age of 65 years. The disease is characterized by tremor, rigidity, bradykinesia and abnormalities of posture and gait. These motor features are caused by a loss of normal nigrostriatal dopaminergic projections. However, as is described below, the pathology of PD is now known to be much wider spread than thought previously, and many patients will also manifest autonomic and psychiatric symptoms.

Macroscopic pathology

At gross examination, the brain of the patient with PD is likely to appear normal and be of normal weight. Distinctive pathology will be seen when the brainstem is examined. Cross-section of the midbrain reveals pallor of the substantia nigra, and a similar loss of pigmented cells from the locus coeruleus can be seen in pontine sections.

Microscopic pathology

PD, like DLB (see above), is an α-synucleinopathy, and immunostaining with antibodies against α-synuclein is now the method of choice for identifying the Lewy bodies that characterize the disease at the microscopic level (Figure 31.7). In the substantia nigra there is loss of pigmented dopaminergic cells, usually more marked in the lateral parts. There is also free pigment either lying in the neuropil or in macrophages. Other areas of the brain often showing pathological α-synuclein include the locus coeruleus, nucleus basalis of Meynert, dorsal nucleus of the vagus (associated with dysphagia) and the intermediolateral columns of the spinal cord (associated with autonomic deficits). Lewy bodies are not unique to PD and DLB but can also be seen in AD and sometimes in individuals with no clinical symptoms (incidental Lewy bodies), where they are assumed to represent preclinical PD.

Progressive supranuclear palsy

PSP is an example of a so-called ‘parkinsonism-plus’ syndrome and is much rarer than PD. The disease is associated with parkinsonism (usually without tremor), falls and vertical gaze problems. Unlike PD, PSP is a tauopathy, with the cellular changes due to pathological accumulation of tau protein.

Macroscopic pathology

As with PD, there is depigmentation of the substantia nigra, but in PSP there is generally sparing of the locus coeruleus. Other subtle changes that can help distinguish the two conditions are the presence of a mild atrophy of the midbrain, superior cerebellar peduncles and discolouration of the dentate nucleus of the cerebellum in PSP.

Microscopic pathology

Along with subcortical neuronal loss and gliosis, the main pathology in PSP is the accumulation of tau in both neurons and glial cells, particularly in the substantia nigra, subthalamic nucleus and globus pallidus. In the neurons the tau deposits form tangles and pretangles. Astrocytes in the striatum containing tau inclusions take on a tufted appearance, while oligodendrocytes in the white matter accumulate the tau in the form of coiled bodies (Figure 31.8).
Multiple system atrophy

MSA is another example of a ‘parkinsonism-plus’ syndrome, but in this case, as in PD, it is an α-synucleinopathy. The term MSA covers three previously distinct disorders: olivopontocerebellar atrophy (OPCA), which is characterized by prominent cerebellar ataxia; Shy–Drager syndrome, a primary autonomic failure; and striatonigral degeneration that presents with a prominent parkinsonism. More recently, the terms MSA-C (cerebellar) and MSA-P (parkinsonism) have come into general use and Shy–Drager syndrome has been dropped because autonomic failure is a feature in all MSA cases.

Macroscopic pathology

In cases where parkinsonism is prominent, there is atrophy of the brainstem and pons and a loss of pigmentation of the substantia nigra. There is often also a characteristic greenish discolouration and shrinkage of the putamen. Cerebellar atrophy is evident in cases with a prominent ataxia.

Microscopic pathology

The grouping of these previously separate conditions is based on the common presence of glial cytoplasmic inclusions. Specifically they are comma-shaped α-synuclein inclusions in oligodendrocytes, sometimes called Papp–Lantos bodies (Figure 31.9), and they are prevalent in the basal ganglia, substantia nigra and cerebellum.

Huntington’s disease

Huntington’s disease (HD) is a hyperkinetic disorder that is inherited in an autosomal dominant fashion and affects approximately 5 in 100 000 of the population. It is caused by an unstable CAG (glutamine) expansion in the IT-15 gene on chromosome 4, which codes for the huntingtin protein. The disease occurs in people who have more than 37 repeats of the glutamine sequence. The age of onset shows an inverse correlation with the number of repeats, and there is anticipation – that is, there is expansion of the number of repeats on parental transmission.

Macroscopic pathology

The frontal cortex is often mildly atrophic, but the cardinal pathology is seen on coronal slicing of the brain, when it becomes clear that there is marked atrophy of the caudate and putamen, with a corresponding increase in the size of the ventricles.

Microscopic pathology

In the striatum there is loss of the medium spiny neurons and a marked astrocytic reaction. There is also neuronal loss and gliosis in the cortex. Ubiquitin or huntingtin immunostaining reveals intranuclear inclusions and also accumulations of the protein in neurites in both the striatum and the cortex. The precise mechanisms of neurotoxicity associated with these inclusions remain unknown.

Motor neuron disease

Motor neuron disease (MND) is a chronic progressive disorder of motor neurons presenting as muscle wasting, weakness and eventually paralysis. The most common form of the disease is amyotrophic lateral sclerosis (ALS), in which both the upper and lower motor neurons are affected, leading to degeneration of the corticospinal tracts and a spastic paraparesis. Sometimes there is selective damage of the brainstem motor nuclei, leading to progressive bulbar palsy. Approximately 10 per cent of all MND cases are familial, and the best characterized genetic cause is a mutation in the copper-zinc-superoxide dismutase gene (SOD1).

Macroscopic pathology

The brain appears normal in the majority of cases, unless there is particularly prominent upper motor neuron disturbance, in which case the precentral gyrus may be atrophic. Additionally, if there is associated dementia, there may be frontotemporal atrophy (see Frontotemporal lobar dementias, above). The main gross pathology is seen in the spinal cord, which is thinner than normal and where the anterior nerve roots appear atrophic and discoloured.

Microscopic pathology

Depending on the clinical subtype of the MND, the main microscopic pathology is the loss of motor neurons from the ventral horn of the spinal cord, lower brainstem motor nuclei and the Betz cells of the primary motor cortex. Luxol-fast blue staining of the spinal cord will show pallor of the corticospinal tracts. Some surviving motor neurons in the spinal cord contain inclusion bodies that can be detected with ubiquitin stains.

CEREBRAL TUMOURS

A detailed description of CNS tumours is way beyond the scope of this chapter, and so this section will be restricted to a very brief outline. For a more comprehensive account, the
reader is directed to the World Health Organization (WHO) classification of tumours of the CNS.

Tumours are classified histologically on the basis of their presumed cell of origin (see Figure 31.10), although biochemical and molecular studies are bringing some of these assumptions into question and the classification of tumour types is reviewed regularly in the light of new research information. The tumours can be either primary or secondary. Primary tumours arise from cells of the CNS (neuroepithelial) and meninges (non-neuroepithelial), whereas secondary tumours arise elsewhere in the body and metastasize to the CNS. In adults 70 per cent of tumours occur supratentorially, while in children this is reversed, with approximately 70 per cent of tumours affecting the brainstem and cerebellum. In adults the most common tumours are (in descending order) metastases, gliomas, meningiomas and Schwannomas. By contrast, in children tumours tend to be neuroectodermal in origin, for example medulloblastomas. Different tumour types are commonly found in certain anatomical locations, as shown in Table 31.1.

Intracranial tumours become clinically manifest for a number of reasons. Depending on their precise localization, they can produce focal dysfunction (e.g. hemiparesis if they impinge on the primary motor cortex), they can initiate epileptic activity in neighbouring tissue, and they can act as mass-occupying lesions, causing raised intracranial pressure. If they are located in the posterior cranial fossa, they can also interrupt normal flow of cerebrospinal fluid (CSF), causing hydrocephalus.

Tumours are graded histologically to give some prognostic indication to clinicians and to help them decide the most appropriate treatment regime. Grade I tumours have a low proliferative potential and, depending on their location, can be treated by neurosurgical resection alone. Grade II lesions tend to be infiltrative in nature, often recur and in some cases are able to transform into grade III lesions over time. Grade III lesions show clear evidence of malignancy in the form of nuclear changes and mitotic activity and in most cases will require adjuvant radiation or chemotherapy. Grade IV lesions are extremely malignant and generally carry a very poor prognosis.

Schizophrenia

Schizophrenia has long been referred to as the ‘graveyard of neuropathology’ because of the difficulty in identifying any precise neuroanatomical changes that might explain the neuropsychological symptoms of the disorder. Numerous detailed structural studies of the brains of patients with schizophrenia have been carried out, but the results have often been conflicting. This lack of a clear structural basis for schizophrenia has led to it being described as a functional psychosis, with the problem being attributed to faulty neural circuitry. However, there are now some relatively robust findings to suggest that there may be subtle structural changes occurring in certain areas of the brain, and this is a research field that is likely to expand over the coming years.

Macroscopic pathology

The most consistent observation in patients with schizophrenia, based largely on imaging studies, is the presence of ventricular enlargement and reduction in brain volume. At the neuropathological level, this is clearly not useful diagnostically because such changes are seen in a whole range of other disorders. However, the fact that there is some loss of brain substance is supported by the observa-
tion that there is a reduction in brain weight of up to 5 per cent.33 What remains unclear is what component of the tissue is actually being lost (neurons, glia, neuropil, etc.). Other macroscopic changes that have been proposed but that are not widely replicated are a loss of normal brain asymmetry, reduced size of the corpus callosum and disruption of normal gyration.

Microscopic pathology

At the microscopic level, one of the key debates has been over the role of gliosis. Early studies suggested that periventricular gliosis may be found in 70 per cent of schizophrenia cases,34 perhaps pointing to an ongoing degenerative process. However, the majority of studies carried out to look at the extent of gliosis do not replicate these findings, and the current consensus is that gliosis is not a feature of the disorder in most cases.35 In the absence of a clear degenerative process, attention has shifted more towards a developmental aetiology for the disorder and, in particular, the presence of cytoarchitectural abnormalities in certain areas of the brain such as the thalamus, hippocampus and prefrontal cortex. For example, based on reproducible stereological studies, the mediodorsal nucleus of the thalamus appears to be smaller than normal and to contain fewer neurons in schizophrenic patients.36 In the hippocampus and prefrontal cortex, there appear to be decreases in neuronal size and changes in synaptic proteins. Exactly how these subtle cytoarchitectural changes might give rise to the symptoms of schizophrenia remains unclear and the debate goes on, but the current state of the field, and the key controversies to be resolved, have been expertly reviewed by Harrison.35

For more in-depth discussion of the neuropathology underlying all of the disorders mentioned in this chapter, and a lot more that are not, the reader is referred to Greenfield’s Neuropathology.37

KEY POINTS

- All cell types of the CNS may be involved in disease pathology.
- Alzheimer’s disease (AD) is characterized by the presence of extracellular Aβ peptide plaques and intracellular neurofibrillary tangles.
- Dementia with Lewy Bodies (DLB) is an α-synucleinopathy.
- The pathology of AD and DLB can coexist in the same patient.
- Fronto-temporal lobar dementias are categorized according to the protein found in the pathological inclusions.
- Creutzfeldt–Jakob disease is a prion disease that may be inherited or acquired.
- Parkinsonism may be caused by different underlying pathologies.
- Parkinson’s disease and multiple system atrophy are α-synucleinopathies.
- Progressive superstructural palsy is a tauopathy.
- Schizophrenia does not have a definitive neuropathology.

REFERENCES

INTRODUCTION

In this chapter, an introductory account is given of some of the main features of computed tomography (CT), magnetic resonance imaging (MRI), blood oxygen level-dependent functional magnetic resonance imaging (BOLD fMRI), magnetic resonance spectroscopy (MRS), fluid-attenuated inversion recovery (FLAIR), diffusion tensor imaging (DTI) tractography, arterial spin labelling (ASL), single-photon-emission computed tomography (SPECT) and positron-emission tomography (PET), with an emphasis on their applications in modern psychiatry. The temptation to include mathematical equations has largely been resisted. Detailed aspects of the physics involved have been omitted, as have details of different magnetic resonance (MR) sequences, echo-planar imaging and the workings of the PET cyclotron. For readers interested in these details, a selection of suitable further reading is given at the end of the chapter.

COMPUTED TOMOGRAPHY

X-ray CT, previously known as computed axial tomography (CAT), is a digital form of structural neuroimaging that utilizes X-ray attenuation married to a tomographic technique that separates out axial or transverse images. It was developed in the UK by Sir Godfrey Hounsfield. The basic design of a CT scanner is shown in Figure 32.1.

Figure 32.1 (a) Basic computed tomography (CT) design, showing an X-ray source collimated to a fan beam rotating around the patient’s abdomen. The X-ray tube and detectors are fixed together as a single rotating unit. (b) The fan beam assembly, showing collimator and detector geometry. The slice has a greater thickness in the middle, and post-patient collimation defines the slice sensitivity profile.

After being scanned, the part of the body of interest is stored in a format digitally divided into voxels, which are cuboids. On any two-dimensional planar display, two-dimensional pixels are shown, as illustrated in Figure 32.2.

MAGNETIC RESONANCE IMAGING

Basic physics

Within a strong external magnetic field, $B_0$, there is a tendency for hydrogen protons, which possess the quantum property of spin and behave like magnetic dipoles, to line up with the external magnetic field, as depicted in Figure 32.3; a majority of these protons point in the same direction.

Figure 32.3 (a) The hydrogen proton compared with a bar magnet, showing the proton spin creating a magnetic dipole $\mu$, analogous to the magnetic pole of a bar magnet. (b) A group of three protons, showing various orientations of their axes in free space. (c) The proton axes are aligned in a strong external magnetic field, $B_0$. A smaller proportion take up the opposing direction.

as the field, but a minority of the protons that line up are in the diametrically opposite direction. For simplicity, consider- ing only those protons that line up in the same direction as the external magnetic field (i.e. those that are ‘parallel’ to the magnetic flux), when such protons are subjected to a radiofrequency (RF) pulse they are displaced (Figure 32.4). This can be thought of as being rather like the precession that a top or gyroscope undergoes when subjected to a small tangential force while spinning and being under the influence of an external gravitational field (Figure 32.5). Recovery from the recession gives rise to the nuclear magnetic resonance (NMR) signal, as shown in Figures 32.6 and

at the time of writing vary in value between 0.5 T and 3 T, the total proton contribution is represented by the vector $M_z$ at equilibrium in the $z$ plane. Here, the $z$-component takes its maximum value and both the $x$ and $y$ components are zero. (b) A radiofrequency (RF) pulse creates the opposing field $B_1$, which displaces $M$ by an angle $\alpha$. The $x$ and $y$ components have now grown. (c) A sufficiently large RF pulse displaces $M$ into the $x,y$ plane ($z$-component is 0; the $x$ and $y$ components are maximum). Longitudinal recovery now takes place.

For a given nucleus type (e.g. hydrogen proton), the angular frequency of precession of the nucleus is directly proportional to the external magnetic field strength (flux density), $B_0$, which is therefore the value of the main magnetic field strength of the MR scanner. The constant of proportionality is known as the gyromagnetic ratio and is denoted by $\gamma$. (The gyromagnetic ratio is calculated by dividing the value of the magnetic moment ($\mu$ in Figure 32.3) by the product of $2\pi$ and the modulus of the spin angular momentum of the nucleus.) Thus, the angular frequency of precession is given by $\gamma B_0$; this frequency is the Larmor frequency, $\omega_L$, and the equation $\omega_L = \gamma B_0$ is the Larmor equation. The unit of the magnetic field strength is the tesla, abbreviated to T in Système International d’Unités (SI units). (Note that, in MR papers and commercial MRI scanner literature, ‘tesla’ is often incorrectly rendered ‘Tesla’.) Typical values of $B_0$ for MRI scanners in clinical use at the time of writing vary in value between 0.5 T and 3 T, while some scanners used for human or rodent in vivo research may have field strengths as high as 7 T or 9 T. MRI scanners used for studying tissue samples and inanimate objects tend currently to have a field strength of over 11 T; patients are not directly scanned using such scanners, and the instruments tend to be called NMR scanners. Note that MRI used to be referred to as NMR; one reason for the change in terminology was the concern that patients might be perturbed by the word ‘nuclear’ – in fact, MRI or NMR scanning does not use any ionizing radiation.

Further details of the physics of MRI are beyond the scope of this book; good accounts are given in some of the books mentioned under further reading at the end of this chapter.
T1- and T2-weighted imaging

T1 is the longitudinal time constant and indexes the rate at which the longitudinal magnetization, $M_L$, returns to its maximum value following an RF pulse, as shown in Figure 32.8. (It is measured when $M_L$ reaches approximately 63 per cent of its maximum value after a 90° RF pulse brings it to zero. This is because $M_L = 1 - e^{-t/T_1}$, and setting $t = T_1$ gives $M_L = 1 - e^{-1}$, which is 0.632 to three decimal places.) The value of T1 varies with the magnetic field strength, as shown in Figure 32.9. At a given field strength, the T1 is longer for CSF than for grey matter, and in turn longer for grey matter than for white matter. It is particularly short for fat. (With its higher concentration of myelinated sheaths, white matter clearly has a higher density of fat than does grey matter.)

T2 is the transverse time constant and indexes the rate at which the transverse magnetization, $M_{xy}$, decays to its minimum value of zero following an RF pulse. (It is measured when $M_{xy}$ decays to approximately 37 per cent of its maximum value because we can take $M_{xy} = e^{-t/T_2}$, and setting $t = T_2$ gives $M_{xy} = e^{-1}$, which is 0.368 to three decimal places.)

In MRI scans of the brain, if scanning sequence parameters are chosen selectively to emphasize T1 characteristics (T1-weighted scans), white matter has a higher signal intensity (i.e. it appears ‘whiter’) than grey matter, which in turn has a higher signal intensity than CSF. In a T2-weighted MRI scan, CSF has a higher signal intensity than grey matter or white matter; such scans are also good for imaging cerebral oedema (which also has a high signal intensity). These differences are shown in Figure 32.10, which also shows how an intravenous contrast agent (in this case, based on gadolinium) may helpfully enhance the imaging of some cerebral tumours.

**Receiver coils**

The NMR signal is detected using a receiver or detector coil, usually specifically designed for the part of the body being investigated. Special coils are becoming available that allow parallel imaging to be carried out. These involve multiple imaging coils that record imaging data simultaneously using techniques such as sensitivity encoding for MRI (SENSE) and simultaneous acquisition of spatial harmonics (SMASH) so that the image acquisition time is shortened. There are also advantages from parallel imaging in terms of reducing certain types of MRI artefacts.

---

**Figure 32.8** (a) Vector diagram identifying the proportion of $M_L$ and $M_{xy}$ in the proton magnetic vector $M$ at time $t$. (b) $M$ traces out an exponential decay curve as it regains equilibrium (achieved when $M_L = 1$). The value of T1 is measured at approximately 63 per cent recovery (see text). Both short and long T1 examples are shown.

**Figure 32.9** Variation of T1 (in milliseconds, ms) with magnetic field strength (in teslas, T) for liquid (water, cerebrospinal fluid) and soft tissue: grey matter and white matter in the brain have intermediate values.

Safety

The magnetic field strengths typically used during in vivo human scanning are very high compared with the strength of the earth’s magnetic field. For example, while the strength of the latter, at the surface of the earth, is around 30–60 mT, a field strength of 3 T inside the bore of a modern 3-T MRI scanner is 50 000–100 000 times stronger. The strength of the magnetic field falls off with increasing distance from the main MRI magnet. Special magnetic shielding is also placed around the scanner. A warning contour, usually in yellow and black, is fixed to the floor around the scanner at the distance corresponding to a field strength of 500 mT. This corresponds to a field strength of 5 G using the previous unit of magnetic field strength (flux density) of the gauss (1 gauss or 1 G) is one ten-thousandth of a tesla; i.e. 1 T = 10 000 G). Therefore, this contour is often still referred to as being the ‘5-gauss line’. It can be very dangerous to bring freely mobile ferromagnetic materials within the 5-gauss line. Even a small piece of metal such as a paperclip or a pen containing ferromagnetic components can turn into an extremely dangerous, and potentially even lethal, object if it is brought within this contour: there is a strong attraction to the bore of the magnet and such an object can fly into this part of the scanner, all the time accelerating while approaching the scanner, so that its momentum increases correspondingly. If a person happens to be lying in the scanner at the time, this can clearly be very dangerous. For similar reasons, in the event of a suspected cardiac arrest or other such emergency, it is important not to allow the ordinary hospital crash team into the scanning area within the 5-gauss area (their stethoscopes, pins for neurological examinations, etc. can turn into potentially lethal missiles) but instead to ensure that medical staff present during the MR scanning are properly trained to carry out emergency resuscitation in the MRI environment. The magnetic field from the scanner may also interfere with certain types of equipment that are nearby. For instance, older cathode ray tube monitors may show images that are permanently displaced, hospital equipment may not function properly, and mobile telephones (if their use is permitted in the area) may fail to receive a normal signal. Weaker contours (e.g. the 2.5-gauss line) also extend right around the scanner, at a greater distance from the main scanner magnet than the 5-gauss line, and so may extend beyond a wall at the back of the scanner; this may have implications for any equipment being operated on the other side of that wall.

In terms of the safety of individuals being considered for scanning, there are several aspects to bear in mind. The imaging safety checklist that I routinely use before scanning anyone checks for the presence of the following:

- Cardiac pacemaker
- Mechanical heart valve
- History of foreign body in the eye
- Occupation as a metal worker, grinder or welder
- Metallic implant, metal prosthesis, orthopaedic plates or screws
- Shrapnel
- Aneurysm clip/haemostatic clip
- Ear implant
- Artificial eye

- Coloured contact lens
- Intervventional radiological device
- Pregnancy
- Intrauterine contraceptive device (IUCD)
- Implantable pump or neurostimulator
- Allergies (if the subject is to receive a contrast agent)
- A watch
- Any jewellery
- Anything in the patient’s pockets (e.g. keys).

The presence of an artificial cardiac pacemaker is an absolute contraindication; failure of the pacemaker inside the scanner could clearly be fatal. Any person who has had a history of one or more small pieces of metal entering the eye (e.g. while carrying out metal grinding) should not be allowed near a scanner unless they have had orbital X-rays taken and cleared by a radiologist; just one small sliver of metal could tear through the cornea and the rest of the eye while the subject is inside the scanner. The presence of a metallic implant might not necessarily be an absolute contraindication, depending on factors such as the location of the implant and the field strength of the scanner; there is a danger not only of displacement but also of the metal heating during the scanning session. Indeed, MRI scanning does impart energy to the patient being scanned, and so during scanning it is important to monitor and regularly record the value of the specific absorption rate (SAR); one should also monitor the scanner room temperature and how uncomfortable the subject may be feeling. The presence of an aneurysm clip or haemostatic clip is an absolute contraindication; displacement of such a clip could be very dangerous and potentially fatal. A coloured contact lens might be dangerous, as some make use of metallic pigments. At the time of writing, MRI is not routinely permitted during pregnancy in many countries without strict permission of the local research ethics committee (indeed, there are some MRI studies specifically of pregnant women). If a female subject is using an IUCD (a ‘coil’), the make of the IUCD should be checked carefully in advance; if the IUCD is not MRI-compatible, then the scanning session might cause the IUCD to be dislodged, potentially leading to failure of contraceptive cover. It is good practice to ask the patient to change into hospital pyjamas before being allowed into the scanner. Any underwear that contains metal should be removed first. For instance, ordinary bras that have metal fasteners should not be worn, while sports bras without such metal fasteners are usually safe. If the patient insists on wearing their own clothes, these should be checked carefully for the presence of any metal components, such as fasteners, zips, metal buttons, metal fasteners and sequins. The pockets of the clothing, even hospital pyjamas, should be checked for a final time before the patient enters the scanner area; under no circumstances should keys and other such objects be allowed into the scanner room.

Claustrophobic feelings inside the scanner are a relative contraindication. Some patients are able to go ahead after verbal reassurance. Others can do so if a second person (who should also be carefully metal-checked first) is present; this second person might sit by the subject (on a non-metallic chair) and perhaps hold gently on to a covered part of one of the subject’s lower limbs during the scan.

It is important to ensure that leads (e.g. from headphones, a patient alarm and the scanner coil) do not make loops on the subject’s body while they are lying in the scanner, as these could cause burns. For a similar reason (related to the need to prevent local electrical circuits from forming within the strong magnetic field), the patient should be asked not to allow bare parts of their body (e.g. the hands and lower arms) to touch each other and not to cross their arms or legs while being scanned. Particularly at field strengths of 3 T and above, care should be exercised with subjects who have tattoos present, and metal-based make-up should be removed completely before entering the scanner room. It is always worth carrying out one final check before the patient enters the scanner room: they may have picked up a pen and put it in a pocket, or they may have forgotten to remove a hairclip.

Advanced structural imaging

Structural MR neuroimaging can be used to carry out ventricular segmentation and thereby measure the volume of the ventricles of the brain. The cerebral tissue itself can be segmented into grey matter and white matter. The cortex can be analysed for features such as its degree of folding.

Voxel-based morphometry (VBM) is based on the distribution of grey matter in the brain and, in a group, may reveal areas of grey matter loss. It has been found that image registration is of particular use, both in terms of research and from a clinical perspective. This technique allows subtle changes in brain structure to be picked up and quantified between consecutive scans from the same patient; these scans may be several months or even years apart. This is helpful, for instance, in following the response of cerebral tumours to chemotherapy or radiotherapy. Image registration can also be used to compare groups, as shown in Figure 32.11. Here, analysis of the

Figure 32.11 Image-registration techniques were applied to structural magnetic resonance imaging (MRI) scans in a Huntington’s disease clinical trial. Voxel-wise local analyses of ethyl-eicosapentaenoic acid treatment versus placebo over 12 months showed significant changes at the head of the caudate nucleus and the posterior thalamus (shown in green along with the putamen; red–yellow colour bar shows the P-value under the null hypothesis of no change).
Reproduced from ref. 12.
MRI scans from patients with Huntington’s disease taking part in a randomized, double-blind, placebo-controlled trial of a new intervention showed that, compared with the placebo, the active treatment was associated with significant group-level reductions in brain atrophy in the head of the caudate nucleus and the posterior thalamus.6 These findings showed that the active treatment was associated with significant reduction in brain atrophy, particularly in the caudate and thalamus.

**BLOOD OXYGEN LEVEL-DEPENDENT FUNCTIONAL MAGNETIC RESONANCE IMAGING**

In 1991, Bruce Rosen’s group at Harvard Medical School published the first quantitative determination of human brain activation using MRI. This fMRI study used the measurement of cerebral haemodynamics, following the injection of the MRI contrast agent gadolinium-diethyltriamine penta-acetic acid (Gd-DTPA). During photic stimulation, localized increases in blood volume were detected in V1 in a study involving seven subjects.7

The following year, the same group published a non-invasive fMRI study that did not involve injections of a contrast agent.8 Instead, the study relied on the BOLD effect. BOLD depends on the fact, that in contrast to oxyhaemoglobin (which is diamagnetic), deoxyhaemoglobin (which is paramagnetic, having unpaired electrons) may be used as an endogenous contrast agent. In theory, the greater the activation of a part of the brain, the greater is its use of oxygen. This in turn leads to a greater concentration of deoxyhaemoglobin. Hence, greater activation is associated with greater signal intensity in BOLD fMRI. In this first human study, V1 was again shown to be activated during photic stimulation in seven volunteers, while M1 was found to be activated during repetitive contralateral hand-squeezing; these results are shown in Figures 32.12–14 from the original paper by Kwong and colleagues.8

BOLD fMRI rapidly established itself as a standard non-invasive functional neuroimaging technique, which is now in widespread use. The detailed physics and methodology are beyond the scope of this book, but for those who are interested further good accounts are to be found in some of the texts recommended for further reading.

**MAGNETIC RESONANCE SPECTROSCOPY**

The above description of the physics of MRI confined itself to a consideration of hydrogen protons. There are other nuclei that also interact with the strong magnetic field of an MRI scanner. Some of these are shown in Table 32.3; it can be seen that they include the 13-carbon and 31-phosphorus isotopes. It can also be seen from Table 32.3 that the value of the gyromagnetic ratio, γ (vide supra), differs between the different nuclei.

The basic principles of MRS have been summarized by the author.9
Spectroscopy revolutionized the study of organic chemistry and biochemistry during the last century. While X-ray crystallography, mass spectrometry and infrared spectroscopy cannot be used non-invasively in the study of fatty acid metabolism in adult human brains, fortunately nuclear magnetic resonance spectroscopy can be so used. In the context of human in vivo studies, nuclear magnetic resonance spectroscopy is more commonly referred to as magnetic resonance spectroscopy, partly to avoid the potentially pejorative and upsetting word ‘nuclear’ when talking to human volunteers and patients, and partly because the technique involves the use of the same magnetic resonance imaging scanners as are employed to carry out structural magnetic resonance imaging.

The technique requires a strong magnetic field, preferably at least 1.5 T when applied to the adult human brain. Certain atomic nuclei in the brain interact with this strong static magnetic field. These include protons and the 13-carbon and 31-phosphorus isotopes. In lay terms, each of these nuclei can be considered to possess more than one possible energy level in the magnetic field. Upon exposure of the brain to a short pulse of radiofrequency energy in a magnetic resonance scanner, some of these nuclei absorb the radiofrequency energy and enter a higher quantum energy state. Recovery of the previous, lower, quantum energy state is associated with the reverse process of the release of energy. The latter is measured as an amplified signal by the head coil receiver.

With all such measurements, there is the phenomenon of ‘noise’. For example, when a normal radio receiver is not tuned correctly to a radio station, then one hears a lot of static – noise. (Actually, some of this noise may derive from electromagnetic radiation which had its origin in the big bang.) Then, as one tunes in to a correct station frequency (a resonance frequency), the signal-to-noise ratio becomes high enough to allow the station to be heard clearly. The individual nuclei also

Table 32.3 Useful nuclei in nuclear magnetic resonance (NMR)

have particular resonance frequencies. In order to improve the signal-to-noise ratio, multiple readings are taken. Since the noise is assumed to be random, successive additions of the readings lead to relative enhancement of the true signals against a diminishing background of noise signals which tend to cancel each other out. Furthermore, in a given molecule, all the protons do not usually resonate at the same frequency, and all the 31-phosphorus nuclei do not usually resonate at another single frequency (different from that for the protons). This is because the resonance frequencies for given nuclei are partly determined by the electron structure of the molecule. (In classical electromagnetic physics, one can consider that the motion of these charged electrons in a magnetic field gives rise to an electric current which in turn gives rise to an associated and opposing magnetic field, in accordance with Maxwell’s equations; this causes varying levels of shielding of the nuclei from the applied external magnetic field.) The difference between the resonance frequencies of a given nucleus and of a reference nucleus is calculated and the chemical shift of the given nucleus is then defined in terms of the ratio of this difference to the resonance frequency of the reference nucleus. The chemical shift is usually expressed in parts per million (ppm). The signals from the brain are plotted as peaks against the chemical shift, the latter constituting the abscissa of the graph. The area under each peak is directly proportional to the concentration of the corresponding nucleus in the sample (for instance, a brain voxel) under study. Moreover, the shape of the peak(s) yields information about the electrochemical environment of the nucleus in the molecule. Further details of this technique are beyond the scope of this chapter but may be found in the paper by Cox and Puri.10

The chemical shift (conventionally denoted as δ) between water and lipid is illustrated in Figure 32.15.

Figure 32.16a shows a normal brain proton MR spectrum. Since water is by far the most abundantly occurring substance containing free hydrogen protons in the brain, the peak corresponding to water is much larger than that from other substances. Therefore, while acquiring proton MRS (1H MRS) data, it is usually necessary to suppress this water peak, using a suitable spectroscopy sequence. Of the remaining peaks, that corresponding to N-acetyl-aspartate (NAA) is particularly prominent and may be thought of as being a neuronal marker. In Figure 32.16c, it can be seen that the NAA peak is reduced in area in a glioblastoma, as a result of there being fewer normally functioning neurons in the tumour. Choline (Cho), among other functions, acts as a polar head group in phospholipid molecules. Lactate is not normally seen in the human brain (apart from in some prematurely born infants), but it may become present during anaerobic respiration (Figure 32.16c). Proton MRS carried out at a stronger magnetic field (≥ 3 T) allows other peaks to be identified and is therefore more informative.

Figure 32.17a shows a spectrum from a 31-phosphorus MRS (31P MRS) study of the brain in schizophrenia. The peak labelled PME (phosphomonoesters) corresponds to the phosphoethanolamine and phosphocholine peaks and indexes membrane phospholipid anabolism, while the peak labelled PDE (phosphodiesters) corresponds to the glycerol 3-phosphoethanolamine and glycerol 3-phosphocholine peaks and indexes phospholipid catabolism. Other peaks shown in Figure 32.17a are inorganic phosphate (Pi), phosphocreatine (PCr) and γ, α and β nucleotide triphosphate (NTP), βNTP indexes adenosine triphosphate (ATP). The majority of adenosine diphosphate (ADP) is 31-phosphorus NMR-invisible, although the γNTP signal overlaps with signals from βADP. The broad component from the 31-phosphorus neurospectroscopy study shown in Figure 32.17b indexes brain cell motion-restricted membrane phospholipids; this has been reported as being unchanged in schizophrenia.12

**FLUID-ATTENUATED INVERSION RECOVERY**

FLAIR refers to a particular type of MRI sequence that produces a strong T2-weighting, suppresses the signal from CSF, and minimizes the contrast between grey matter and white matter, thereby producing images with significantly increased lesion-to-background CSF contrast and enhancing the visibility and detectability of lesions, particularly in the peripheral subcortical and periventricular regions.13,14 Figure 32.18 is a FLAIR MRI scan showing a hyperintense middle cerebral artery infarct.

**DIFFUSION TENSOR IMAGING TRACTOGRAPHY**

DTI can be used to infer the location of white matter tracts in the brain. Parker and colleagues have summarized the methodology.15
Diffusion tensor imaging probes the random thermal motion of water molecules in tissue. Obstructions to this motion, including cell cytoskeleton and membranes, cause restricted diffusion. When these microscopic obstacles are arranged coherently over the scale of an imaging voxel, the bulk diffusion properties within that voxel become directional or anisotropic; water molecules may be less restricted in their motion in certain orientations than others. DTI is sensitive to this anisotropy. The information gained from a DTI study may therefore be interpreted to provide information concerning the orientation of tissue microstructure. This microstructure has a high degree of regional directional coherence in white matter and low coherence in gray matter. Thus DTI is able not only to distinguish these tissue types, but also to elucidate the bulk orientation of microstructure therein. This information provides the basis of DTI tractography – methods developed to determine the pathways of anatomical CNS connections in vivo.
Tractography involves calculating the fractional anisotropy (FA), which is a measure of the anisotropy of the tensor that indicates the degree of directional preference of the fibre bundles in any given voxel.\(^{15}\)

**ARTERIAL SPIN LABELLING**

ASL is a form of fMRI in which endogenous water molecules in arterial blood are given a special magnetization tag (‘inversion’) in the neck before entering the brain. The tagged images of the brain are then collected and allow cerebral blood flow to be determined. Owing to the lack of ionizing radiation, ASL is replacing PET in some studies.

**SINGLE-PHOTON-EMISSION COMPUTED TOMOGRAPHY**

SPECT, also known as single-photon-emission tomography (SPET), is a form of functional imaging that involves the use of a radioactive ligand. For assessing cerebral blood flow, the radioisotope or radiolabelled ligand needs to be introduced into the cerebral circulation, which can be carried out by, for example, injecting a solution of the radioactive ligand into the bloodstream or by asking the patient to inhale a gaseous form of the radioactive ligand. An example of the former is the radioligand \(^{99m}\)technetium hexamethylpropylene amine oxime (\(^{99m}\)Tc-HMPAO), while an example of the latter is the gas 133-xenon (\(^{133}\)Xe).

The radioactive ligand emits single \(\gamma\) photons. These are detected using gamma cameras. In the case of SPECT neuroimaging, the reconstruction of the \(\gamma\) photon data may reflect cerebral blood flow or cerebral tissue binding, depending on the nature of the ligand used.

One particular advantage of SPECT is that some \(^{99m}\)Tc-based ligands can be used to determine the cerebral blood flow at a time when the patient is not even in the same room as the gamma camera. For example, \(^{99m}\)Tc-HMPAO may be injected into the bloodstream in its lipophilic form. In this form, it can readily cross the blood–brain barrier. However, having done so, it may then be converted into a hydrophilic form in a reaction that is almost irreversible (Figure 32.19).\(^{16}\) As the hydrophilic form does not freely cross the blood–brain barrier, one has, as it were, obtained a binding of the radioligand in the brain that corresponds to the cerebral blood flow shortly after the time of injection into the bloodstream. There is then a window of opportunity of at least half an hour before the level of radioactivity has decayed too much, during which time the patient may undergo SPECT scanning. Clearly this is useful if one is trying to study unpredictable symptomatology, such as auditory hallucinations or epilepsy, which occurs when the patient is at a location different from that of the gamma camera (e.g. a patient with schizophrenia may be on a hospital ward at the time when he or she experiences auditory hallucinations). Although the spatial resolution of SPECT (of the order of 10 mm) is generally poorer than that of PET (around 5–7 mm) and fMRI, the advantage just mentioned of SPECT with radiotracers such as \(^{99m}\)Tc-HMPAO has made it a useful neuroimaging modality in some neuropsychiatric research studies. For example, McGuire and colleagues used SPECT to demonstrate increased blood flow in Broca’s area during auditory hallucinations in schizophrenia,\(^{17}\) while our
group have used it to study abnormal saccadic distractibility\textsuperscript{18} and religious delusions\textsuperscript{19} in schizophrenia.

Although largely taken over by PET and combined PET/CT (higher quality, higher spatial resolution, higher quantitative accuracy), and fMRI and ASL (no ionizing radiation), SPECT may have a role clinically in demonstrating early changes in cerebral blood flow in disorders such as Alzheimer’s disease\textsuperscript{20} and early dementia in Down syndrome.\textsuperscript{21}

**POSITRON-EMISSION TOMOGRAPHY**

PET is a form of functional imaging that is currently being replaced in many centres by scanners that combine PET and multi-slice helical CT. These combined PET/CT scanners allow structural CT data to be collected rapidly and then allow the PET functional data to be registered accurately to the structural data. The patient being scanned does not need to change his or her position in respect of the table on which they are lying; the CT and PET components are adjacent to each other in the single scanner gantry, as shown in Figure 32.20.

**Basic physics**

In 1928 Paul Dirac derived an equation in quantum mechanics, which has become known as the Dirac equation, from which he deduced the existence of an anti-particle to the electron. This was purported to have similar properties to the electron (e\textsuperscript{\textminus}), but with the opposite electrical charge (hence, e\textsuperscript{\textplus}). Dirac was proved to be right, with the positron, as this anti-particle is called, being observed in 1932. When a particle and its anti-particle interact, they undergo an annihilation reaction and their joint mass is converted into energy, in accordance with Einstein’s 1905 special theory of relativity. In the case of the interaction between a positron and an electron (each with mass 511 keV/c\textsuperscript{2}, where c is the velocity of electromagnetic radiation in vacuo and keV stands for kiloelectron volts), this energy, of 1022 keV, or approximately $2 \times 8.19 \times 10^{-14}$ joules, manifests itself as a dual $\gamma$ photon emission, with each $\gamma$ photon travelling in a direction that is diametrically opposite to that of the other, and each photon having an energy of 511 keV, or approximately $8.19 \times 10^{-14}$ joules.

In PET neuroimaging, a positron-emitting radionuclide is introduced into the cerebral circulation; as with SPECT, common methods are via intravenous administration of a radiotracer in solution or by inhalation of a gaseous radiotracer. A difference from SPECT is that in the brain the radionuclide emits a positron and a neutrino. After the positron interacts with an electron, the PET scanner detects the resulting dual $\gamma$ photon emission; with SPECT, only one $\gamma$ photon is emitted. The PET scanner detects these two photons (which, since they travel in opposite directions, are termed ‘anti-parallel’) in coincidence; two suitable photons detected within a certain period of each other, the coincidence window, are assumed to originate from the same positron–electron interaction. This process is summarized in Figure 32.21.

Not all coincidence pairs of $\gamma$ photons are true coincidences that pertain to the image. Some are caused by photon scattering or by random single-photon emissions, as shown in Figure 32.22. These scatter and random coincidences cause background noise in the imaging.

**Radionuclides**

Properties and production routes for radionuclides commonly used in PET are shown in Table 32.4. The table gives...
Neuroimaging

the maximum energy, \( E_{\text{max}} \), of positrons emitted from the radionuclides, in megaelectron volts (MeV). Note that 1 MeV is approximately \( 1.602 \times 10^{-13} \) J. The higher the positron energy, the further the positron can travel in tissue and the poorer the spatial resolution of the corresponding PET image.

The positron-emitting radionuclides in Table 32.4 that have low atomic numbers (conventionally denoted by \( Z \)) – that is, low numbers of protons in the nucleus – can be produced in small cyclotrons. These radionuclides are \(^{11}\text{C}, ^{13}\text{N}, ^{15}\text{O}\) and \(^{18}\text{F}\). Figure 32.23 shows a commercial PET cyclotron and the inner workings of one schematically; the dee is an electrode. Further details of how a cyclotron works are beyond the scope of this book. Once the radionuclides have been produced, the radionuclides have to be separated from non-radioactive by-products; this is achieved by a technique such as high-performance liquid chromatography (HPLC).

### 2-\(^{18}\text{F}\)Fluoro-2-deoxy-\(\beta\)-glucose

The radiotracer 2-\(^{18}\text{F}\)fluoro-2-deoxy-\(\beta\)-glucose (\(^{18}\text{F}-\text{FDG}, or just FDG), based on the radionuclide \(^{18}\text{F}\), is a marker for glucose metabolism. It is a synthetic analogue of the glucose molecule, in which a hydroxyl group is replaced with a radioactive fluorine-18 atom. Like glucose, \(^{18}\text{F}-\text{FDG}\) is readily transported into cells from the plasma, but, unlike

glucose-6-phosphate, after intracellular phosphorylation by hexokinase. $^{18}$F-FDG-6-phosphate is not acted upon by glucose-6-phosphatase and so remains trapped intracellularly, as shown in Figure 32.24. With a relatively long half-life of approximately 110 min and a cellular uptake similar to that of glucose, $^{18}$F-FDG is a particularly good radiotracer for use in PET neuroimaging. There is a relatively high uptake, of approximately 6 per cent, of administered $^{18}$F-FDG by the brain. Another advantage of this radiotracer is that units are now available that allow automated synthesis from reagents of quantities of $^{18}$F-FDG suitable for PET imaging in only around 40 min; Figure 32.25 shows one such unit.

The following techniques have been suggested to reduce physiological uptake of $^{18}$F-FDG in PET neuroimaging:\(^{22}\)
- Inject the patient in silence in a quiet darkened room
- Avoid stimulation during the uptake period
- Avoid any sedation for the uptake period
- The subject should avoid any glucose-containing sedation before visiting the PET centre.

**Research with radioligands**

PET neuroimaging has been used widely for psychiatric research. Specific radioligands are required when researching neurotransmission. For example, the study of dopamine (D2/D3) receptors in the brain using PET can be carried out with the dopamine receptor radioligand $[^{11}$C]raclopride; 5-hydroxytryptamine (5-HT)\(_{1A}\) receptors can be studied with [carbonyl-$[^{11}$C]WAY-100635 and [carbonyl-$[^{12}$C]desmethyl-WAY-100635; cannabinoid CB\(_1\) receptors (in non-human primates) can be studied with $[^{11}$C]MePPEP and $[^{18}$F]AM5144; and nicotinic acetylcholine receptors (nAChR) can be studied with the fluoropyridine derivatives 2-$[^{18}$F]FA and 6-$[^{18}$F]FA.
Neuroimaging

An example of the use of $[^{11}C]$raclopride is a study by Reeves and colleagues of the relationship between striatal dopamine (D2/D3) receptor availability and delusions in Alzheimer’s disease. This study tested the hypothesis that the symptom domains delusions and apathy are associated with striatal dopamine (D2) receptor function in Alzheimer’s disease. In vivo dopamine (D2/D3) receptor availability was determined with $[^{11}C]$raclopride PET in 23 patients with mild or moderate probable Alzheimer’s disease. Figure 32.30 shows the right-sided striatal regions of interest, derived from structural MRI, superimposed on a $[^{11}C]$raclopride PET image. The mean $[^{11}C]$raclopride binding potential in the striatum was found to be higher in patients with delusions than in those without delusions, as shown in Figure 32.26, showing that striatal dopamine (D2/D3) receptor availability is increased in Alzheimer disease patients with delusions.

PET is also useful in differentiating between intracerebral infection (commonly toxoplasmosis), which has no or low-grade $^{18}$F-FDG uptake, and intracerebral malignancy (commonly lymphoma) in patients with human immunodeficiency virus (HIV) disease presenting with neurological illness. This is illustrated in Figure 32.28, in which a focus of high $^{18}$F-FDG uptake in a patient with HIV disease was consistent with the diagnosis of lymphoma, and Figure 32.30, in which the photopaenic defect corresponding to an MRI lesion in a patient newly diagnosed with HIV was consistent with toxoplasmosis and not lymphoma.

PET is also useful in the diagnosis of dementia. Table 32.5 details the MRI and $^{18}$F-FDG PET findings in various dementias (see also Chapters 37 and 72). In addition to

---

**Clinical applications**

PET can be useful in determining whether or not a lesion seen on structural MRI of the brain is a recurrence of a tumour in a patient with a history of malignancy. The use of PET to identify metabolic changes associated with a recurrent high-grade tumour is illustrated in Figure 32.27. These scans are from a patient with a history of treated glioblastoma multiforme, in whom a structural MRI scan (Figure 32.27a) showed a large mass with oedema, pointing to a possible diagnosis of recurrent tumour. The PET scan (Figure 32.27b) showed increased metabolic activity associated with the mass in the interposterior aspect of the left frontal lobe compatible with recurrence. The diffuse decreased activity in the left frontal region is consistent with post-radiation changes.

**Figure 32.27** Magnetic resonance imaging (MRI) scan, showing a 50cm mass with oedema, suggestive of recurrent tumour, in a patient referred with a history of glioblastoma multiforme treated with surgery, chemotherapy and radiotherapy 4 years earlier. (b) Positron-emission tomography (PET) scans, showing increased metabolic activity associated with the mass in the interposterior aspect of the left frontal lobe compatible with recurrence. The diffuse decreased activity in the left frontal region is consistent with post-radiation changes

aiding in the differential diagnosis of dementia. $^{18}$F-FDG PET is useful in differentiating between early Alzheimer’s disease and benign memory loss, and also in differentiating dementia from pseudo-dementia or depression. Three examples of the use of PET in different dementias follow.

Figure 32.28 Magnetic resonance imaging (MRI) and positron-emission tomography (PET) scans of the brain of a child who had undergone multiple surgery, chemotherapy and radiotherapy for an anaplastic ependymoma. Although neurologically stable with a left hemiplegia, she complained of new headaches. The MRI scan (left) showed an enhancing region in the right parietal lobe suggestive of recurrent disease. $^{2-}$[F]fluoro-2-deoxy-o-glucose ($^{18}$F-FDG) (middle) was registered to the MRI scan (right). The region of enhancing tissue on MRI did not take up $^{18}$F-FDG (solid arrow), indicating that this was likely to be scar or inflammatory tissue. The small focus of $^{18}$F-FDG uptake (broken arrow) in the right parietal region corresponded to an island of normal cortex on MRI.

Figure 32.29 $^{2-}$[F]fluoro-2-deoxy-o-glucose ($^{18}$F-FDG) positron-emission tomography (PET) findings from a patient with human immunodeficiency virus (HIV) disease, who was referred with a magnetic resonance imaging (MRI) lesion of unknown nature in the right parietal lobe. There was a focus of intense uptake in the right parietal lobe posterior to the thalamus. Biopsy revealed lymphoma.

Figure 32.30 This patient with newly diagnosed human immunodeficiency virus (HIV) presented with a 6-week history of headache and increasing confusion associated with pyrexia. (a) Magnetic resonance imaging (MRI) showed a lesion centred on the right lentiform nucleus, with surrounding oedema and mass effect, consistent with toxoplasmosis or lymphoma. (b) There was a photopaenic effect on positron-emission tomography (PET) corresponding to the MRI lesion and consistent with toxoplasmosis and not lymphoma. The PET scan also shows diffuse reduction in the right frontoparietal region. The patient showed good clinical response to treatment with anti-toxoplasmosis therapy.

Figure 32.31 shows $^{18}$F-FDG PET images from a patient who presented with word-finding difficulties and memory impairment; cognitive testing revealed a global pattern of impairment, but with the left hemisphere more severely affected. The bitemporal, posterior parietal and temporal hypometabolism seen on PET were consistent with Alzheimer’s disease; note that the preservation of cortical $^{18}$F-FDG uptake in the posterior cingulate cortex weighs against a diagnosis of Lewy body dementia.

**Figure 32.31** 2-\[^{18}\text{F}\]fluoro-2-deoxy-d-glucose (\(^{18}\text{F}\)-FDG) positron-emission tomography (PET) findings in a patient with word-finding difficulties and memory impairment. The bitemporal, posterior parietal and temporal hypometabolism seen on PET were consistent with Alzheimer’s disease. The two black arrows on either side of the middle transverse image in the most right-hand column of images correspond to the level of the coronal scan shown at the top left. Reproduced with permission from Barrington, *Atlas of Clinical Positron Emission Tomography*, 2nd edn. Hodder, London. (2005).
Figure 32.32 shows $^{18}$F-FDG PET images from a patient with Lewy body dementia; metabolism was reduced in the parietotemporal association cortices and frontal association cortex. The pattern of reduction in metabolism in the association cortices in Lewy body dementia is similar to that seen in Alzheimer’s disease; although the cerebral hemispheres are involved bilaterally, the involvement may be asymmetrical in Lewy body dementia (in Figure 32.32 the metabolic reduction is more severe on the left); and metabolic reduction often occurs in the occipital cortex in Lewy body dementia.\(^{22}\)

Figure 32.32 shows $^{18}$F-FDG PET images from a patient with Pick’s disease (frontotemporal dementia), in which there is bilateral reduction in $^{18}$F-FDG uptake in the frontal lobes. Reduced uptake in the temporal lobes is also sometimes seen.

**KEY POINTS**

- CT is a form of structural imaging that offers very high spatial resolution and uses X-rays.
- Structural MRI is a form of structural imaging that offers very high spatial resolution and does not involve the use of ionizing radiation. Image registration and voxel-based morphometry are just two of many advanced techniques that can be applied to MRI data.
- BOLD fMRI is a form of functional imaging that does not involve the use of ionizing radiation.
- MRS is a form of functional imaging that allows tissue chemistry to be studied in vivo.
- FLAIR is an MRI sequence that suppresses the signal from CSF and minimizes the contrast between grey matter and white matter.
- DTI tractography is an MR technique that allows the determination of the pathways of anatomical central nervous system connections in vivo.
- ASL is a form of functional imaging that allows cerebral blood flow to be determined without the use of ionizing radiation.
- SPECT is a form of functional imaging employing radiotracers to study regional cerebral blood flow and ligand binding.
- PET is a form of functional imaging employing radiotracers to study metabolic changes, regional cerebral blood flow and ligand binding.

BASIC CONCEPTS

Introduction
Genetics is the scientific study of the inheritance of traits both physical and behavioural. Genes provide the assembly code for the molecules that make up life and enable reproduction of living organisms. Genes are located on chromosomes, which are highly folded and compressed linear molecules of deoxyribonucleic acid (DNA) housed in the nuclei of cells. They pass from generation to generation, providing familial resemblance and individual variation, which, through evolution, is responsible for the diversity of life. This chapter describes the basic principles of genetics and their relevance to psychiatric disorders. The first use of the term ‘genetics’ was in 1906 by the biologist William Bateson, but the science of genetics began much earlier. Gregor Mendel, a monk working in the monastery in Brno in 1866, described laws of inheritance based on his observations of the inheritance of seven simple bimodal traits in pea plants. Mendel suggested that each parent plant had a pair of units of inheritance for each trait but contributed only one unit from each pair to its offspring.

Mendel’s first law (the law of segregation) states that one of an individual’s two units of inheritance (alleles) at any location is randomly distributed to each gamete. This is seen in the pattern of inheritance of autosomal dominant disorders such as Huntington’s disease.

Mendel’s second law (of independent assortment) states that the segregation of the alleles for any one trait to a gamete occurs independently of the segregation of the alleles for any other trait to that gamete. This law is true only for alleles not genetically linked (physically located close) to each other, and departure from it forms the basis of linkage analysis and has enabled genetic maps to be constructed and used to locate genes responsible for disorders.

Thomas Morgan demonstrated that genes were arranged linearly on chromosomes within cell nuclei and could be inherited together, depending on the physical distance between them and the frequency of recombination (see below) in the region. Morgan also demonstrated that linkage is rarely complete and that some traits are sex-linked.

In 1944, Oswald Avery, a Canadian bacteriologist, confirmed that genes were composed of DNA by transferring DNA from one strain of bacteria to another. He showed that the second strain acquired traits from the first and could pass these traits to future generations. In 1953, geneticists James Watson and Francis Crick discovered that the DNA molecule is composed of two long strands in the form of a double helix. Their deduction of the structure of DNA was made from X-ray photographs taken by a British scientist Rosalind Franklin and a New Zealander Maurice Wilkins. Crick and Watson deduced that DNA resembled a long spiral ladder with a sugar–phosphate backbone and rungs composed of pairs of complementary nucleotide bases. This structure immediately suggested that the molecule could unwind, separating at the nucleotide bases, and each half-strand could form a template for rebuilding the second strand and generating two identical copies. Thus, the genetic code could be replicated and transmitted to dividing cells and across generations.

By this time, it was known that genes produced proteins and scientists speculated that a genetic code, encrypted in the order of nucleotide bases, must determine the sequence of amino acids in proteins. Only four different nucleotides had been identified in DNA, but at least 20 different amino acids were known to occur in proteins. In 1962, Crick determined that the coding sequence is a series of three nucleotide bases and that each amino acid is specified by at least one of these sequences, called a codon.

More recent developments have made significant contributions to the new science of molecular genetics. Fredrick Sanger developed methods for analysing the molecular structure of proteins and for rapidly determining the nucleotide sequence of nucleic acids. Ed Southern provided a method for transferring DNA from a gel to a membrane, where it could be detected, and Kary Mullis developed the polymerase chain reaction (PCR), which allowed rapid enzymatic synthesis of multiple copies of a specific DNA sequence.

Chromosomes, cell division and genes
DNA is tightly packaged and protein-bound into 22 homologous pairs of chromosomes and two X chromosomes in
females or an X and a Y in males (46 chromosomes in all). The total DNA complement in a cell is referred to as its genome. If placed end to end and unraveled, human DNA is over 2 m long and contains approximately 3.9 x 10^9 base pairs. Only 2–3 per cent of the genome consists of the coding sequences of approximately 30,000 genes. Much of the remaining DNA has no apparent function, but emerging possibilities include the regulation of DNA structure, repair and expression.

A gene is a length of DNA, some of which codes for a string of amino acids. Because chromosomes exist in homologous pairs, there are normally two copies of each gene in the human genome. The two copies are termed alleles. Due to mutations over time, the DNA base sequence throughout the genome, including within genes, varies between individuals and between the two copies possessed by an individual. This and the environment – the ‘slings and arrows of outrageous fortune’ – are what create differences between individuals. Thus, alleles may be the same (homozygous) or different (heterozygous). If different, the locus can be described as polymorphic. Mendel’s first law states that only one allele for each gene may be inherited from each parent. At a given locus, the two alleles constitute the individual’s genotype. If the locus is a gene, then the expression of the trait coded for by the genotype is called the phenotype. In this context, ‘phenotype’ is a broad term that would include the results of biochemical or protein analysis or might be outwardly observable in the form of a normally distributed trait (e.g. height) or the presence or absence of a disease state (e.g. Huntington’s disease). If individuals with one copy of a given allele have the same phenotype as individuals with two copies, then the allele is said to be dominant. If two copies of an allele are required to produce the phenotype, then the allele is termed recessive. If the phenotype of individuals with one copy is intermediate between those with none and those with two, then the allele is co-dominant.

Somatic cells are the general cells throughout the body and are diploid, having 23 pairs of chromosomes, but sex cells (gametes) have only 23 chromosomes and are termed haploid. These differences in chromosome number, on which sexual reproduction depends, arise because somatic cells replicate by mitosis and gametes by a more complicated process called meiosis. In mitosis, chromosomes are duplicated in the prophase stage of the cell cycle. The duplicated chromosomes join at a constricted chromosomal region called the centromere to form sister chromatids. In metaphase, a spindle forms from a centriole at each cell pole to the centromere. During anaphase, the spindles retract, pulling a chromosome to each pole and distributing the chromosomes equally between two daughter cells identical to the parent cell (telophase).

Gametes are produced by meiosis, in which daughter cells receive only half the number of chromosomes. During the prophase stage of meiosis, each chromosome of each homologous pair duplicates itself, and the resulting sister chromatids are joined at the centromere. Each homologous pair of chromosomes produces a tetrad consisting of four chromatids. Non-sister (one from each parent) chromatids pair together and physically recombine (cross over), exchanging DNA. The cell now divides into four cells, each haploid and each containing a single chromatid from the tetrad. At fertilization, when gametes fuse, the normal diploid state of 46 chromosomes is restored. These two processes, recombination and random assortment of chromosomes at fertilization, contribute to individual differences and diversity within species.

Each chromosome is divided by the centromere into two arms, termed p and q, usually of different lengths. Staining procedures of chromosomes produce pale or dark bands of varying thickness specific to each chromosome, allowing individual chromosomes or chromosomal regions to be consistently identified. A standard nomenclature is used when studying chromosomal regions. For example, a locus in the second subdivision of the first band on the p arm of chromosome 8 would be termed 8p1.2.

**Molecular genetics**

Molecular genetics is the branch of genetics that investigates the chemical and physical nature of genes and the mechanisms by which genes control development, growth and physiology. Each chromosome contains a molecule of DNA composed of a backbone of sugar (deoxyribose) and phosphate, the purine bases adenine (A) and guanine (G), and the pyrimidine bases cytosine (C) and thymine (T). These repeating units of five-carbon sugar, phosphate and organic bases are called nucleotides. The DNA molecule is a double helix, resembling a spiral ladder, where each side is composed of alternating deoxyribose and phosphate molecules, with pairs of bases as rungs. Because bases can pair only by forming hydrogen bonds between T and A, or G and C, the sequence of one DNA strand is dependent on the sequence of the other, and so the strands are complementary. The DNA molecule unwinds during cell division, and each strand acts as a template for the production of a new strand with a complementary sequence of nucleotides. As this new sequence forms, DNA polymerase enzymes bind deoxyribonucleotides and fit them in place with the phosphate group of each incoming nucleotide being joined enzymatically to the 3’-deoxyribose group of the previous nucleotide. Because of the number of base pairs in a chromosome, replication is initiated at many different sites along each template and the segments of newly formed DNA are joined together with phosphodiester bonds by ligase enzymes. In mammalian chromosome replication, approximately 3000 nucleotides are added per minute, with an estimated accuracy of greater than 99.98 per cent. Errors in this process are called mutations; these can be occur naturally but are also induced by external agents (mutagens) such as radiation, ultraviolet light, and various chemicals.

The information for protein production contained in
DNA is decoded (transcribed) by a similar molecule (ribonucleic acid, RNA) and transported from the nucleus to ribosomes in the cytoplasm for translation into amino acids and protein construction.

Transcription begins when a section of the DNA molecule unzips and one of the DNA strands acts as a template for synthesis of an RNA transcript. The DNA gene sequence is preceded by an upstream signal region that initiates transcription and is succeeded by a downstream region containing a termination sequence. RNA differs from DNA by being single-stranded, having ribose instead of deoxyribose as its sugar, and having uracil (U) instead of the base thymine. Within a DNA gene sequence, there may be redundant, non-coding regions (introns) and coding regions (exons). After transcription, the introns are enzymatically removed and the exons spliced together in the correct order to form functional messenger RNA (mRNA). Exons can be spliced together in many different ways, so that different gene products can be generated in different tissues from the same structural gene. The Human Genome Project has shown that it is the complexity of gene regulation and alternative splicing rather than a large increase in the number of genes that largely explains the evolution of more complex organisms.

Translation involves transfer of genetic information from mRNA into a sequence of linked amino acids to form proteins. As described above, specific three-base sequences (codons) individually code for each amino acid, and this code is the same in all living organisms. The mRNA transcript initially attaches to a ribosome. Amino acids are brought to the ribosomes by transfer RNA (tRNA) molecules, which also have specific three-base sequences (called anticodons) complementary to the codons of mRNA. Thus, mRNA is translated into the amino acid sequence when tRNA anticodons line up along mRNA codons and construct the amino acid sequence specified by the mRNA. The ribosome moves along, ‘reading’ the mRNA until the protein specified by the original DNA sequence has been produced.

Cells require the ability to activate or repress transcription of genes during development or in response to the environment. Proteins called transcriptional factors can bind to DNA to activate or repress transcription, and extracellular factors such as hormonal activity can also influence transcription.

Mutations

A mutation that arises during mitotic division in non-gamete cells is called a somatic mutation and is not heritable. Mutations in cells that go on to produce gametes are called germ-line mutations and may be transmitted to the next generation. The simplest form of mutation involves a single base pair (a point mutation). The term ‘mutation’ refers to any change in sequence or structure, but it is sometimes taken to mean a change that causes or contributes to a disease or abnormal phenotype. If the DNA variant created by a mutation event becomes common in the population over time, then it is known as a polymorphism.

Point mutations are made up of base-pair changes or the loss (deletion) or gain (insertion) of a single base. If the change occurs in the coding region of a gene, then it may produce a codon that specifies a different amino acid (missense mutation) or that changes the sequence to a stop codon, causing production of an incomplete protein (a nonsense mutation).

Deletions, insertions and inversions involve larger sequences of DNA up to the point at which they become visible cytogenetically. It has become apparent that this type of mutation (and variation) is much more common in the human genome than previously considered. These types of submicroscopic chromosomal abnormality are called copy number variations (CNVs; see page 472).

Chromosomal mutations are often lethal, as they involve a change in the number of chromosomes or the translocation or rearrangement of large sections of chromosomes. The condition where the number of chromosomes is different from the normal diploid complement of 46 is called aneuploidy. Where embryonic development is possible, the phenotypic effects of aneuploidies are often clinically recognizable. Down syndrome (caused by an extra chromosome or rarely a translocation at chromosome 21), Edwards’ syndrome (trisomy 18) and Patau syndrome (trisomy 13) are examples of autosomal aneuploidies. Aneuploidies that involve extra sex chromosomes often have less biological impact, although distinct phenotypes are recognized, such as Turner’s syndrome (XO, females with one X chromosome) and Kleinfelter’s syndrome (XXY).

Human Genome Project and DNA variation

Despite the description about DNA variation above, in any two randomly selected human genomes 99.9 per cent of DNA sequence is identical. The 0.01 per cent that is variable accounts for the genetic contribution to individuality, susceptibility to disease and population diversity. The Human Genome Project and the subsequent HapMap project have generated vast biological and database resources, including the sequence of the human genome and a catalogue of sequence, and more recently, structural variation. To date, many millions of DNA variants have been identified and are publicly available to researchers (see www.ncbi.nlm.nih.gov/SNP) seeking to map disease or trait genes.

Mendelian inheritance

Mendelian inheritance applies to the patterns of inheritance in human diseases caused by single mutations, where the mutation is both necessary and sufficient to cause the disease and is said to have a major gene effect.

 Autosomal dominant disorders are the most common Mendelian disorders (7 per 1000 live births) and are
apparent in individuals having one (heterozygous) or two (homozygous) mutant genes. Such conditions will, on average, affect half of all individuals in a sibship. If a proband has a dominant disorder, then one of their parents will also be affected, unless the disorder represents a new mutation. The extent to which a heterozygote shows features of the disorder is described as the penetrance of the condition; for example, the Huntington’s mutation has an age-related penetration of almost 100 per cent.

Autosomal recessive disorders are less common (<3 per 1000 live births), partly because the disorder is expressed only if the individual has two copies of the mutated gene. As with dominant disorders, the extent of expression depends on the penetrance of the mutations. If both parents are heterozygous for the mutant gene, then on average one in four children will be affected, as is the case in cystic fibrosis, for example.

X- (or sex-) linked disorders arise from mutations of the sex chromosomes and follow different inheritance patterns because males can only pass on their Y chromosomes to sons. Most X-linked conditions are recessive. A heterozygotic mother may pass on the mutant gene to her son, and he will be affected, while a heterozygote sister of the son will be a carrier. Affected males transmit the carrier state to half of their daughters but do not transmit the disease to their sons, as is the case with Duchenne muscular dystrophy.

Mitochondrial disorders are rare single-gene disorders caused by mutations in a mitochondrial gene. These follow a distinct maternal inheritance pattern because mitochondrial DNA in fertilized embryos is acquired exclusively from the ovum, as sperm do not contain mitochondria.

**COMPLEX MODELS OF INHERITANCE**

Common biological traits and behaviours are not categorical but are distributed quantitatively in the general population. These are likely to be determined by the interaction between many genes and the environment. Each gene (strictly speaking, each gene variant) contributes a small incremental effect, and these are known as genes of minor effect. Genes or locations on the genome that contribute to biological traits or behaviours that display these characteristics are called quantitative trait loci (QTLs).

Many common disorders with a demonstrated genetic component are thought to be due predominantly to genes of minor effect, which are neither necessary nor sufficient to cause the disorder but increase risk. Each minor or risk gene may have an effect independent of all other genes (an additive component), effects that are dependent on the other allele at that locus (a dominant interaction), or effects that are influenced by genotype at other loci (epistatic interactions). The proportion of the total variance of a trait in a population explained by additive genetic effects is called its heritability ($h^2$).

**MOLECULAR GENETICS: TECHNIQUES AND TERMINOLOGY**

**Recombinant DNA technology**

Recombinant DNA technology, or molecular cloning, is an umbrella term for the process of introducing a gene from an organism into a host cell, where it can be replicated and studied. When two different DNA samples are mixed together in the presence of a DNA ligase enzyme, the two ends anneal, forming a new DNA sequence that can be inserted into a cloning vector, often a plasmid, a small circular piece of DNA found naturally in bacteria and other organisms. This vector, when inserted into a host bacterial cell, replicates with the bacteria when cultured, allowing millions of copies of the original DNA sequence to be obtained (cloned).

**Polymerase chain reaction: enzymatic DNA amplification**

In the PCR, small pieces of DNA, called oligonucleotide primers, are chemically synthesized to be complementary to the DNA on either side of the sequence to be amplified. Mixing these primers with DNA containing the sequence to be amplified, a supply of individual nucleotides and a heat-stable DNA polymerase enzyme at a suitable temperature, these primers bind to their complementary sequences on each strand. Next, the individual DNA bases extend along the strand reforming the double helix. On heating to over 90 °C, the strands separate and the process begins again, with twice the number of molecules at the target. This procedure is automated by machines that cycle the reaction mixture through at the different temperatures to produce a large number of copies of the target DNA sequence.

**Genotyping**

Newer methods of detecting DNA variation have developed rapidly over the past 10 years, at least in part due to the Human Genome Project and HapMap. Using the DNA ‘chip’ technologies, the genotypes at thousands and even millions of locations across an individual’s genome can now be produced rapidly. Recent developments include specialized chips designed to identify DNA CNVs across the genome. CNVs are now thought to contribute a substantial component of risk for many common disorders, including neuropsychiatric disorders.

**Genomics and bioinformatics**

Genetics is the study of individual genes and their effects. Genomics is the study of the functions and interactions of all the genes in the genome. Bioinformatics is a new science that has evolved to cope with the growing banks of
molecular sequence and structural data. This involves computational methods for retrieval and analysis of data, including algorithms for sequence similarity searches, and prediction of the structure and function of genes. The available bioinformatics resources are now so extensive that, coupled with the increasing public availability of raw genomic data from government-funded research, much genetics research is being conducted in silico.

CONFIRMING A GENETIC CONTRIBUTION TO DISEASE: FAMILY, TWIN AND ADOPTION STUDIES SUPPORTING GENOMIC RESEARCH

Family studies can demonstrate that a disorder is familial, occurring more commonly in relatives of a proband than in the general population. This information can be collected either by taking a detailed family history from affected individuals or their relatives (the family history method), or more rigorously by using a family study approach, where all affected individuals are directly interviewed. Familiality may be due to shared genes or shared environment. For example, speaking the same language or going to medical school/being a doctor are familial but are due (mostly) to shared environment. Two natural forms of biological and social experiment, namely twin births and adoption, allow some separation of genetic and environmental effects.

Twin studies

Monozygotic (MZ) twins arise from a single fertilized ovum and so share identical genomes. Dizygotic (DZ) twins develop from different ova and, like any full siblings, share on average 50 per cent of their genes. Twin research assumes that twins share environmental effects equally. If both twins have a disease, then they are said to be concordant for that condition, but if only one twin is affected, then they are described as discordant. Higher concordance of disease in MZ twins than in DZ twins is strong evidence of a genetic contribution to disease, but there are several caveats. Ascertainment bias at recruitment is a potential flaw, but researchers try to overcome this problem by exploiting national or local twin registers to systematically screen all twin births. Twin studies assume that twins within a family share the same environment. This may not be completely true: environmental factors, including prenatal nutrition and birth trauma, may differ between twins. Being a twin in itself may contribute to illness.

Adoption studies

These studies examine the effect of being adopted into or out of a family with a specific disorder using a variety of designs. Adopted children who become ill may be identified and rates of illness compared in their adoptive and biological families (the adoptee family method). Adoption can also be studied prospectively, by using the parent as the proband. In this adoptee study method, the rates of illness in adopted offspring of affected individuals are compared with rates in adopted offspring of individuals without the disorder. As with twin studies, there are caveats. A child having affected biological parents may influence potential adoptive parents; adopted children may experience particular intrauterine effects; age at adoption is often overlooked; and adoption is a rare event.

If independent evidence from family, twin and adoption studies points to a significant genetic component for a disease or a trait, then it is reasonable to assume that one exists. An examination of the pattern of transmission in families coupled with twin results and general population frequency may suggest a particular Mendelian mode of inheritance or point to more complex patterns, including oligogenic models (5–20 genes) or polygenic models with hundreds of genes, each of very small effect. Genetic heterogeneity is also possible, with different genes causing the same or a similar disorder in different families, and mixed models are also likely. Few of these models can be determined conclusively in advance of molecular genetic studies.

QUANTITATIVE AND MATHEMATICAL ASPECTS OF GENETICS

Hardy–Weinberg law

This law states that the frequencies of alleles will, in the presence of random mating and in the absence of disturbances including mutation, natural selection, migration, inbreeding and random genetic drift, remain constant from generation to generation. Thus, let two polymorphic alleles A and a exist in a population. If their frequencies of occurrence (expressed in decimals) are p and q, respectively, then p+q = 1, and if mating between individuals is random, then after one generation the frequencies of the three genotypes will be p², 2pq and q². This generation will produce gametes A and a with frequencies p and q, similar to the previous generation. A sample of individuals is said to be in Hardy–Weinberg equilibrium if the frequencies of the observed genotypes AA, Aa and aa are statistically the same as the expected frequencies derived from allele frequencies using the above formula.

Recombination fraction

The process of recombination occurs during meiosis and, according to Mendel’s second law, polymorphic DNA variants on separate chromosomes will segregate independently of each other. Even on the same chromosome, many variants will segregate independently if they are physically separated along the chromosome by some distance. The
recombination fraction is defined as the number of recombination gametes divided by the total number of gametes and, for independently segregating variants, takes the value 0.5. This measure is termed Morgans and 50 cM is the value relating to independent segregation between variants (or between a variant and a disease mutation). This means that if the recombination fraction (θ) between two loci is less than 0.5, then they are not independently segregating and instead are linked, meaning in physical terms that they lie close together on the same chromosome. Genetic distance in cM is closely but not completely correlated with physical distance, because the probability of recombination varies across the genome. 1 cM is the genetic distance corresponding to a recombination fraction (θ) of 0.01, which is roughly equivalent to 1 million base pairs of DNA. The analysis of recombination in families is used in linkage analysis to identify polymorphic DNA variants that are linked to the disease mutation (θ < 0.5), thus showing the approximate location of the mutation. Linkage analysis estimates θ and tests whether its is significantly less than 0.5. The conventional statistical method of doing this is to calculate a log of the odds (LOD) score. This is the common logarithm of the probability that the recombination fraction θ has some given value, divided by the probability that the value is 0.5. Where the mode of inheritance is known and the phenotype can be clearly defined, a LOD score of 3 (odds in favour of linkage 1000:1) is accepted as statistical proof of linkage and a score of −2.0 (odds against of 100:1) as proof of exclusion of linkage. However, the LOD score takes Bayesian theory into account, whereby the prior odds that two loci are linked is about 1:50. The observed odds ratio (OR) of a LOD score of 3 is 1000:1, leading to a posterior probability of about 20:1, roughly equivalent to a P value of 0.05. The LOD score method depends partly on the specified model of inheritance of the disease mutation and so may be less reliable when the model is unknown.

**GENETIC ASSOCIATION METHODS AND LINKAGE DISEQUILIBRIUM**

In their simplest form, association studies look for differences in allele frequencies between populations of patients and healthy controls. If the patient population has a specific allele more frequently than the control population, then that allele is said to be associated with the disorder. It is important to match populations carefully for studies of this type, because different allele frequencies among ethnic groups, called population stratification, can cause false positive results. To avoid this difficulty, many studies use ethnically homogeneous populations or a family-based approach including the non-transmitted parental allele as the control group. This design tests for departure from Mendel’s first law. Until recently, association studies were hypothesis-driven and selected potential candidate genes or DNA variants based on genes associated with known biological systems. However, with technological advances, it has been possible to take a genome-wide hypothesis free approach. Apart from the technological advances required, this approach is also possible because of the presence of linkage disequilibrium (LD) within populations. LD is a form of linkage where the ‘pedigree’ selected is the entire population and the number of generations is unknown. If two genetic variants are in very close proximity, then they are said to be in LD when recombination between them is rare, even over many generations. Thus, a limited selection of DNA variants can statistically represent the majority of variation in the genome. Current DNA chips contain up to 1 million variants and the coverage of sequence variation is constantly improving.

**CHROMOSOMAL ABNORMALITIES**

Structural chromosomal abnormalities can result from deletions (part of the genetic material is lost), duplications (a portion of the chromosome is duplicated, leading to extra genetic material), inversions (a chromosomal rearrangement in which a segment of the chromosome is reversed), insertions (a portion of one chromosome is inserted into another chromosome) and translocations (reciprocal translocation occurs when there is exchange of material between two different chromosomes). Studying such chromosomal abnormalities in people with mental illness can lead to identification of candidate genes and help to refine areas of linkage.

**Deletions and micro-deletion syndromes**

Velocardiofacial syndrome (VCFS), Prader–Willi syndrome and Angelman syndrome are commonly caused by micro-deletions.

**Velocardiofacial syndrome**

In more than 90 per cent of cases, VCFS is caused by a hemizygous micro-deletion in chromosome 22q11.2. The phenotype of the syndrome is diverse but is of particular interest to psychiatry because of the behavioural and psychiatric aspects of the condition. Between 10 per cent and 30 per cent of individuals with VCFS are diagnosed with schizophrenia, bipolar affective disorder (BPAD), autism spectrum disorder or schizoaffective disorder. Attention deficit hyperactivity disorder (ADHD) and poor social skills are also observed at a higher than expected frequency in VCFS. Estimates of prevalence of VCFS vary, but it is thought to occur in 1 in 4000 live births. The disorder can be inherited in an autosomal dominant fashion, but de novo mutations are more common. A large study investigating the cause of the deletion has reported that it appears to result from aberrant meiotic interchromosomal
exchange. The deleted region of 22q11.2 associated with VCFS contains approximately 35 genes. Within this deletion, the TBX1 gene is thought to be largely responsible for the phenotype of VCFS. This gene plays a relatively clear role in cardiac development, but its influence on the behavioural and psychiatric phenotype is less well understood. Catechol-O-methyltransferase is another gene in the deleted region that been implicated in the psychiatric manifestation of the disorder.

**Prader–Willi syndrome and Angelman syndrome**

Prader–Willi syndrome and Angelman syndrome are rare neurogenetic disorders that result from loss of expression of paternal (Prader–Willi syndrome) or maternal (Angelman syndrome) genes on chromosome 15q11–13. Prevalence of Angelman syndrome is estimated to be between 1 in 20 000 and 1 in 10 000 live births, and prevalence of Prader–Willi syndrome is estimated to be between 1 in 15 000 and 1 in 12 000 live births.

Molecular mechanisms that can lead to the imbalance between maternal and paternal gene expression include micro-deletions, point mutations, uniparental disomy and imprinting. Micro-deletions are the most common cause of Prader–Willi syndrome and Angelman syndrome. Uniparental disomy occurs when a person receives two copies of a chromosome, or part of a chromosome, from one parent and no copies from the other parent. This is thought to account for about 20–30 per cent of cases. Imprinting refers to the phenomenon whereby genes are expressed only from the allele inherited from the mother or the father. Imprinting defects in Prader–Willi syndrome and Angelman syndrome are thought to result from abnormal methylation status of important regions in the Prader–Willi syndrome/Angelman syndrome imprinting centre.

The most common genetic abnormality in Angelman syndrome is a maternal deletion of a region on chromosome 15q11–q13, which results in loss of functional expression of the gene UBE3A. This gene codes for an enzyme called ubiquitin protein ligase 3A, which attaches ubiquitin protein to proteins that should be degraded. However, the molecular mechanisms leading to the phenotype in Angelman syndrome are not yet understood.

In Prader–Willi syndrome, the majority (about 75%) of cases are due to de novo deletion of a region on the paternal chromosome 15q11–q13, with subsequent loss of functional expression of paternal copies of the small nuclear ribonucleoprotein polypeptide N (SNRPN) gene and necdin gene among others. The role of these genes is not well understood. The protein encoded by the necdin gene may suppress growth in postmitotic neurons, but to date little is known about how it influences the phenotype in Prader–Willi syndrome.

**Translocation disrupting DISC1 gene**

Disrupted-in-schizophrenia 1 (DISC1) is a gene whose mutant truncation is associated with major psychiatric illness, in particular schizophrenia. Cytogenetic, linkage and association studies have identified the DISC1 gene on chromosome 1 as a positional candidate conferring susceptibility to schizophrenia. DISC1 may play a role in the regulation of cytoskeletal function. The variant of DISC1 affects neuronal functions such as migration and intracellular transport, as these require intact cytoskeletal function.

**Duplications and unstable repeat disorders**

An interstitial duplication on chromosome 15 – dup(15)(q24q26) – has been associated with panic disorder, agoraphobia, social phobia, simple phobia and joint laxity.

There are many nucleotide repeat sequences in the human genome. Pathogenic duplication, or expansion, of such repeat sequences results in a number of neuropsychiatric disorders including fragile X, myotonic dystrophy, Friedrich’s ataxia, spinal and bulbar muscular atrophy, Huntington’s disease, the spinocerebellar ataxias, dentatorubral-pallidolusyans atrophy and Machado–Joseph disease.

Unstable repeats can be coding (resulting in altered protein function) or non-coding (resulting in loss of protein function or altered RNA function). Unstable CAG repeats cause alteration of protein function in a number of disorders, including most of the spinocerebellar atrophies, Huntington’s disease, dentatorubral-pallidolysa atrophy and spinal and bulbar muscular atrophy. For example, Huntington’s disease is caused by multiple copies (> 35 repeats) of a trinucleotide repeat sequence (CAG) within the coding region of the huntingtin gene on chromosome 4; the mutation leads to an abnormally expanded polyglutamine tract in huntingtin. Unstable trinucleotide repeats in fragile X syndrome (CGG repeat), fragile X syndrome E (CCG repeat) and Friedrich’s ataxia (GAA repeat) result in loss of protein function (FMR1, FMR2 and FRDA proteins).

The myotonic dystrophies are caused by trinucleotide (CTG) and tetrancleotide (CCTG) expansions, which result in altered RNA function. Fragile X tremor/ataxia syndrome also results from an expanded repeat (CGG), which alters RNA function. In a number of other disorders, including some of the spinocerebellar atrophies, the pathogenesis of the nucleotide repeats remains unknown.

Genetic anticipation occurs in many of the nucleotide expansion disorders. This refers to the effect whereby a parent carrying a copy of the gene with a moderate number of repeats may not exhibit any (or only minor) symptoms of the disorder, and yet when the gene is inherited by their child the number of repeats expands dramatically, leading to disease manifestation at a young age.

**Inversions**

An inversion of chromosome 9 – inv(9)(p11q13) – has been associated with schizophrenia in a number of studies.
Insertions

Insertion of 2q11.2–q21.1 into 8p21.3, leading to a partial trisomy of 2q, has been associated with schizoaffective disorder, psychotic illness and learning disability.5

Translocations

A reciprocal translocation – t(1;11)(q42;q14.3) – is associated with schizophrenia, BPAD and major depression.6 Bipolar disorder and unipolar depression have also been associated with a reciprocal translocation between chromosomes 9 and 11 – t(9;11)(p24;q23.1).7 Another reciprocal translocation – t(18;21)(p11.1;p11.1) – has been associated with schizophrenia, psychotic episodes and paranoid traits in one family.8

Copy number variants

A CNV is a structural chromosomal abnormality characterized by variation in the number of copies of a particular gene or sequences of DNA in a person’s genome. Normally, humans have two copies of each region of the genome, one per chromosome. CNVs may be inherited, may result from aberrant replication, or may be caused by mutations including deletions, duplications, inversions, insertions and translocations. It is now thought that CNVs may have a significant influence on susceptibility to a number of common diseases, including neuropsychiatric conditions. CNVs have been reported in autism and schizophrenia (see below), and work is ongoing in the search for CNVs in other psychiatric conditions.

Clinical genetic services

In the UK and Ireland, there are centres providing clinical genetic services. In general, these services include genetic counselling, clinical cytogenetics and molecular genetics. Prenatal genetic testing may also be offered.

Genetic counselling

Genetic counselling has both a diagnostic and a supportive role and is offered to individuals with a genetic disorder or relatives at risk of developing a genetic disorder. People attending genetic counselling are provided with information about the causes and consequences of the disorder. The risk of developing and transmitting the condition is evaluated, and the options available in terms of tests, treatment or prevention are outlined and discussed in a supportive environment.

Clinical cytogenetics

In clinical cytogenetics, the chromosome complement of an individual is analysed to determine whether there is a change from the expected number of 46 chromosomes or whether there is a change in chromosome structure that could be of pathological significance.

Clinical molecular genetics

Molecular biological techniques are used to investigate individual genetic abnormalities associated with specific genetic disorders. Molecular genetic tests can be used to confirm or exclude diagnosis of a genetic disorder in a symptomatic individual, or to assess carrier status in asymptomatic relatives. However, molecular genetic testing is not used widely in psychiatric conditions because of the genetic complexity of the majority of these disorders.

Prenatal genetic testing

Prenatal genetic testing refers to screening for genetic conditions in a fetus before it is born. Chromosomal abnormalities (e.g. Down syndrome) and molecular genetic abnormalities (e.g. in cystic fibrosis) can be detected.

Ethics in genetics research

There are a number of ethical issues in genetics research that differ from those that arise in other kinds of clinical research. These include privacy and confidentiality, informed consent and risks of harm.

Privacy and confidentiality are extremely important, due to the risk of bias, discrimination and stigma that could result if a person’s genetic information were disclosed. It is essential that genetic researchers clearly inform study participants of all individuals or institutions who will have access to their data. DNA samples for research are commonly stored in repositories called DNA banks. Commonly, genetic researchers unlink personal identifiers from genetic data to reduce the threat to privacy and confidentiality.

In order to meet the criteria for informed consent, participants must be adequately informed, be free from coercion or undue influence, and be competent. In genetic research, it is often difficult to decide how much information is adequate; it is equally difficult to describe the risks of harm associated with the research. Risks in genetic research are generally not physical but instead are psychological, social or economic. For example, genetic testing can cause significant anxiety before and after testing, and disclosure of results could result in discrimination and stigmatization or increased cost of health/life insurance. In addition, family members of the participant may face similar problems even if they are not involved in the study. It has been suggested by many that genetic counselling should be mandatory in future genetic research in order to ensure fully informed consent. To give informed consent, the participant must understand the purpose of the research; how and where the specimens will be stored; who will have access to the
information from the samples; whether the samples are anonymous or are linked to the participants with a code; whether the participants will be contacted about study findings; and whether the research will be used to develop any products for financial gain.

PRINCIPAL INHERITED CONDITIONS IN PSYCHIATRY

Alzheimer’s disease

Epidemiology

Alzheimer’s disease (AD) is the most common cause of dementia. Prevalence rises steeply from 5 per cent in the age group 65 years and older, to 22 per cent among those aged 95 years and older. Women are at slightly higher risk than men, with AD, and 25 per cent of people who develop late-onset AD have had a close relative with dementia. Twin studies have reported an estimated heritability of AD of up to 80 per cent. The disease appears to be a complex and genetically heterogeneous disorder.

Family, twin and adoption studies

Family studies and twin studies suggest a genetic aetiology. The risk of developing Alzheimer’s disease is increased approximately 3.5-fold in first-degree relatives of probands with AD, and 25 per cent of people who develop late-onset AD have had a close relative with dementia. Twin studies have reported an estimated heritability of AD of up to 80 per cent. The disease appears to be a complex and genetically heterogeneous disorder.

Chromosomal abnormalities

Mutations in three genes – amyloid precursor protein (APP), presenilin 1 (PSEN1) and presenilin 2 (PSEN2) – are associated with rare forms of autosomal-dominant early-onset AD. APP is a cell-membrane protein cleaved by three proteolytic enzymes called secretases. Mutations in the APP gene on chromosome 21 cluster near sites where the beta-amyloid peptide is cleaved from APP (at beta and gamma secretase sites) and also where the beta-amyloid peptide itself is cleaved (alpha secretase site). Mutations in PSEN1 (chromosome 14) and PSEN2 (chromosome 1) affect the gamma-secretase cleavage of beta-amyloid from APP. The net result of mutations in these three genes is that proteolytic processing of the protein is disrupted and there is an increase in the deposition of abnormal beta-amyloid in the brain. The amyloid cascade hypothesis of AD holds that the formation of abnormal beta-amyloid is the primary deficit in the disorder, which leads to all other pathology (tau aggregation and phosphorylation, neuronal loss and cholinergic deficits).

Molecular genetics

Interestingly, mutations in APP, PSEN1 and PSEN2 have not been found in the more common late-onset AD, despite the fact that family history is the largest risk factor for AD. The only clearly identified genetic risk factor for late-onset AD involves the apolipoprotein E (APOE) gene. This gene has three common alleles (E2, E3, E4) and thus six possible genotypes. Presence of the APOE4 allele is a susceptibility gene for AD, and it influences age of onset of the disorder. The most common genotype in the general population is E3/E3. In white people, E4/E4 genotype is associated with a significantly (15-fold) increased risk of AD compared with E3/E3 genotype. The E2/E4 and E3/E4 genotypes are also associated with an increased risk of AD (approximately three-fold). The E2 alleles are protective compared with E3/E3, with a reduction in risk of about 40 per cent. The pathogenic mechanism of the E4 allele is not fully understood. Higher serum cholesterol is reported in people with the E4 genotype, and altered lipid metabolism might affect AD pathogenesis. The APOE4 protein might also have differential binding to amyloid and tau proteins. However, many people without the APOE4 allele develop AD, and many people with the APOE4 risk allele do not develop AD.

Linkage studies

It is thought likely that there are at least four risk genes for AD that have not yet been localized, and the search for these susceptibility genes is ongoing. For the more common, late-onset form of AD, a large number of chromosomal regions linked to or associated with the disease have been discovered, but their underlying genes have not been identified unequivocally. Large genetic linkage analysis studies have reported linkage at regions of chromosomes 6, 9, 10, 12 and 19. However, investigation of these regions has not resulted in the identification of a definitive ‘Alzheimer’s gene’.

Association studies

A meta-analysis of all the genetic association studies in autism reported over a dozen potential Alzheimer susceptibility genes. These authors have created a publicly available, continuously updated database that comprehensively catalogues all genetic association studies in the field of AD (www.alzgene.org).

Animal models

Animal models have been useful in unravelling the molecular pathogenesis of AD (see Gottz and Ittner for a review). Much work has been carried out in transgenic mice, Drosophila (fruit flies) and nematodes. Work on animal models has yielded a number of important findings and identified therapeutic targets. For example, reduction of the intracellular protein tau was found to block beta-amyloid toxicity in mice models. Reduction of tau levels can be achieved by vaccination against tau in a mouse model, and it will be exciting to see whether this strategy will be safe and effective in humans. Abnormal beta-amyloid has also been targeted using vaccination strategies in animal models. An early trial in humans was discontinued prematurely after a number of participants developed meningoencephalitis. However, new vaccinations are under
investigation and reports are eagerly awaited. The role of diet has also been investigated using mouse models, with reports that caloric restriction, the antioxidant ginkgo biloba and omega-3 polyunsaturated fatty acids are all associated with reduction of beta-amyloid.

### Schizophrenia

#### Epidemiology

Schizophrenia affects between 0.5 per cent and 1 per cent of the population at some stage in their lives. It has a point prevalence of three to five cases per 1000. It is equally common in males and females, but with a peak onset of symptoms between age 15 and 25 years in males and between 20 and 30 years in females. It occurs in all parts of the world with approximately equal frequency. There is some evidence to suggest that the incidence of the disorder has decreased over recent decades. There is a well-replicated seasonal variation in the birth rates of people who later develop the disease, with an excess in the late spring and early summer in the northern hemisphere.

#### Family, twin and adoption studies

Schizophrenia is a highly familial disorder. Lifetime risk for schizophrenia in first-degree relatives is 10–15 per cent; in monozygotic twins, it is about 50 per cent, as it is in the offspring of two parents with schizophrenia. Risk for monozygotic twins (40–60%) compared with risk for dizygotic twins (10–15%) suggests a heritability of approximately 80 per cent. Adoption studies have supported a genetic risk, with risk to biological offspring of schizophrenic parents greater than risk to adopted offspring, and risk in biological parents of adoptees who develop schizophrenia greater than risk in adoptive parents. Segregation analysis supports a polygenic, complex genetic aetiology in most affected families. The standard linkage approach to identify susceptibility loci of moderate effect may lack statistical power even for samples with thousands of families. Association studies of schizophrenia have a low prior probability because the neuropathology of schizophrenia is unknown (meaning that there are thousands of plausible candidates).

#### Chromosomal abnormalities

Cytogenetic studies have reported numerous associations between schizophrenia and chromosomal mutations such as translocations, inversions, deletions and trisomies. Because schizophrenia is relatively common, many may be coincidental. However, chromosome 22q deletions are more common in individuals with schizophrenia, and expression of the chromosome 22q deletion phenotype (VCFS) increases risk of psychosis. Strong evidence for linkage has also been reported for a balanced (1;11)(q42.1;q14.3) translocation that segregates with schizophrenia and related psychiatric disorders in a large Scottish pedigree. This translocation disrupted a previously unknown gene on chromosome 1 (DISC1) expressed in the brain and involved in neurodevelopment. A translocation between chromosomes 1 and 16 in another family disrupts the phosphodiesterase-4 type B gene (PDE4B), the protein product of which is a binding partner to the DISC1 protein.

### Molecular genetics: linkage studies

Many genome-wide linkage scans of schizophrenia have been performed. Individually, these have provided evidence suggestive of linkage to many different loci. A meta-analysis of these studies (n = 2000 affected individuals) provided statistical evidence that a number of these loci (including chromosome 6p, 8p and 22q) are true positive findings. Linkage studies on a sample of Irish high-density schizophrenia families have identified linkage on chromosome 6p22.3, where later the Dysbindin gene was identified by genetic association, and on chromosome 8p21–22 in Irish and Icelandic families, where later the Neuregulin 1 gene was identified. Gene expression studies have also contributed to advances in the molecular genetics of schizophrenia. This approach looks for differences in expression of genes in postmortem brain tissue between affected individuals and controls. A review of 25 genome-wide linkage studies suggests eight chromosome regions with suggestive linkage evidence that contain promising candidate genes (in brackets) including 22q12–q13 (COMT, PRODH2, ZDHHC8), 8p22–p21 (NRG1, PPP3CC), 6p24–p22 (DTNBP1), 13q14–q32 (G72, DAAO), 6q21–q22 (TRAR4), 1q32–42 (DISC1) and 1q21–q22 (RG54).

### Molecular genetics: association studies

The literature on association studies in schizophrenia is very large. The Schizophrenia Forum hosts a database of potential candidate genes for schizophrenia emerging from association studies published in peer-reviewed journals. There are 730 different gene/reference entries to date, showing the complexity of the task of making sense of the literature. Early candidate genes studies focused out of necessity on a limited number of genes and hypotheses, such as the dopamine hypothesis and the dopamine D2 and other receptor genes. These studies were limited, both by the lack of strength of the a priori hypothesis and by the sample sizes studied. Many studies reporting nominal evidence for association were followed by several negative reports. Stronger hypotheses have emerged, backed by linkage evidence (NRG1, DTNBP1, G72, DAAO) or cytogenetic evidence (DISC1). A meta-analysis of 12 ‘top’ candidate genes selected from the Schizophrenia Forum database found genome-wide significant allelic association for seven, all with very small ORs for the associated risk allele. Statistical power and rigour, strong biological hypotheses and supportive genetic evidence may go some way to dissociate signal from noise in this literature.

### Genome-wide association studies

These studies are under way and a small number have been reported to date. The first used a small sample but reported
strong evidence for association with (colony-stimulating factor 2 receptor, type A (CSF2RA)),23 The second used a pooling strategy and identified a strong but not genome-wide significant signal in the coiled coil domain (CCDC60).23 The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) project reported a preliminary genome-wide association study of 738 cases and 733 controls, but with no signal reaching genome-wide significance.24 O’Donovan and colleagues carried out a genome-wide association study of 479 cases and 2937 controls and followed up those signals with \( P < 10^{-5} \) in more than 16000 additional cases and controls.25 Of 12 loci followed up, three had strong independent support (\( P < 5 \times 10^{-8} \)), with the strongest reaching genome-wide significance at zinc finger protein 804A (ZNF804A).

Copy number variants

Smaller, submicroscopic CNVs have been shown to be more common in schizophrenia measured as total burden,26 and at particular positions on the genome. More recently, two regions of the genome, one on chromosome 1q21.1 and another on chromosome 15q13.3, have been shown to occur in a small number of cases of schizophrenia at a frequency of similar order to the VCFS deletions.27,28 Surprisingly, these deletions and their reciprocal duplications, are also found to cause a wide array of neurodevelopmental phenotypes, including mental retardation, minor physical abnormalities, cardiac abnormalities and autism.29,30 The 1q21.1 and 15q13.3 CNVs are large at approximately 1.35 Mb and 1.5 Mb respectively, each containing many genes, including the A7 subunit of the nicotinic acetylcholine receptor (CHRNA7) gene on 15q, previously reported as showing evidence for linkage with schizophrenia. It is also becoming clear that small CNVs may disrupt individual genes, with a report from Rujescu and colleagues describing small (18–420 kb) deletions and duplications involving neurexin 1 (NRXN1) in approximately one in 200 cases of schizophrenia compared with 1 in 660 controls.31

Bipolar affective disorder

Epidemiology

BPAD is characterized by extreme mood dysregulation, with repeated episodes of elevated or depressed mood. BPAD occurs in 0.5–1 per cent of the population. The male/female ratio is equal.

Family, twin and adoption studies

Family, twin and adoption studies consistently indicate a strong genetic component to BPAD. Heritability of BPAD is high, in the region of 85 per cent.32 Twin studies show a markedly elevated concordance rate of BPAD in monozygotic compared with dizygotic twins – 40 per cent versus 5 per cent.32 BPAD is more common among biological parents than adoptive parents of adoptees with BPAD.33 The mode of inheritance is unknown but is probably due to a number of genes, each of small effect.

Molecular genetics: linkage studies

A number of areas of the genome have repeatedly shown linkage with bipolar disorder. Some of these regions (4p16.1, 11p15.5, 12q24.31, 18p11.21, 21q22.2–3, 22q12.3) are particularly interesting because they contain genes that have been identified in association studies of BPAD. Linkage has also been replicated for regions of chromosome 5, 6, 8, 10, 13, 17, 18, 20 and the X chromosome, but these regions do not contain genes that have been implicated in association studies on BPAD (see Serretti and Madelli34 for a review).

Molecular genetics: association studies

There have been an enormous number of studies over the past 20 years seeking to find the risk gene(s) for BPAD. There are now a number of genes that appear to be consistently associated with the disorder, including SLC6A4, TPH2, DRD4, SLC6A3, DAOA, DTNBP1, NRG1, DISC1 and BDNF, which are discussed in more detail below. Other promising genes include DRD1, HTR1A, HTR2A, HTR2C, COMT, MAOA, GABRA1 and GABRA5 (see Serretti and Madelli34 for a review).

One of the most widely studied genes in BPAD is the serotonin transporter gene (SLC6A4). This gene is located on chromosome 17 and is a strong functional candidate gene. The serotonin transporter coded for by the SLC6A4 gene is a single protein responsible for serotonin uptake into presynaptic neurons. Tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) reduce serotonin reuptake by preventing serotonin binding to the protein. Variants of the promoter region of this gene affect transcriptional efficiency of the serotonin transporter protein. The neuronal tryptophan hydroxylase gene (TPH2) located on chromosome 12 codes for a rate-limiting enzyme in the synthesis of serotonin in the central nervous system. Genetic polymorphisms within this gene have been associated with BPAD in a number of studies.

Dopamine plays a key role in the regulation of emotion and motivation, and two genes involved in the dopamine system have shown consistent association with BPAD. DRD4 located on chromosome 11 (11p15.5) codes for the D4 subtype of the dopamine receptor. Variants of the DRD4 gene have shown association with BPAD in a number of studies. The dopamine transporter gene (SLC6A3/DAT), which has been mapped to 5p15.3, codes for a protein that mediates dopamine reuptake, and variants of this gene have shown association with BPAD.

The glutamate system has not been investigated widely in BPAD. However, two genes involved in the glutamatergic system have shown consistent association with BPAD. D-Amino acid oxidase activator (DAOA/G72) is a strong positional candidate gene in BPAD in that it is located in a region in positive linkage with BPAD (13q33.2).35 A number
of studies have shown association of this gene with BPAD. The biological mechanism is not understood, but DAOA is involved with the activation of N-methyl-D-aspartate (NMDA) receptors, a type of glutamate receptor.

Genetic association studies have provided strong evidence to support the theory that DNA variation at the neuregulin, BDNF and DISC1 genes confers susceptibility to BPAD. These genes are all thought to play a role in cell growth or cell maintenance. A number of single nucleotide polymorphisms (SNPs) within the neuregulin 1 (NRG1) gene appear to be associated with BPAD. The mechanism by which neuregulin may influence disease susceptibility is unknown. It is hypothesized that abnormal neuregulin may lead to abnormal myelination, alter expression and activity of neurotransmitters, or cause synaptic destabilization. There is mounting evidence (11 studies to date) confirming an association between brain-derived neurotrophic factor (BDNF) and BPAD. This gene is located at 11p13, and the BDNF protein coded for is a neuronal growth factor that plays an important role in growth, development and survival of neuronal populations. A novel study demonstrated the potential functional importance of this gene. Poorer episodic memory and reduced hippocampal activation on functional magnetic resonance imaging (fMRI) were shown to be associated with a variant (val to met polymorphism) of this gene. In addition, transcription of BDNF is modulated by antidepressants. BDNF has also been implicated in unipolar depression.

Linkage and association studies have identified the DISC1 gene on chromosome 1 as a positional candidate conferring susceptibility to BPAD. This gene is located in 1q42.1. It is thought that DISC1 may regulate cytoskeletal function. The variant of DISC1 may therefore affect neuronal functions such as migration and intracellular transport, as these require intact cytoskeletal function.

Genome-wide association studies
Researchers at the National Institute of Mental Health (NIMH) have published a genome-wide association study in BPAD in which they report association with diacylglycerol kinase eta (DGKH) and several other genes in the aetiology of bipolar disorder. The DGKH gene is particularly interesting, as it codes for a key enzyme in the lithium-sensitive phosphatidyl inositol pathway. In the landmark genome-wide association study carried out by the Wellcome Trust Case Control Consortium (WTCCC), there was only one association in BPAD (on 16p12) that met criteria for significance. Results from a subsequent genome-wide association study have been compared with those of the WTCCC, and the report suggests that there are discordant signals for SNPs within the voltage-dependent calcium channel, L-type, alpha 1C subunit (CACNA1C) gene. Since then, another genome-wide association study has identified association with CACNA1C. Another gene, ankyrin G (ANK3), also showed significant association with BPAD. The authors theorize that dysfunction of ion channels may be involved in pathogenesis of bipolar disorder.

Unipolar depression

Epidemiology
Unipolar depression or major depressive disorder is characterized by pervasive low mood, loss of interest and anhedonia. It is thought to be a multifactorial disorder involving predisposing personality traits, genetics and precipitating stressful life events. Point prevalence for unipolar depression is approximately 6 per cent.

Family, twin and adoption studies
Heritability is estimated to be 30–40 per cent when cases are ascertained from population surveys; however, heritability estimates are much higher (up to 70%) when probands with unipolar depression are ascertained from hospital or clinic settings (i.e. in more severe cases). Twin studies show that concordance rates for monozygotic twins are about 40 per cent and for dizygotic twins about 20 per cent.

An interesting consistent finding regarding the familiality of affective disorders is that first-degree relatives of probands with bipolar disorder have an increased risk of bipolar disorder and unipolar depression, whereas first-degree relatives of probands with unipolar depression have an increased risk of unipolar depression only.

Molecular genetics: linkage studies
Regions of interest have been identified in genome-wide linkage studies of unipolar depression. An area of chromosome 12 (12q22–23) shows linkage with unipolar depression; interestingly, this area overlaps with a region of interest in bipolar disorder. A region of chromosome 2q also showed strong linkage with unipolar depression. This region is close to the gene coding for cyclic adenosine monophosphate (cAMP)-responsive element binding protein 1 (CREB1).

Molecular genetics: association studies
Genes for major depression appear to overlap with those for anxiety and neuroticism. In a study designed to investigate the relationship between personality and depression in women, it was reported that high trait neuroticism accounted for approximately 55 per cent of the genetic liability for major depression.

As in BPAD, the serotonin transporter gene is a promising functional candidate gene in unipolar depression. One polymorphism of this gene (the short variant affecting the promoter region) causes reduced expression of the serotonin transporter protein and reduced presynaptic serotonin uptake. However, this polymorphism is not associated uniquely with major depression but also with anxiety-related personality traits.

Gene–environment interactions
Gene–environment interactions are likely to be important in the aetiology of unipolar depression. Caspi and colleagues showed that the presence of one or two copies of the short
allele of the serotonin transporter promoter polymorphism increases susceptibility to major depression occurring in relation to stressful life events, and this finding has been replicated in two other samples. Hariri and colleagues reported that humans with one or two copies of the short allele have greater amygdalar activation when exposed to a fearful stimulus than individuals homozygous for the long allele. Thus, human response to environmental stressors may, at least in part, be influenced by their genetic make-up.

**Autism**

**Epidemiology**

Autistic spectrum disorders (ASD) are devastating neurodevelopmental disorders of childhood characterized by deficits in social interaction and communication and restricted, repetitive patterns of behaviours, interest and activities. The term ASD is commonly used clinically to describe conditions on the autistic spectrum not meeting the strict criteria for autism as defined by International Classification of Diseases, 10th revision (ICD-10) or Diagnostic and Statistical Manual, 4th edition (DSM-IV). The reported prevalence of ASDs has increased over the past 20 years, with rates for childhood autism of 38.9 per 10,000, and 116.1 per 10,000 for all ASDs, from one study of 56,964 children in the south Thames region of the UK. The male/female ratio in ASD is approximately 4:1, although when only severe cases of autistic disorder are considered the ratio approaches 1:1.

**Family, twin and adoption studies**

Autism has a strong genetic basis, and the estimated heritability of autism is more than 90 per cent. The relative risk of a child being diagnosed with autism is increased at least 25-fold over the population prevalence in families in which a sibling is affected. First-degree relatives of a child with ASD are more likely than controls to show subtle cognitive or behavioural features that are qualitatively similar to those observed in probands (the broader autism phenotype). Twin studies report that concordance rates for monozygotic twins (70–90%) are very significantly higher than the corresponding values for dizygotic twins (0–10%).

The aetiology of autism is poorly understood at both the cellular and the molecular level. However, there are theories about abnormal neuronal connectivity and defective synaptic function, which are gaining support from genetic findings and which may account for the core features of autism. Approximately 10–20 per cent of ASD cases are associated with defined mutations, genetic syndromes and de novo CNVs, none of which individually accounts for more than 1–2 per cent of cases.

**Chromosomal abnormalities**

A number of chromosomal abnormalities have been identified in multiple patients with ASDs. However, such abnormalities are present in only 6–7 per cent of ASDs. Important regions that have been identified include 15q11–13, 22q13 and 2q37. Within the 15q11–q13 locus, two genes (ubiquitin protein ligase, UBE3A; γ-aminobutyric acid A receptor beta 3, GABRB3) are thought to be central. Investigation of mutations in the 22q13 and 2q37 regions has led to the discovery of other genes, including SHANK3, which codes for a synaptic adaptor protein, and a gene coding for a GTPase-activating protein (CENTG2).

**Molecular genetics: linkage studies**

Linkage studies have not been particularly successful in the search for autism-susceptibility genes. Linkage of genome-wide significance has been replicated at only two regions – 17q11–q21 and 7q. This reflects the genetic and phenotypic heterogeneity of autism. Current research is focusing on studying autism endophenotypes (measurable traits that are bothheritable and related to a specific aspect of the condition under investigation).

**Molecular genetics: association studies**

Association studies have identified a number of potential susceptibility genes for autism. Strongest evidence exists for CNTNAP2 (7q35, positional candidate), EN2 (7q36, positional candidate linked to cerebellar abnormalities in animal studies), GABRB3 (15q11–15q12, a positional candidate linked to neurexin signalling), ITGB3 (17q21, a positional candidate involved in regulation of serotonin), OXTR (3p25, an important gene in rodent social behaviour), RELN (7q22, a positional candidate), SLC25A12 (2q24, a positional candidate related to neurite outgrowth and up-regulated in the prefrontal cortex of people with autism) and SLC6A4 (17q11, a positional candidate involved in the regulation of serotonin).

DNA sequencing of candidate genes has allowed researchers to obtain evidence for the involvement of specific candidate genes in the ASDs. A number of genes involved in synaptic function (neurexin 3, NLGN3; neurexin 4–x linked, NLGN4X; SHANK3; neurexin 1, NRXN1) have been identified in this way, but the function of these genes is not fully understood. The interaction between neurexin and neureitin proteins at the synapse is thought to play an important role in controlling the balance between excitatory glutamate and inhibitory γ-aminobutyric acid (GABA) inputs.

**Copy number variants**

De novo and inherited CNVs are emerging as important causes of ASDs. Interesting CNVs that are under investigation are located at 16p11 (containing about 30 genes), 7q31 (containing 8 genes), and 20p13 (containing the oxytocin gene and arginine vasopressin gene, among 30 others).

Sebat and colleagues showed that de novo CNVs were significantly associated with autism. They identified such CNVs in 10 per cent of patients with sporadic autism, in 3 per cent of patients with an affected first-degree relative,
and in 1 per cent of the general population. Arising out of that work, a model for the genetic inheritance of autism has been proposed, whereby sporadic autism might be caused by spontaneous mutations with high penetrance in males and multiply affected families occur when these mutations are transmitted to the next generation typically from females who are less likely to be affected.

**Attention deficit hyperactivity disorder**

**Epidemiology**

ADHD is a childhood-onset neurodevelopmental disorder characterized by inattention, hyperactivity and impulsiveness. ADHD affects 2–5 per cent of children and can persist into adolescence and adulthood. One study estimates the prevalence of current adult ADHD in the USA at 4.4 per cent. Males are diagnosed with ADHD three to five times more frequently than females.

**Family, twin and adoption studies**

Family studies have found increased rates of ADHD in family members of affected probands. Adoption studies support a genetic component to the familiality, with adopted children with ADHD more likely to have biological parents rather than adoptive parents with ADHD. Twin studies have consistently suggested a large (60–90%) genetic component when ADHD is considered a categorical diagnosis or a continuous trait.

**Chromosomal abnormalities**

Bastain and colleagues assessed the prevalence of genetic abnormalities in an unselected population of 100 children with ADHD and intelligence quotient (IQ) over 80. Only one subject had a clear cytogenetic abnormality (a girl with trisomy 47, XXX), but this was not different from the expected rate in the general population. No subjects were found with either the fragile X mutation or chromosome 22q11.2 VCFS deletion.

**Molecular genetics: linkage studies**

A small number of genome linkage scans in ADHD have been performed. Suggestive evidence (LOD scores of 3.73, 3.54 and 4.0) has been reported from American, Dutch and Colombian family datasets. In only one region, 5p13, close to the dopamine transporter (DAT1), was there evidence for linkage (LOD score > 1) deriving from all three studies. This work was later extended by pooled analysis, indicating a common risk locus on chromosome 5p13. A further study found no evidence for linkage on the most established ADHD-linked genomic regions of 5p and 17, but it found suggestive linkage signals on chromosomes 9 and 16, respectively, with a LOD score of 2.13 at 9q22 and 3.1 at overlapping findings from previous studies.

**Molecular genetics: association studies**

Most association studies followed a candidate gene approach targeting dopaminergic, serotonergic and noradrenergic system genes. In contrast to many other neuropsychiatric conditions, the a priori evidence for these hypotheses was reasonably substantial. Also in contrast to other disorders, many initial findings have stood the test of replication and meta-analysis. Beginning with Cook and colleagues, the dopamine transporter has been the target of many individual studies and meta-analyses. This protein is the target of methylphenidate, the medication used to treat ADHD. Many individual studies and the majority of meta-analyses support a role for genetic variation at DAT1 in the aetiology of ADHD. Also supported by several individual studies and meta-analyses are DRD4 and DRD5 variants, with overall ORs of approximately 1.3 for both risk variants. Serotonergic system gene variant with some consistent evidence for association with ADHD include 5-HT transporter (5-HTT), the 5-HT1B receptor and tryptophan hydroxylase 2 isoform. Noradrenergic candidate genes include dopamine beta hydroxylase (DBH) and the noradrenergic transporter (NET).

One study reported from the large collaborative International Multi-center ADHD Genetics Project (IMAGE) group focused on 51 of the most likely candidate genes from a review of the literature. The study reported nominal significance with one or more variants in 18 genes, including DRD4, DAT1 and TPH2, mentioned above.

**Genome-wide association studies**

A large ADHD sample from the IMAGE study has been included in the Genetic Association Information Network (GAIN) study, and the first publications are beginning to emerge. In the first of many expected reports, six quantitative phenotypes from 18 ADHD symptoms were used in genome-wide association analyses. Two variants, within genes CDH13 and GFD1, met the criteria for significance within a specified phenotype. The study also evaluated the association of variants from 37 candidate genes that were specified a priori, 17 of which had association P values lower than 0.01, including DAT1, TPH2, DBH and 5-HTR2A mentioned above.

**Anxiety disorders**

**Epidemiology**

Anxiety disorders, including panic disorder, social phobia, specific phobias, generalized anxiety disorder, post-traumatic stress disorder (PTSD) and obsessive–compulsive disorder (OCD, discussed separately below), are the most prevalent class of DSM-IV disorders, with an overall lifetime prevalence of 28.8 per cent. Phobic disorders are the most common, having a lifetime prevalence of 12.5 per cent (specific phobia) and 12.1 per cent (social anxiety disorder). Lifetime prevalence of panic disorder is 4.7 per cent, agoraphobia without panic disorder 1.4 per cent, generalized anxiety disorder 5.7 per cent and PTSD 6.8 per cent. There is a high degree of co-morbidity with each other and with other psychiatric disorders, especially affective disorders.
Family, twin and adoption studies

There is evidence from genetic epidemiological studies that anxiety disorders are familial and moderately heritable. Family studies show that there is an increased risk of anxiety disorders in first-degree relatives of probands; for example, phobic disorders are six to nine times more common in first-degree relatives with these disorders, and panic disorder is seven times more likely to occur in relatives of affected individuals. Anxiety disorders appear to be moderately heritable, with estimates of heritability ranging from 30 per cent to 40 per cent, implying that there are substantial environmental influences on the development of these disorders. As mentioned earlier, population twin studies have shown that genes for anxiety and neuroticism overlap with those for depression.

Molecular genetics: linkage studies

Despite much research over the past years, susceptibility genes for anxiety disorders have remained elusive. Several whole-genome linkage studies investigating anxiety disorders have been published. However, there is limited overlap in the linkage sites between these studies. Linkage sites that do overlap include regions of chromosomes 7p, 16p and 8p. Loci on 7p and 16p may harbour susceptibility genes for panic disorder, and loci on 8p have been linked to anxiety-related personality traits.

Molecular genetics: association studies

Candidate gene studies in anxiety disorders are numerous. Most of the candidate genes studied are related to neurotransmitter systems known to be involved in anxiety and genes related to stress response.

SLC6A4 has been intensively investigated in anxiety disorders. This gene codes for the serotonin transporter, a protein of particular interest because it is the target for SSRI drugs in anxiety and because it is responsible for the uptake of serotonin from the synaptic cleft. There are two alleles of the gene; short and long. The short allele causes reduced expression of the disease.

Animal studies

A common polymorphism (val to met) in the BDNF gene has been implicated in the development of anxiety disorders. Modelling this polymorphism in mice gives rise to increased anxiety and changes in neuroanatomy (reduced hippocampal volume and deficient BDNF release from neurons) and reduced responsiveness to SSRI medication. This variant of the BDNF gene may play a critical role in genetic predisposition to anxiety.

Genome-wide association studies

To date there has been only one genome-wide association study of neuroticism. This study identified only a single locus, which explained less than 1 per cent of the variance. This would suggest that there are multiple genes contributing to the heritability of neuroticism.

Obsessive–compulsive disorder

Epidemiology

Lifetime prevalence of OCD is estimated at 1.1–3.3 per cent.

Family, twin and adoption studies

Twin and family studies provide convincing evidence for a genetic contribution to the disease. A review of all twin studies in OCD concludes that obsessive–compulsive symptoms are heritable, with genetic influences in children ranging from 45 per cent to 65 per cent and in adults from 27 per cent to 47 per cent. That OCD is familial is evident from numerous family studies (see Pauls for a review). Similar to the data from twin studies, evidence from family studies suggests that genetic influence is stronger for OCD that occurs in childhood. The rate of OCD in relatives of adult probands with OCD is increased approximately two-fold; however, in relatives of children and adolescents with OCD, the rate of OCD is increased ten-fold. In addition, OCD-spectrum disorders appear to be more common among relatives of probands with OCD. These include body dysmorphic disorder, somatoform disorders, grooming disorders and tic disorders. The mode of inheritance is not fully understood, but it is likely that OCD is a complex genetic disorder with a number of genes important for the expression of the disease.

Molecular genetics: linkage studies

There have only been two genome-wide linkage studies in OCD, and both have had relatively small sample sizes. Hanna and colleagues found linkage to regions on chromosomes 2, 9 and 16, with maximum linkage at a region on chromosome 9p24. A subsequent study has also demonstrated linkage very close to this region of 9p24. This area is particularly interesting because it includes the gene coding for the glutamate transporter that has been implicated in OCD in three independent association studies. However, the largest linkage study to date did not find
evidence for linkage at 9p but reported that there was evidence for linkage on chromosomes 3q, 1q, 15q and 6q, with maximum linkage at 3q27–28. None of the linkage studies to date have achieved genome-wide significance.

**Molecular genetics: association studies**

Candidate gene studies have been focused on neurotransmitters thought to be involved in OCD. The serotonergic system has been of particular interest because of the well-documented efficacy of serotonin reuptake inhibitors in the treatment of OCD. Other neurotransmitter systems that have been investigated include the dopaminergic, glutamatergic and opioid systems. Two neuropeptides (arginine vasopressin and oxytocin) have also been implicated in the pathobiology of some forms of OCD. However, results from candidate gene studies of these systems have been disappointing. None has achieved genome-wide significance, and the majority have not been consistently replicated. Three independent studies have reported an association to the glutamate transporter (**SLC1A1**).

The next step in molecular genetic studies of OCD will involve whole-genome association studies. Larger sample sizes are essential in future studies.

**Anorexia nervosa**

**Epidemiology**

Anorexia nervosa (AN) is a serious psychiatric condition characterized by an inability to maintain a normal body weight. Despite severe weight loss, individuals with AN perceive themselves to be heavier than they are in reality and engage in severe dieting, exercise and purging. The prevalence of narrowly defined AN is 0.3 per cent; including sub-threshold cases, the prevalence ranges from 0.37 per cent to 1.3 per cent.

**Family, twin and adoption studies**

Along with female sex, a family history of AN is a strong risk factor, with first-degree relatives having a ten-fold increase in risk, not only for AN but also for a range of eating disorders, including bulimia nervosa.\(^9^9\) Twin studies are not common in AN, but those conducted have been well designed, including studies that utilize twin registers. From these studies, the heritability of narrowly defined DSM-IV AN has been estimated at 56 per cent,\(^9^0\) with shared environment and unique environment accounting for 5 per cent and 38 per cent, respectively.

**Molecular genetics: linkage studies**

A limited number of linkage studies with AN have been reported. The evidence that there is shows some support for a susceptibility locus on chromosome 1p36–1p34 when the phenotype is restricted to classical AN. This region contains two genes of interest in AN: the serotonin 1D receptor and the \(\delta\) opioid receptor. An analysis of linkage taking into account AN traits such as obsessiveness, age at menarche and minimum body mass index (BMI) provides suggestive evidence for several other regions of the genome. Overall, the findings are not conclusive and further work is required.

**Molecular genetics: association studies**

Association studies have focused on candidate genes, including the serotonergic genes, thought to be involved in body weight regulation; and dopaminergic genes, thought to be involved in weight loss, hyperactivity, menstrual abnormalities, obsessive behaviours, and a range of additional genes including neuropeptide genes, growth genes and satiety-related genes. To date, variants at the serotonin 1D receptor gene, the dopamine D2 gene and the **BDNF** gene provide modest evidence for being associated with risk (see Bulik et al.\(^9^1\) for a review).

**Alcoholism**

**Epidemiology**

Alcoholism is a worldwide public health problem that is costly both in human and in economic terms. In the USA, alcoholism costs the economy an estimated $185 billion per annum in healthcare, loss of productivity and legal/penal costs. The Epidemiological and Catchment area (ECA) study in the USA reported a 14 per cent lifetime prevalence of alcohol dependence, with a male/female ratio of 2 : 1.\(^9^2\) In the USA, prevalence of alcohol use disorder in the preceding 12 months is reported at 8.6 per cent.\(^9^3\) There are major demographic and environmental influences, including age, type of drink, religion, culture, occupation, marital status and socioeconomic class.

**Family, twin and adoption studies**

There is an estimated four-fold increased risk of alcohol dependency in first-degree relatives of alcoholics. There is overlap of risk such that family members of alcoholics have increased risk of other substance use disorders, but there is also evidence of specificity of familial aggregation of the predominant drug of abuse, suggesting that there may be risk factors that are specific to the particular class of drug and risk factors that underlie substance abuse in general. Monozygotic twins have a higher risk of both being concordant for alcohol dependency than dizygotic twins. Studies based on large population samples of twins confirm that there is a mixture of genetic and environmental factors. Adopted children of alcoholic parents have the same four-fold increased risk of alcohol dependency as do children raised by their alcohol-dependent parents.\(^9^4\) Taken together, these studies confirm that alcohol dependence is substantially inherited, with estimated heritability of 50–60 per cent for both women and men.\(^9^5\) Given the observed monzygotic/dizygotic twin ratio for alcohol dependency at approximately 2 : 1, likely modes of inheritance include an oligogenic model, or multiple alleles of strong individual effect, a genetic heterogeneity model. Genetic studies that
cross compare risks for two phenotypes in twins or other relative pairs indicate that some risk factors are alcohol-specific whereas other are shared between different substances. For example, alcoholism and nicotine dependence are co-morbid, and it has been shown that about 50 per cent of the genetic liability to nicotine dependence is shared with alcoholism and about 15 per cent of the genetic liability to alcoholism is shared with nicotine dependence.

**Molecular genetics: linkage studies**

Several papers describe genome-wide linkage scans in alcohol abuse using phenotypes most supported by twin studies such as dependence diagnosis made according to DSM-IV criteria or estimates of quantity and frequency. Initially, few of the linkage ‘peaks’ from these scans appeared to overlap between studies. However, in the light of more recent genome-wide association studies, these linkage peaks are in the same regions as the variants identified by association.96 In addition, the magnitude of the signal from each study at a given location was strongly correlated. Signals on chromosomes 1, 2, 4, 7, 10 and 11 appear to be the most consistent.95

**Molecular genetics: association studies**

The allelic variations most strongly associated with alcoholism are the functional variants at alcohol and acetaldehyde dehydrogenase genes, carriers of which flush in response to alcohol consumption. For the $ADH^*2$ gene variant, carriers are incapable of metabolizing acetaldehyde at a rate sufficient to remove it from the blood, and in the case of the $ADH1B$ and $ADH1C$ variants, the variants produce an enzyme that metabolizes alcohol more rapidly, increasing the levels of acetaldehyde in the blood. Such individuals are highly unlikely to become alcoholic, the variants providing strong protection. However, because these variants are rare in white people, the impact at a population level is minimal. Candidate gene approaches have focused on GABA subunit genes that underlie some of the linkage peaks, the serotonin transporter and the $COMT$ Val158Met variant.

**Genes and behaviour**

The monoamine oxidase A (MAOA) gene is a putative candidate gene for antisocial and other behavioural disorders in humans. MAOA is involved in serotonin degradation following its reuptake from the synaptic cleft. There is a variable-number tandem repeat polymorphism at the promoter of the $MAOA$ gene, which is known to affect expression. Variants of $MAOA$ can result in reduced enzymatic activity, and there is some evidence suggesting a link between low activity alleles of the $MAOA$ gene and aggression and antisocial behaviour. Two separate studies have reported that in males exposed to maltreatment/childhood adversity, antisocial outcomes were more prevalent in those with the low activity $MAOA$ allele; that, conversely, the high-activity allele conferred protection against antisocial behaviour.97,98 Of note, in the absence of environmental adversity, there does not appear to be a simple association between low-activity $MAOA$ and aggression or antisocial behaviour. Much work is still needed in this area.

**PHENOTYPE–GENOTYPE CORRELATION**

Phenotype definitions in psychiatry are descriptive and, even with more recently developed operational criteria, the focus is on reliability in the absence of biological validity. Given the level of symptom overlap between disorders, it is likely that there will be overlap of genetic susceptibility between disorders. This is particularly likely for the major psychoses, schizophrenia, bipolar disorder and the intermediate phenotype schizoaffective disorder. Here, genetic epidemiology and molecular genetic studies are challenging the Kraepelinian dichotomy. Twin studies have shown evidence of shared genetic susceptibility,99 with cases of monozygotic twins where one individual is diagnosed with schizophrenia and one with bipolar disorder. Similarly, in the large Scottish family segregating the translocation disrupting the DISC1 gene, some members with the translocation have schizophrenia, some bipolar disorder and some recurrent major depression.6 Linkage and association studies have also produced evidence to suggest that there may be overlap in genetic susceptibility (see Owen et al.100 for a review).

Extreme levels of phenotypic diversity have emerged from studies of structural variation in the genome. Mefford and colleagues tested for deletions and duplications at a locus on chromosome 1q21.1 previously reported to be deleted in individuals with mental and growth retardation and facial dysmorphism.29 In a screen of more than 5000 patients, they found 25 with deletions and 9 with duplications of a region approximately 1.35 Mb in length. There was considerable variation in phenotype, including mild to moderate mental retardation, microcephaly and facial dysmorphism, cardiac abnormalities, cataracts and autism. Two large multicentre studies of copy number variation in schizophrenia, published about the same time, identified deletions of the same 1.35-Mb region in 10 from 3391 patients and in 11 from 4718 patients.27,28 Similar findings were reported for a region on chromosome 15q13.3. These findings show that schizophrenia, a known neurodevelopmental disorder, might be one possible outcome of a chromosomal abnormality, the other outcomes including autism, mental retardation, cardiac abnormalities, cataracts, dysmorphism and other signs of aberrant development. It will be important to examine the phenotype carefully in the individuals identified as carrying these and other recently identified mutations to see whether and how they might differ with respect to other patients. Why the same genetic mutation might lead to so many different outcomes is
unknown, but the answers will lead to significant insights into the genetic architecture of neurodevelopment.

There are likely to be implications for the future of psychiatric nosology, with disorder classification based increasingly on biological validity. With psychiatric disorders in individuals being characterized at a genetic and molecular level, it does not require much of a leap of the imagination to see the possibilities with respect to treatments and early interventions based on knowledge of underlying aetiology.

**KEY POINTS**

- Mendel’s laws are important in understanding the principles of inheritance and the application of linkage and association methods.
- Complex patterns of inheritance generally apply to common traits and this is likely to be the case in neuropsychiatric disorders.
- Much of the genetic risk for psychiatric disorders will consist of multiple DNA variations each of small effect size. These are likely to be common throughout the population but in combination with other risk variants and environmental effects can produce the disorder phenotype.
- Identifying risk genes, even if their individual effect on risk is small, will provide important insights into disease pathophysiology.
- Major genes have been identified in Alzheimer’s disease and in rare cases of schizophrenia and other major psychiatric disorders. In the case of the Disrupted in Schizophrenia 1 gene (DISC1) on chromosome 1, abnormal neuronal morphology and motility during neurodevelopment has been observed, underpinning the neurodevelopmental hypothesis of schizophrenia.
- Genome-wide association studies in sufficiently powered samples are beginning to emerge. Determining the function role of risk genes/DNA variations will be a major task for the neuroscience research community.
- Some DNA variation appears to be shared between disorders, in particular between schizophrenia and bipolar affective disorder.
- Sub-microscopic deletions and duplications, known as copy number variations (CNVs), play an important role in a significant proportion of cases of autism and schizophrenia. Apparently similar CNVs appear to underlie a diverse range of neurodevelopmental phenotypes, including autism and schizophrenia.
- Gene-environment studies will be increasingly important as risk genes are identified in the coming years.

Mental health problems and mental illness
This page intentionally left blank
INTRODUCTION

In this chapter we consider important issues in the psychiatric classification of disorders and then discuss how the World Health Organization’s (WHO) International Classification of Diseases (ICD) and the American Psychiatric Association’s (APA) Diagnostic and Statistical Manual (DSM) constructed their diagnostic systems.

What is ‘mental disorder’? When are we justified in describing a behaviour or personality as ‘abnormal’? These thorny questions have especially exercised psychiatrists since accusations by the anti-psychiatry movement in the 1960s that psychiatric diagnoses are actually stigmatic stamps of social deviations. Our determination of what is considered a mental disorder can have ramifications for diagnosis, treatment, forensics and healthcare coverage, and can not only reflect but also influence cultural mores. The history of psychiatry is littered with moral judgements disguised as medical diagnoses. Examples include drapetomania, described as a ‘disease of the mind’ causing black slaves in the nineteenth-century southern USA to betray their naturally submissive natures by absconding to freedom; and, more recently, homosexuality. Without a definition of mental abnormality, we will be hard-pressed to discern whether and when depression will be considered adaptive (as in grieving), sanctioned (as in religious penitents) or diseased; to distinguish between hearing voices as a mystical or a psychotic phenomenon; and to determine when the compulsive ingestion of an addictive substance will be normative (caffeine), disordered (alcohol) or verboten (heroin).

What, then, is a mental disorder? Here are some of the possible definitions, and their problems:

- Mere statistical deviation, as one might employ in determining a ‘normal’ level of serum liver enzyme or height, cannot suffice, lest anyone pursuing an unusual activity, or a usual activity with unusual persistence, be considered abnormal.
- Social deviation cannot serve as a criterion either, although some totalitarian regimes in the recent past have acted otherwise.
- Disruptive behaviour, were it to serve as a definition of abnormality, would logically lead to the massive transfer of the prison population to psychiatric wards.
- Personal distress seems necessary for determining abnormality, but it is hardly sufficient, for at least two reasons: How much distress is necessary? And, what about the individual, perhaps in the throes of a manic episode, or well settled in their home for the past couple of decades with agoraphobia and not suffering?
- Dysfunction is often invoked in the definition of disorder, but what, if anything, that term adds to our understanding is uncertain.
- Anchoring mental abnormality in an anatomical or physiological abnormality, as seems to be more easily done in other fields of medicine, will also not suffice. This is not just, because of the technical reason that we have yet to find any consistent biological substrate for mental disorder. It is also so because ultimately a mental disorder will be determined by behavioural or psychological function or dysfunction, in the absence of which no conceivable finding of brain imaging or receptor function can by itself justify a psychiatric diagnosis.
- Karl Jaspers, a German psychiatrist and phenomenologist, considered the sign of true mental disorder, as opposed to mere stressful reactions to trying circumstances, to be an inexplicable loss of understandable mental functioning and connections. When the form of the patient’s cognitions and perceptions are no longer graspable by the attentive, empathic interview – for example, if the delusion cannot be found to carry any metaphoric meaning, or the depression is vastly disproportionate to any possible trigger – then we may speak of a primary mental disorder. This definition is perhaps narrow and depends upon very subjective judgements by the psychiatrist. Nevertheless, among many psychiatrists, especially in central Europe, Jaspers’ influence remains strong today.
- A possible approach has been to define disorders and dysfunction in evolutionary terms. The argument goes that all functions, bodily as well as mental, have been honed by evolutionary forces, and when behaviour is maladaptive, we can diagnose a disorder. Although the wedding of evolutionary theory to psychiatry can enrich our understanding of health and pathology, this theory
also has its limitations. Some disorders may actually have been advantageous for the conditions under which they evolved. For example, hyperactive children are often considered disordered, but it is possible that roaming attention and constant movement, which are so disruptive in the modern classroom, may have been better adapted to the surroundings in the hostile environment of our origins in the African savannah.

The major diagnostic classification systems are well aware of the difficulties of defining disorder. The International Classification of Diseases, 10th revision (ICD-10) explains that “Disorder” is not an exact term, while the Diagnostic and Statistical Manual, 4th edition (DSM-IV) admits:

...no definition adequately specifies precise boundaries for the concept of ‘mental disorder’. The concept of mental disorder, like many other concepts in medicine and science, lacks a consistent operational definition that covers all situations.

The definitions of mental disorder nevertheless supplied by ICD-10 and DSM-IV are provided in Box 34.1. As the reader of the above will see, their definitions are subject to the problems we discussed. The seemingly straightforward stress upon subjective distress, an important part of both definitions, also raises an important question. Consider two individuals with a fear of heights, one living in a major metropolitan centre and rendered by her phobia unable to visit friends or seek work, and the other dwelling in a distant village of single-level huts. Their fear, and its psychological or biological substrate, may be identical, and yet only one would fulfil the proffered definitions of mental disorder.

Some will claim that the question is ultimately not important, that psychiatrists will simply treat whoever seeks treatment, and that ultimately our definitions will deductively adapt to that clinical reality. But that is a poor basis for providing therapy and hardly adequate for justifying what psychiatrists do when called upon to administer coercive treatment.

**VALIDITY**

In diagnosing mental illness, essential validity means that the names we give to psychiatric disorders are semantically capturing categories that are present in nature before we label them. This is a far-reaching claim, and many settle for nominal or conceptual validity, which demands of our category names only that they be internally coherent, consistent with empirical findings and of heuristic value. Either way, the disorders that we name provide a common language for communication among clinicians and researchers.

Other forms of validity assume one of the two types we have just mentioned. Face validity refers to the consensus of experts that the disorder named indeed exists. Experts can be wrong, and one should never be satisfied with face validity alone. Descriptive validity means that the different features of a syndrome indeed appear together. For example, individuals with dysphoric moods and reduced appetite will often also suffer from insomnia and have difficulty concentrating. A statistical method called latent class analysis examines whether certain clinical features tend to occur together. Predictive validity means that, based upon

---

**Box 34.1 Definition of mental disorder**

**INTERNATIONAL CLASSIFICATION OF DISEASES, 10TH REVISION (ICD-10)**

The term ‘disorder’ is used throughout the classification, so as to avoid even greater problems inherent in the use of terms such as ‘disease’ and ‘illness’. ‘Disorder’ is not an exact term, but it is used here to imply the existence of a clinically recognizable set of symptoms or behaviour associated in most cases with distress and with interference with personal functions. Social deviance or conflict alone, without personal dysfunction, should not be included in mental disorder as defined here.

**DIAGNOSTIC AND STATISTICAL MANUAL, 4TH EDITION (DSM-IV)**

...each of the mental disorders is conceptualized as a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g. a painful symptom) or disability (i.e. impairment in one or more important areas of functioning) or with a significantly increased risk of suffering death, pain, disability, or an important loss of freedom. In addition, this syndrome or pattern must not be merely an expectable and culturally sanctioned response to a particular event, for example, the death of a loved one. Whatever its original cause, it must currently be considered a manifestation of a behavioral, psychological, or biological dysfunction in the individual. Neither deviant behavior (e.g. political, religious, or sexual) nor conflicts that are primarily between the individual and society are mental disorders unless the deviance of conflict is a symptom of a dysfunction in the individual, as described above.
our diagnosis, we can anticipate certain developments, such as clinical course or response to therapy. The surest form of validity, construct validity, implies that we know the aetiology of the disorder. This is the validity most sorely lacking in psychiatry, which is the major reason that psychiatry textbooks, as opposed to those in other fields of medicine, need to carry chapters exploring issues in classification.

One result of lacking a clear aetiological basis for mental disorders has been a proliferation of separate diagnoses according to varying clinical syndromes, which may actually share underlying mechanisms. For example, an individual may check the door 40 times at each exit to confirm that it is locked when leaving the flat; or she may check her reflection in the mirror from 40 different angles each morning to assess possible excess weight; or he may check his nose 40 times daily to evaluate whether it is crooked. These three cases will receive different diagnoses (obsessive-compulsive disorder, anorexia nervosa and dysmorphophobia, respectively), even though they share compulsive behaviours and respond to similar pharmacological treatments.

As a helpful contrast, one can consider the situation with, for example, myocardial infarction. The clinical symptoms and physical examination may vary from patient to patient, but the development of myocardial anoxia and death brought about by occlusion of the coronary arteries is a concept that unifies the differing presentations and outcomes of a single diagnostic entity. Of course, medicine is not free of its own diagnostic conundrums. One thinks of systemic lupus erythematosus (SLE) as a case where internal medicine, uncertain about pathophysiological mechanisms, seeks recourse in complex and changing criteria in an effort to provide nosological coherence.

These difficulties are an important reason that most psychiatrists are willing to consider their diagnostic labels as possessing conceptual rather than essential validity. Psychiatric diagnoses are best considered conceptual tools useful for organizing the current state of knowledge and for communicating in a common language.

RELIABILITY

Reliability refers to the extent to which different mental healthcare workers will arrive at the same diagnostic conclusion regarding a particular individual. A relatively simple mathematical formula for measuring inter-rater reliability, known as Cohen's kappa, is \( \kappa = (P_o - P_e) / (1 - P_e) \), where \( \kappa \) is reliability, \( P_o \) is the observed agreement between raters, and \( P_e \) is the level of agreement expected between raters by chance.

High inter-rater reliability is a crucial part of any diagnostic system, because it permits clinicians and researchers to agree that a particular patient or subject is suffering from a particular diagnosis. Without such reliability, research into disorders cannot advance, since it will not be certain which disorder is actually being investigated.

It is well worth noting that reliability and validity can operate independently. Consider by illustration the following vignette:

A new syndrome is described as follows: a person, usually male, is bald, prefers open sandals, and resolutely and continuously listens to Radiohead music, to the detriment of his various occupational and familial obligations. Two of his friends are similarly afflicted. Have we discovered a new disorder?

The reliability of this purported syndrome would certainly be high; that is, we can easily elucidate the criteria so that different raters will agree whether the syndrome is present in any given individual. However, the validity would be doubtful, either in its essential sense – does such a concatenation of symptoms actually occur in nature? – or in its nominal sense – have we produced an idea that will withstand empirical testing or be of heuristic value? Any claims to predictive validity – for example, the prediction that a ‘sufferer’ will be found at the next Radiohead concert tour – derives from the individual symptom of Radioheadophilia and not from the syndrome.

This somewhat absurd example demonstrates the dilemma afflicting much of psychiatric nosology today, where considerations of reliability have taken precedence over those of validity. Depressive episodes, for example, can be reliably diagnosed, but its validity as a diagnosis, and not merely a collage of differing pathologies with overlapping clinical presentations, is being hotly disputed.

Nevertheless, if the inter-rater reliability is poor, then the validity of the diagnostic entity being examined is undermined, for the obvious reason that one cannot be certain to what exactly one is referring when using a diagnosis.

CATEGORICAL OR DIMENSIONAL DIAGNOSES?

The diagnoses used in psychiatry are usually categories: schizophrenia, anorexia nervosa, premature ejaculation, and so on. It is the use of categories, with assumptions that they describe psychopathological entities relatively well delineated from healthy personality traits, that raises the complex problems of validity. A different approach is to use dimensional diagnoses, either instead of or in addition to categorical diagnoses. Dimensional diagnoses describe the individual along a continuum. For example, reduced appetite may be rated on a scale; depressive syndrome might be assessed by scores on standardized rating scales such as the Beck Depression Inventory. In a purely dimensional diagnostic system, the patient will receive a number on a dimension rather than a diagnosis. No claim is made about the reification of the diagnostic category; on the contrary, an implication of a purely dimensional diagnostic system is that the disorder does not exist as a discrete entity but rather is an extreme case of normal variability, similar
to hypertension in general medicine. The dimensional diagnosis can also supplement the categorical diagnosis, so that, for example, a patient may be said to suffer from a depressive episode with a severity of 30 on the Beck Depression Scale.

Studies utilizing various scales of symptom severity are in effect employing dimensional diagnoses. Dimensional diagnosis is also commonly used in scales of personality. A hint of dimensional diagnosis, tightly tethered to the categorical diagnosis, is found in the DSM and ICD codes for some disorders, which allow for the severity to be rated (e.g. mild, moderate, severe).

LUMPERS VERSUS SPLITTERS

A further issue in nosology is how broadly to define each diagnosis. Different diagnostic schemes include more or fewer patients, which can affect treatment decisions and epidemiological findings. ‘Lumpers’ tend to provide a broad definition of a disorder, allowing for manifestations varying in symptoms and severity, while ‘splitters’ distinguish between different narrowly and well-defined symptom clusters. An example of lumping coming under increasing scrutiny today is ‘major depressive episode’, which can include depressive syndromes of vastly varying symptomatology arising in a wide array of contexts, all receiving the same diagnosis. Proponents of purely dimensional diagnoses have less difficulty with this issue, since they can describe different clinical features without making claims for a specific diagnosis.

DIAGNOSTIC AND STATISTICAL MANUAL OF THE AMERICAN PSYCHIATRIC ASSOCIATION

First and second editions – DSM-I and DSM-II

The precursor to the first edition of the DSM was a classification for the treatment of soldiers developed in the middle of the twentieth century by the psychiatrist and psychoanalyst William Menninger. The APA was involved in the development of the DSM-I. DSM-I diagnoses frequently carried the phrase ‘reaction’, as in ‘schizophrenic reaction’, reflecting the ideas of Adolf Meyer (1866–1950), a prominent Swiss-born psychiatrist who stressed the social causation of much mental illness.

The second edition of DSM, prepared by the APA and published in 1968, was based upon the eighth edition of the ICD. The original 106 diagnoses in DSM-I grew to 182 in DSM-II. The term ‘reaction’ was no longer used. Nevertheless, like the first edition, the second also implied a largely psychoanalytical framework for understanding psychopathology, reflecting regnant professional opinion in the USA at the time.

Both DSM-I and DSM-II described in general terms, for each disorder, the way that a typical case of the disorder would appear. It was up to the clinician to decide how closely the description corresponded to a particular patient. However, through the 1970s, dissatisfaction grew. One notable study in the early 1970s found that patients diagnosed by American psychiatrists as having schizophrenia were likely to be diagnosed as manic-depressive, neurotic or personality-disordered by their British counterparts. These and similar studies indicating abysmal reliability spurred efforts to improve reliability.

Third edition – DSM-III

In 1972, a group of researchers at Washington University established the Feighner criteria. This was a landmark in the way diagnosis was made. For 15 diagnoses, the researchers provided detailed inclusion and exclusion criteria. They also suggested criteria for validating a diagnosis, with five elements: a clearly defined clinical description (including demographic features, age of onset and precipitating events), delimitation from other disorders, biological and psychological tests, similar outcomes, and support from family studies.

The Research Diagnostic Criteria (RDC), published in 1978, modified the Feighner criteria, based on study findings. Robert Spitzer and colleagues, who developed the RDC, also established the Schedule for Affective Disorders and Schizophrenia (SADS), a structured interview intended for improving still further inter-rater reliability.

Robert Spitzer also headed the effort to produce the third edition of the DSM. When it appeared in 1980, it heralded a seismic shift in psychiatric nosology. Building upon the approach developed in the RDC, DSM-III provided criteria for 265 diagnoses, as well as information about clinical features, associated features, cultural considerations, course of illness and differential diagnosis.

Among the innovations instituted by DSM-III are the following:

- **Atheoretical formulations**: DSM-III attempted to detail the features and criteria for each diagnosis in a way that psychiatrists of varying and even contradictory theoretical schools could agree. For example, DSM-III deleted the term ‘neurosis’ from its diagnoses, in order to refrain from reliance upon a term associated with a particular school of thought and difficult to validate empirically.

- **Diagnosing without dependence upon theories of aetiology**: required the use of operationalized definitions, wherein each disorder was diagnosed by empirically determined criteria indifferent to prior ideological assumptions. The idea of operationalized, atheoretical formulations had already been suggested in the late 1950s by the British psychiatrist Edward Stengel and reached full flower in the DSM-III.

- **Multi-axial diagnoses**: in keeping with the DSM’s thoroughly empirical ambitions, they developed a scheme...
Diagnostic and Statistical Manual of the American Psychiatric Association

Part 4: Mental health problems and mental illness

(subsequently adopted by the ICD-10 as well) of diagnosing in various axes, or dimensions. The two ideas behind multi-axial diagnoses are (i) each individual is too complex to be grasped simply by a diagnosis of disorder; multi-axial diagnoses allow for greater complexity by including other aspects of the individual’s condition and circumstances; and (ii) a biopsychosocial model of illness requires diagnosis on different levels, as can best be encompassed by multi-axial diagnoses. In principal, one can entertain an endless number of axes, each describing the patient from a different perspective. DSM-III settled for five axes, which have been altered slightly by DSM-IV and will be presented below.

- **Axis I:** clinical disorders or other disorders that may be a focus of clinical attention. These include the many disorders, usually not lasting a lifetime, that the psychiatrist can diagnose. If the patient fulfils criteria for various disorders, they should all be noted (Box 34.2).

- **Axis II:** personality disorders and developmental disorders (in DSM-IV, this became personality disorders and mental retardation). Personality disorders, like the axis I disorders, have operationalized criteria. However, because of the greater difficulty assessing personality characteristics than symptoms, the inter-rater reliability has generally been lower for axis II disorders (Box 34.3).

- **Axis III:** medical conditions, which can have any sort of bearing upon the patient’s mental disorder. The non-psychiatric condition is listed using ICD codes. If, for example, a patient is depressed due to hypothyroidism, then they will receive a diagnosis of ‘a mood disorder due to hypothyroidism’ on axis I and hypothyroidism (E03) on axis III.

- **Axis IV:** severity of psychosocial stressors (in DSM-IV, this axis became ‘psychosocial and environmental problems’). In DSM-III, the stress produced by these problems was quantified on a scale of 1–7, but in light of the great variety in responses to adversity, the illusion of quantifiable accuracy produced by numbers was replaced in DSM-IV by a verbal description of the stressful circumstances, listed in the relevant categories: primary support group, social environment, education, occupation, housing, economic, access to healthcare services, interaction with the legal system or being a victim of crime, and other psychosocial problem.

- **Axis V:** highest level of adaptive functioning past year (which in DSM-IV is called ‘global assessment of function (GAF)’). This is a scale from 1 to 100 and intended to provide a generalized assessment of function (Box 34.4). In DSM-IV this may include level of functioning at the present time and be supplemented by assessments for past periods as well. The highest level of function attained during the past year can have prognostic significance.

DSM-III-R [revised], again led by Robert Spitzer, was published in 1987 and grew to 292 diagnoses. Criteria were amended based on new research findings.

---

**Box 34.2 Axis I: clinical disorders**

**OTHER CONDITIONS THAT MAY BE A FOCUS OF CLINICAL ATTENTION**

| Disorders usually first diagnosed in infancy, childhood, or adolescence (excluding mental retardation, which is diagnosed on Axis II) |
| Delirium, dementia, and amnestic and other cognitive disorders |
| Mental disorders due to a general medical condition |
| Schizophrenia and other psychotic disorders |
| Mood disorders |
| Anxiety disorders |
| Somatiform disorders |
| Factitious disorders |
| Dissociative disorders |
| Sexual and gender identity disorders |
| Eating disorders |
| Sleep disorders |
| Impulse-control disorders not elsewhere classified |
| Adjustment disorders |
| Other conditions that may be a focus of clinical attention |

**Box 34.3 Axis II: personality disorders**

**MENTAL RETARDATION**

- Paranoid personality disorder
- Schizoid personality disorder
- Schizotypal personality disorder
- Antisocial personality disorder
- Borderline personality disorder
- Histrionic personality disorder
- Narcissistic personality disorder
- Avoidant personality disorder
- Dependent personality disorder
- Obsessive–compulsive personality disorder
- Personality disorder not otherwise specified
- Mental retardation

---

**Fourth edition – DSM-IV**

Under the leadership of Allen Frances, DSM-IV arrived in 1994, with 297 diagnoses. It had several substantive changes from the DSM-III-R. ‘Organic mental syndromes’ no longer appeared, for such a term hinted at an untenable distinction between brain and mind. Instead, a new section appeared for ‘mental disorders due to a general medical condition’. A second important revision in DSM-IV was the addition for many disorders of the criteria that the symptoms cause ‘clinically significant distress or impairment in social, occupational, or other important areas of functioning’,
thereby responding to criticism that too many people were diagnosable under DSM-III.

The evolution of a diagnosis across the subsequent editions of the DSM is offered in Box 34.5, with schizophrenia serving as the example.

**Fourth edition (text revision) – DSM-IV-TR**

DSM-IV-TR was published in 2000. It included revisions of the supporting information (e.g. clinical course) but not of the diagnostic criteria themselves.

DSM-V is scheduled to be published in 2012, and the results are eagerly awaited by many in the field. The proceedings of the many committees working on revising criteria are shrouded in secrecy, which is a source of controversy. The APA has made an effort to recruit researchers and clinicians relatively unmarked by pharmaceutical support in their work. It is possible that the categorical diagnoses will be complemented by dimensional subdiagnoses.

---

**Box 34.4 Global assessment of function (GAF) scale**

Consider psychological, social, and occupational functioning on a hypothetical continuum of mental health–illness. Do not include impairment in functioning due to physical (or environmental) limitations.

**CODE (NOTE: USE INTERMEDIATE CODES WHEN APPROPRIATE, E.G. 45, 68, 72.)**

| 100 | Superior functioning in a wide range of activities, life’s problems never seem to get out of hand, is sought out by others because of his or her many positive qualities. No symptoms. |
| 91  | |
| 90  | Absent or minimal symptoms (e.g., mild anxiety before an exam), good functioning in all areas, interested and involved in a wide range of activities, socially effective, generally satisfied with life, no more than everyday problems or concerns (e.g., an occasional argument with family members). |
| 81  | |
| 80  | If symptoms are present, they are transient and expectable reactions to psycho-social stressors (e.g., difficulty concentrating after family argument); no more than slight impairment in social, occupational or school functioning (e.g., temporarily falling behind in schoolwork). |
| 71  | |
| 70  | Some mild symptoms (e.g., depressed mood and mild insomnia) OR some difficulty in social, occupational, or school functioning (e.g., occasional truancy, or theft within the household), but generally functioning pretty well, has some meaningful interpersonal relationships. |
| 61  | |
| 60  | Moderate symptoms (e.g., flat affect and circumstantial speech, occasional panic attacks) OR moderate difficulty in social, occupational, or school functioning (e.g., few friends, conflicts with peers or co-workers). |
| 51  | |
| 50  | Serious symptoms (e.g., suicidal ideation, severe obsessional rituals, frequent shoplifting) OR any serious impairment in social, occupational, or school functioning (e.g., no friends, unable to keep a job). |
| 41  | |
| 40  | Some impairment in reality testing or communication (e.g., speech is at times illogical, obscure, or irrelevant) OR major impairment in several areas, such as work or school, family relations, judgment, thinking, or mood (e.g., depressed man avoids friends, neglects family, and is unable to work; child frequently beats up younger children, is defiant at home, and is failing at school). |
| 31  | |
| 30  | Behavior is considerably influenced by delusions or hallucinations OR serious impairment in communication or judgment (e.g., sometimes incoherent, acts grossly inappropriately, suicidal preoccupation) OR inability to function in almost all areas (e.g., stays in bed all day; no job, home, or friends). |
| 21  | |
| 20  | Some danger of hurting self or others (e.g., suicide attempts without clear expectation of death; frequently violent; manic excitement) OR occasionally fails to maintain minimal personal hygiene (e.g., smears feces) OR gross impairment in communication (e.g., largely incoherent or mute). |
| 11  | |
| 10  | Persistent danger of severely hurting self or others (e.g., recurrent violence) OR persistent inability to maintain minimal personal hygiene OR serious suicidal act with clear expectation of death. |
| 1   | |
| 0   | Inadequate information. |
Box 34.5 Schizophrenia: an evolving definition

**DIAGNOSTIC AND STATISTICAL MANUAL, FIRST EDITION (DSM-I)**

This term is synonymous with the formerly used term dementia praecox. It represents a group of psychotic reactions characterized by fundamental disturbances in reality relationships and concept formations, with affective, behavioral, and intellectual disturbances in varying degrees and mixtures. The disorders are marked by strong tendency to retreat from reality, by emotional disharmony, unpredictable disturbances in stream of thought, regressive behavior, and in some, by a tendency to ‘deterioration.’ The predominant symptomatology will be the determining factor in classifying such patients into types.

**DIAGNOSTIC AND STATISTICAL MANUAL, SECOND EDITION (DSM-II)**

This large category includes a group of disorders manifested by characteristic disturbances of thinking, mood and behavior. Disturbances in thinking are marked by alterations of concept formation which may lead to misinterpretation of reality and sometimes to delusions and hallucinations, which frequently appear psychologically self-protective. Corollary mood changes include ambivalent, constricted and inappropriate emotional responsiveness and loss of empathy with others. Behavior may be withdrawn, regressive and bizarre. The schizophrénias, in which the mental status is attributable primarily to a thought disorder, are to be distinguished from the major affective illnesses ... which are dominated by a mood disorder. The paranoid states ... are distinguished from schizophrenia by the narrowness of their distortions of reality and by the absence of other psychotic symptoms.

**DIAGNOSTIC AND STATISTICAL MANUAL, THIRD EDITION (DSM-III)**

A. At least one of the following during a phase of the illness:

1. bizarre delusions (content is patently absurd and has no possible basis in fact), such as delusions of being controlled, thought broadcasting, thought insertion, or thought withdrawal
2. somatic, grandiose, religious, nihilistic, or other delusions without persecutory or jealous content
3. delusions with persecutory or jealous content if accompanied by hallucinations of any type
4. auditory hallucinations in which either a voice keeps up a running commentary on the individual’s behavior or thoughts, or two or more voices converse with each other
5. auditory hallucinations on several occasions with content of more than one or two words, having no apparent relation to depression or elation
6. incoherence, marked loosening of associations, markedly illogical thinking, or marked poverty of content of speech if associated with at least one of the following:
   - blunted, flat, or inappropriate affect
   - delusions or hallucinations
   - catatonic or other grossly disorganized behaviour

B. Deterioration from a previous level of functioning in such areas as work, social relations, and self-care

C. Duration

Continuous signs of the illness for at least six months at some time during the person’s life, with some signs of the illness at present. The six-month period must include an active phase during which there were symptoms from A. with or without a prodromal or residual phase, as defined below.

**Prodromal phase:** A clear deterioration in functioning before the active phase of the illness not due to a disturbance in mood or to a Substance Use Disorder and involving at least two of the symptoms noted below, not due to a disturbance in mood or to a Substance Use Disorder.

**Residual phase:** Persistence, following the active phase of the illness, of at least two of the symptoms noted below, not due to a disturbance in mood or to a Substance Use Disorder.

**Prodromal or Residual Symptoms**

1. social isolation or withdrawal
2. marked impairment in role functioning as wage-earner, student, or homemaker
3. markedly peculiar behavior (e.g., collecting garbage, talking to self in public, or hoarding food)
4. marked impairment in personal hygiene and grooming
5. blunted, flat, or inappropriate affect
6. digressive, vague, overelaborate, circumstantial, or metaphorical speech
odd or bizarre ideation, or magical thinking, e.g., superstitiousness, clairvoyance, telepathy, “sixth sense,” “others can feel my feelings,” overvalued ideas, ideas of reference
unusual perceptual experiences, e.g., recurrent illusions, sensing the presence of a force or person not actually present

D. The full depressive or manic syndrome (criteria A and B of major depressive or manic episode), if present, developed after any psychotic symptoms, or was brief in duration relative to the duration of the psychotic symptoms in A.

E. Onset of prodromal or active phase of the illness before age 45.

F. Not due to any Organic Mental Disorder or Mental Retardation.

A. Characteristic symptoms

1. delusions
2. hallucinations
3. disorganized speech (e.g., frequent derailment or incoherence)
4. grossly disorganized or catatonic behavior
5. negative symptoms, e.g., affective flattening, alogia, or avolition

Note: Only one Criterion A symptom is required if delusions are bizarre or hallucinations are bizarre or hallucinations consist of a voice keeping up running commentary on the person’s behavior or thoughts, or two or more voices conversing with each other.

B. Social/occupational dysfunction

For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

C. Duration

Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. Schizoaffective and Mood Disorder exclusion

Schizoaffective Disorder and Mood Disorder With Psychotic Features have been ruled out because either (1) no Major Depressive, Manic, or Mixed Episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

E. Substance/general medical condition exclusion

The disturbance is not due to the direct physiological affects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

F. Relationship to a Pervasive Developmental Disorder

If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of Schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

The ICD has far older roots than the DSM, starting out in the late nineteenth century as an internationally recognized list of causes of death. The sixth edition, appearing in 1948 under the auspices of the WHO, was expanded to include a classification of illness as well as causes of death. In this edition, psychiatric morbidity makes its first appearance, albeit with the single category ‘mental illness and deficiency’. In the seventh edition, appearing in 1955, the chapter on mental disorders was unchanged.
The eighth (1966) and ninth (1978) editions of the ICD had an expanded chapter on mental disorders. ICD-8 also influenced the DSM-II, which appeared 2 years later.

The ICD-10, completed in 1992, had an enlarged Chapter V covering mental disorders. The ICD-10 has produced companion volumes (which may be downloaded free from the public domain at the WHO website, at www.who.int/classifications/icd/en). This includes the clinical descriptions and diagnostic guidelines, or the ‘Blue Book’, which contains diagnostic criteria intended for use mainly by clinicians, and the diagnostic criteria for research (DCR), or the ‘Green Book’, with more precise and restrictive criteria for use by researchers. The DCR has adopted several of the DSM-III innovations. A short glossary has also been published, for use alongside both works.

The ICD-10 adopted the DSM’s multiaxial system. However, the axes are slightly different:

- **Axis I** included psychiatric disorders, personality disorders, mental retardation and medical illness – that is, the first three DSM-IV axes.
- **Axis II** assesses the disability resulting from the axis I diagnosis. Instead of the GAF of DSM’s axis V, it uses a short disability assessment schedule (DAS-S).
- **Axis III**, corresponding to axis IV of the DSM-IV, refers to psychosocial problems confronting the patient.

The ICD-10 makes a greater effort to be adaptable to varying cultural environments, and seeks to be a basis for local schemes of classification.

The latest editions of the DSM and ICD show a great deal of cross-fertilization and a convergence of diagnostic approaches. DSM-IV-TR lists, in Appendix H, the ICD-10 codes for the DSM disorders. Nevertheless, differences between the two systems remain.

**KEY POINTS**

- No definition has been agreed upon for the term ‘mental disorder’. Part of the difficulty lies in the lack of a clear aetiology.
- Similarly, the essential validity of the various diagnoses – that is, the claim that our diagnostic labels are semantically capturing categories that are present in nature – is uncertain.
- The value of a diagnosis is its conceptual validity, or internal coherence, providing a common language and a heuristic direction.
- Inter-rater reliability is the extent to which different clinicians will arrive at the same diagnostic conclusion.
- Diagnoses can be categorical, describing a well-delineated entity, or dimensional, along a continuum from health to disease with uncertain boundaries.
- DSM-IV features the use of operationalized diagnoses to improve reliability, and multiple axes to enhance biopsychosocial understanding.
- ICD-10 also uses multiple axes and attempts to provide an international basis for a common nosology.

**INFORMATION SOURCES AND FURTHER READING**

WHAT IS COGNITION?

Cognition, briefly, is the capacity to acquire, store and use knowledge. Indeed, it shares its etymological origin with ‘knowledge’ in the Indo-European root *gno* (*gnós*). It has also been defined as ‘the totality of capacities underlying complex adaptive behaviour’ and, more lengthily, as ‘the capacity of the brain to process information accurately and to program adaptive behaviour, involving the abilities to solve problems, communicate, memorize information or focus attention’.1

Listing the elements of cognition is more revealing than providing abstract definitions: the major cognitive functions comprise consciousness, attention, perception, memory, language, numeracy, executive function and praxis.3–5 In this chapter we explain what each of these functions involves, sketch their neural bases, describe how best to assess them, and mention their common pathologies, including the clinical features of the major varieties of delirium and dementia. We outline a practical approach to a brief but sensitive and wide-ranging cognitive assessment and explain what a neuropsychologist can add to the assessment of cognition, including the measurement of intelligence quotient (IQ).

Three common misconceptions about cognition are worth correcting at the outset:

- Cognition is not an entirely independent function. Although cognitive testing is a distinctive aspect of assessment, cognitive processes are tied closely to general medical, neurological and behavioural functioning. The clue to the cause of a cognitive disorder may come from general medical examination (e.g. the slow pulse and coarse skin of hypothyroidism), neurological examination (e.g. the choreiform movements of Huntington’s disease), cognitive assessment itself (e.g. the pure anterograde memory deficit of early Alzheimer’s disease) or neuropsychiatric observations of behaviour (e.g. the disinhibition of frontal lobe dementia).

- Cognitive processes are not restricted to certain higher brain regions. The belief that cognitive functions are localized in the association cortex has given way to the view that they depend on interconnected networks of regions distributed around the brain, both cortical and subcortical. Damage to the thalamus, for example, can profoundly disable cognition.6 There is also a growing recognition of the cognitive, affective and behavioural importance of subcortical regions such as the cerebellum and basal ganglia, which have classically been associated with motor functions.7,8 This richer understanding of the way in which cognition is represented in the brain should help to explain how cognitive processes arise from more basic sensorimotor functions.

- Cognitive functions are not entirely separate from one another, or from related neuropsychological functions such as personality, mood and motivation. Difficulty sustaining attention, for example, inevitably impacts on memory, and impairments of language have widespread effects on cognition. Low mood, apathy or a deliberate decision to withhold effort will also influence the results of cognitive testing. This is not to say that cognitive deficits cannot occur in relative isolation. Damage to the hippocampi, for example, causes predominant problems with memory. But the interdependence of neuropsychological functions does mean that individual test results must be interpreted in a broader cognitive and clinical context.

THE ELEMENTS OF COGNITION

Consciousness

Definition

Consciousness normally implies both a particular global behavioural state – wakefulness – and the occurrence of experience – awareness.9

Neural basis

The cycle of sleep and waking is controlled by a network of structures in the upper brainstem, thalamus, hypothalamus and basal forebrain.10 These structures are the components of the ascending reticular activating system, which, it is now recognized, incorporates several neurochemically distinct subsystems, strategically placed to modulate the level...
and mode of function in the cerebral hemispheres (Figure 35.1). The key neurotransmitters involved in the control of conscious state are serotonin (raphe nuclei), noradrenaline (locus coeruleus), acetylcholine (nuclei at the pons–midbrain junction and in the basal forebrain), dopamine (ventral tegmentum), histamine (hypothalamus), hypocretin (hypothalamus) and glutamate (reticular nuclei).

It is possible to be awake but unaware, as in the vegetative state, in which brainstem function is relatively intact (ventral tegmentum), histamine (hypothalamus), hypocretin (Hcrt) activity results in synchronized and widely distributed activity in the cerebral hemispheres.9,11

### Assessment

The state and level of consciousness are usually assessed using the Glasgow Coma Scale (GCS),12 which requires examination of the eyes and of verbal and motor responses (Figure 35.2). Although this is an extremely useful tool, it is important to remember, especially in the intensive care unit (ICU), that a paralysed patient may be fully conscious and yet score 3/15 on the GCS. Clues to the preservation of awareness in patients with apparently impaired consciousness include any evidence of perceptual distinctions (e.g. between relatives and strangers), of purposeful actions (e.g. sustained visual tracking or reaching for an object) and of communication (either expressive or receptive). Conscious state is not usually a major consideration during cognitive assessment in the clinic, but relative impairments of

**Figure 35.1 Schematic model of neurotransmitter circuits involved in the three states of vigilance.** During wakefulness, hypocretin (Hcrt) activity excites noradrenergic (green), histaminergic (deep blue) and serotonergic (yellow) neurons, which give rise to enhanced cortical activity and arousal. Slow-wave sleep (SWS) is characterized by synchronous intrinsic cortical activity, and most subcortical afferents show reduced activity. During rapid-eye-movement (REM) sleep, low hypocretin activity results in disorganization of REM-on cholinergic neurons (orange) DRN, dorsal raphe nucleus; LC, locus coeruleus; PPT, pedunculopontine tegmental nucleus; TMN, tuberomammillary nucleus.

EEG, electroencephalogram; GCS, Glasgow Coma Scale.

Figure 35.3 Basic rhythms of the electroencephalogram (EEG). Records from diagnostic EEGs performed in four different patients, exemplifying β rhythm (> 14 Hz), α rhythm (8–13 Hz), θ rhythm (4–7 Hz) and δ rhythm (0–4 Hz). In each case the dotted line bisects a 2-s sample.
vigilance are common: sleepy patients, for example, perform poorly on cognitive tests. The Epworth Sleepiness Scale (Box 35.1) is a very useful questionnaire in patients who complain of excessive daytime sleepiness: scores over 10–11 indicate pathological levels warranting further assessment.

Pathologies
Psychiatrists should be familiar with the major pathologies of consciousness outlined in Table 35.1 – coma, the vegetative state, the minimally conscious state, the locked-in syndrome and brain death. Excessive daytime sleepiness is an underrecognized cause of cognitive impairment, due most commonly to insufficient sleep, obstructive sleep apnoea or narcolepsy.

**Attention**

**Definition**
William James wrote that 'my experience is what I agree to attend to.' The essence of attention is selection. At any moment, numerous external and internal targets are available to consciousness: attention decides on which of these we should focus our mental energies. The term is often qualified: preparatory attention is deployed when we await an expected event, such as a ring on the doorbell; we speak of selective attention when we concentrate on the voice on the phone rather than the music on the radio; sustained attention, which is particularly relevant to cognitive testing, allows us to maintain mental focus on a task; and spatial attention refers to our ability to allocate attention in space or to the neural processes that allow this.

---

**Figure 35.4** Electroencephalograms (EEGs) from the same patient during (a) and after recovery from (b) an episode of delirium
Neural basis
The neural basis of attention is both distributed and localized. It is distributed in the sense that it involves the concerted activity of widespread brain regions. Factors that disrupt the coherence of distributed brain activity – such as drugs, drug withdrawal, metabolic upset and confusion – are the most common causes of impaired attention. The resulting global brain dysfunction is manifest clinically as a confusional state and, often, in the electroencephalogram (EEG) as a slowing of cerebral rhythms (Figures 35.3 and 35.4).

However, aspects of the neural basis of attention are localized. The expression of attention in the brain is a heightening of activity in brain regions subserving the attended material, for example in visual areas if attention is directed toward vision. In the case of visual attention, the neural mechanisms by which attention is engaged and switched include the posterior parietal cortex, the pulvinar nucleus of the thalamus and the superior colliculus in the midbrain. Finally, the control of attention is tied to the frontal lobe systems involved in cognitive control – executive function – more generally (see below).

Assessment
Sustained attention is assessed clinically by asking the patient to perform a moderately demanding repetitive task, for example subtracting 7 from 100 five times, spelling the word ‘world’ backwards, or reciting the months of the year backwards. Clearly, specific difficulties with arithmetic or spelling can impair performance on the first and second of these tests: the results, as always, need to be interpreted in the context of the patient’s cognitive performance as a whole.

Spatial attention is tested by giving the patient a task that requires an even allocation of attention across space, such as bisection of a straight line or the drawing of a clock face including its numbers and hands (Figure 35.5).

Pathologies
As indicated above, sustained attention is most commonly disrupted by factors that globally impair brain function, such as drugs, drug withdrawal, metabolic upset and confusion, giving rise to confusional states (also known as ‘delirium’). Focal pathology in the structures that engage and switch specific forms of attention, for example visual attention, can, not surprisingly, impair that form of attention. Finally, impairment of attention is a common accompaniment of a dysexecutive syndrome in which the executive network that directs attention is impaired.

Spatial attention is most commonly impaired by right inferior parietal damage, causing neglect, the failure to attend to the contralateral (in this case, left) side of space. The severity of neglect can vary from a minor failure to identify stimuli in a task requiring visual search to a disabling failure to act towards the left side of space or to use the left side of the body. Extinction is a related deficit, involving the failure to detect one of two stimuli presented simultaneously in matching positions in the two visual fields, although each is detected when present separately. Dressing dyspraxia is also associated with right parietal lesions and results from difficulty in orienting garments correctly with respect to body parts because of spatial disorientation.

Perception
Definition
Perception is the ability to gain knowledge of the world through the senses.
Neural basis

Much of the brain, especially the posterior parts of the cerebral cortex, is involved in the processing of sensory information. There are now known to be around 30 maps of the visual world in the occipital, parietal and temporal lobes, dedicated to analysis of the principle features of visual stimuli – form, depth, colour and motion. Two major streams of visual perceptual processing have been distinguished: a ventral steam, running from the occipital into the parietal lobe, concerned particularly with object identification, and a dorsal stream, running from the occipital into the parietal lobe, concerned particularly with the visual guidance of action (Figure 35.6). As information passes through the visual areas in these streams, it is gradually transformed in ways that correspond to the uses to which it is put; for example, cells in later areas in the ventral stream, which enable object recognition, respond to higher-order properties of objects such as their identity or colour, whereas cells in earlier visual areas respond to simpler properties such as the presence of edges. Similar general principles apply to the other senses. Although perception is less strongly lateralized than language (see below), the right hemisphere takes the leading role in some aspects of perception: disorders of face recognition, for example, and the syndrome of neglect are associated more strongly with right than with left hemisphere pathology.

Assessment

Auditory perception is assessed incidentally by conversation and visual perception by naming tasks. The standard specific bedside test of visual perception involves copying a drawing, such as the overlapping pentagons of the Mini-Mental State Examination (MMSE). This test can certainly reveal perceptual impairment, but it will also be affected by difficulty in producing or organizing the drawing.

Pathologies

Agnosias, literally ‘failures of knowledge’, are disorders in which the early stages of sensation are intact but the perception or knowledge to which they normally gives rise is impaired. Visual agnosias are classically divided into apperceptive and associative types: apperceptive visual agnosias include specific impairments of colour, movement and form perception; associative visual agnosias include abilities to recognize objects or faces, although these can, in many cases, be copied or matched. These disorders usually result from damage to the ventral stream of visual processing.

Balint’s syndrome follows bilateral damage to the dorsal stream. It involves simultanagnosia (the inability to make out more than one item in the visual scene at a time), optic ataxia (difficulty reaching for a seen object) and oculomotor dyspraxia (difficulty in directing eye movements accurately).

Memory

Definition

Memory is the capacity that allows our behaviour and experience to change in response to what has happened to us in the past. Some familiarity with the terminology of memory is useful. Memories of every kind must be acquired (or encoded), stored and later retrieved if they are to be useful. Many memories undergo a complex process of consolidation by which they become less vulnerable to loss over time. Anterograde memory refers to the ability to acquire memories from a given point in time; retrograde memory refers to the ability to retrieve memories that were formed previously. Figure 35.7 shows a widely accepted contemporary classification of the types of memory: this classification maps on to the neural systems subserving the different kinds of memory (see below). The key distinctions in this classification are between declarative memories (those we can articulate) and procedural memories (which underlie our know-how); short-term declarative memory, also known as working memory (memory for information with which we are actively working) and long-term declarative memory (memory for information that is in store and can be recollected but that may not be in consciousness currently); and episodic memory (memory for single events) and semantic memory (our database of knowledge about the world and language). Autobiographical memory, of particular importance in psychiatry, involves both personal semantic and personal episodic
memory (you can probably remember where you lived when you were 8 years old – a semantic fact – and some of the first-hand details of an important event from your primary school – an episodic memory).25

**Neural basis**

Memory formation depends ultimately on modifications of the strengths of synaptic connections between neurons.26 As modifiable synapses are present everywhere in the brain, memory, in a sense, is everywhere too. However, different kinds of memory involve different brain regions. Short-term, or working, memory depends on neural systems that represent the material with which we are working, for example language systems if we are repeating a name and address, and frontal executive systems that select what we work with at a given moment. Entering material from working memory into long-term declarative memory requires that the circuit of Papez is intact (Figure 35.8): this limbic circuit includes structures in the medial temporal lobe (MTL), especially the hippocampus, the fornix, the large fibre bundle that interconnects the MTL and the thalamus, and structures in the thalamus, particularly the anterior thalamic nuclei and mamillary bodies. Damage anywhere along the course of the circuit of Papez can give rise to an amnesic syndrome (see below). The long-term storage of semantic memories depends on the lateral temporal neocortex.27 The frontal lobes play a strategic role in memory formation and retrieval. Rich recollection of past personal experiences activates a widespread network of brain regions in all four lobes of the brain.28 There is lively current debate over whether or not intact MTLs are permanently required for such rich recollection.29 Procedural memories are much less dependent on the MTLs. The cerebellum, basal ganglia and sensory cortices are required for conditioning, learning of motor skills and sensory priming, respectively.
Figure 35.9 Coronal magnetic resonance imaging (MRI) scans from the patient “HM” (a–c) and a control subject (d–f).

CS, collateral sulcus; EC, entorhinal cortex; H, hippocampus; LGN, lateral geniculate nucleus; MMN, medial mammillary nucleus; V, ventricle.
Assessment

Short-term or working memory is assessed by asking the patient to repeat three words or a name and address. Long-term declarative memory is assessed by asking the patient to retrieve the three words or name and address after a period of distraction sufficient to ‘wipe’ the working memory. Semantic memory is assessed by asking the patient to name objects or to answer general knowledge questions. These simple tests are useful but fail to tap important aspects of memory, including longer-term retention, autobiographical memory and procedural memory.

Pathologies

Severe damage anywhere along the course of the circuit of Papez causes an amnesic syndrome – an inability to acquire new long-term declarative memories, associated with some degree of retrograde amnesia. Examples include the bilateral excision of the MTLs in the famous patient HM (Figure 35.9), whose anterior MTLs were surgically removed as a treatment for epilepsy; the early pathology of Alzheimer’s disease, which begins in the MTLs; and Korsakoff’s syndrome, due to established thiamine deficiency, in which the causative lesion lies in the anterior thalamus. A transient amnesic syndrome occurs in disorders that transiently disable these structures, including concussion, transient global amnesia, transient epileptic amnesia (Figure 35.10) and drug-induced amnesia. Damage to the temporal neocortex, most often seen in the temporal lobe variant of frontotemporal dementia, causes semantic memory impairment (Figure 35.11). This affects knowledge of objects and language if the left temporal lobe is principally affected, and knowledge of people if the right temporal lobe is worse affected. The existence of focal retrograde amnesia (loss of past memories in the absence of any impairment of the ability to form new ones) as a result of brain damage is controversial, and such cases often turn out to have a psychiatric or forensic explanation. However, there are now a few well-documented cases of this kind, suggesting that brain damage can occasionally give rise to this pattern of deficit.
Language

Definition
Language is the capacity to communicate using words. Language functions include the abilities to speak, understand, repeat, name, read, write and spell.

Neural basis
Language is the most clearly asymmetrical function of the human brain. It is predominantly represented in the left hemisphere in almost all right-handed people and in the majority of left-handed people. Broca’s area, in the left inferior frontal lobe, processes fluent speech; Wernicke’s area in the left superior temporal lobe is required for comprehension of one’s own and others’ speech (Figure 35.12). These areas are connected by a fibre bundle, the arcuate fasciculus. Cortical regions surrounding Broca’s and Wernicke’s areas contribute to their function. Although language is predominantly a dominant hemisphere function, the right hemisphere contributes to prosody, the musical and emotional aspects of speech and speech perception.

Assessment
The critical elements of assessment are to listen to the patient’s spontaneous speech to establish whether it is fluent or dysfluent, and to determine whether the patient’s comprehension is intact. Comprehension can be tested by using instructions of increasing complexity (one to several stages), or by using language of increasing sophistication to frame the request (‘Please point to the drawing of the marsupial’). A more comprehensive assessment tests naming, repetition, reading, writing and spelling.

Pathologies
Dysphasia, or aphasia, is a disorder of language function that must be distinguished from dysarthria, a disorder of articulation (Table 35.2, Box 35.2). The term ‘dyslexia’ is specifically applied to disorders of reading, and the term ‘dysgraphia’ to disorders of writing. Damage to Broca’s area particularly disrupts fluency and syntax, the grammatical ordering of language. Patients with Broca’s dysphasia produce meaningful but dysfluent and effortful speech, from which function words (e.g. ‘the’, ‘to’) are often omitted. Patients may produce phonetic word approximations known as phonemic paraphasias (e.g. ‘mister’ for ‘matter’). Comprehension of syntactically complex sentences may be impaired. Patients are usually aware of their deficit and frustrated by it. Damage to Wernicke’s area disrupts the semantic aspect of language, impairing comprehension both of one’s own and others’ speech: this gives rise to fluent but empty or nonsensical output, containing paraphasic errors (semantic, e.g. ‘hand’ for ‘foot’, and phonemic, e.g. ‘pot’ for ‘put’). Patients are usually unaware of their deficit. Wernicke’s dysphasia is sometimes mistaken for thought disorder. Patients with thought disorder should, however, be able to follow instructions, indicating that their comprehension is relatively intact (although it is noteworthy that the region of the brain associated with thought disorder in schizophrenia overlaps Wernicke’s area). Writing in Broca’s aphasia and comprehension of the written word in Wernicke’s aphasia are usually affected in similar ways to speech production and comprehension, respectively. Damage to the arcuate fasciculus causes conduction aphasia, impairing repetition out of proportion to other functions. Damage to surrounding cortical regions but sparing Broca’s or Wernicke’s area gives rise to aphasia with similar

+ indicates affected; – indicates unaffected functions.
characteristics to Broca’s or Wernicke’s aphasia, but with relative sparing of repetition (transcortical motor and transcortical sensory aphasias, respectively).

Dyslexia can occur as a result of damage to the left visual cortex and adjacent corpus callosum, disconnecting the left hemisphere from information about the written word (alexia without agraphia); as a result of visual neglect (neglect dysgraphia); or in central forms in association with left hemisphere damage, for example due to stroke or dementia, causing surface dyslexia (in which patients become dependent on letter-by-letter reading with resulting difficulty in reading irregular words such as ‘pint’, which are read to rhyme with ‘mint’), or deep dyslexia, in which the ability to read letter by letter is lost (with resulting inability to read nonsense words such as ‘proke’, and semantic reading errors, e.g. ‘brother’ for ‘sister’).

Dysgraphia can occur in association with other types of dyspraxia (dyspraxic dysgraphia, see below), in association with neglect (‘neglect dysgraphia’) and in central forms due to left hemisphere damage analogous to surface and deep dyslexia (see above). Dysgraphia is particularly associated with damage to the angular gyrus, the focus of damage in Gerstmann’s syndrome of central dysgraphia, agraphia (see below), right–left disorientation and finger agnosia (inability to name or point to indicated fingers).

**Pathologies**

Dyscalculia is an acquired disturbance of the ability to calculate. It can result from an inability to comprehend, read or write numbers, generally associated with aphasia. Spatial dyscalculia involves difficulty with written calculations occurring in association with neglect. Anarithmetria, or primary dyscalculia, is the specific inability to perform calculations such as addition and subtraction. Spatial dyscalculia is associated with right hemisphere pathology, whereas impaired use of numerical symbols and anarithmetria occur in association with damage to the posterior left hemisphere, including the angular gyrus.

**Executive function and social cognition**

**Definition**

Executive function is the capacity to organize thought and behaviour. This includes the abilities to plan, initiate, monitor and adjust a course of action; to ‘shift set’, changing tack from one activity or approach to another; to reason; and to problem-solve. These abilities are linked closely to the capacities for appropriate social interaction and empathy, capacities that are, in turn, important determinants of personality. As self-monitoring is a cardinal executive function, patients with dysexecutive disorders commonly lack insight into their predicament.

**Neural basis**

Executive functions are particularly associated with the frontal lobes (Figure 35.13). Whereas the primary motor cortex and premotor areas are involved in the moment-to-moment control of action, the prefrontal cortex – lateral prefrontal, ventromedial prefrontal and anterior cingulate – plays a more strategic role. The lateral prefrontal cortex has been linked particularly with working memory functions, of the kind required, for example, to solve the Wisconsin Card Sort Test in which one must keep track of the correct criterion – symbol shape, colour or number – by which to sort a pack of cards and then make appropriate adjustments when the criterion changes. The ventromedial (or orbitofrontal) cortex is associated with the control of behaviour, especially social behaviour, under guidance by emotion, empa-
Cognitive assessment

thy and theory of mind (our ability to impute mental states such as desires and beliefs to others). The anterior cingulate cortex is thought to play a key role in the allocation of attention. It mediates between arousal systems, the lateral prefrontal cortex and motor output, thus integrating arousal, cognition and action.

The control of executive function is not limited to the prefrontal cortex. The frontal lobes have crucial subcortical connections with the basal ganglia, thalamus and cerebellum (Figure 35.14). Disruption to these structures, or to the links between them, can also give rise to a dysexecutive syndrome.

**Assessment**

Executive function is notoriously difficult to test in the clinic: patients with dysexecutive syndromes severe enough to cause major disruption to long-term decision-making can score full marks on standard cognitive tests such as the MMSE. The single most useful simple clinical measure of executive function is verbal fluency: this task requires generation of as many examples as possible in a minute from a particular category, for example ‘animals’ or ‘words beginning with the letter p’. This task requires an ability to search semantic memory flexibly, remembering for example that the category ‘animals’ includes fish as well as household pets. The lower limit of normal is ten exemplars. The ability to copy motor sequences is also dependent on frontal lobe function: Luria’s fist–side–palm sequence and alternating bimanual sequences (Figure 35.15) can be used to assess this. Dysexecutive disorders commonly give rise to disinhibition: in the go–no go task, the patient is asked to tap the table when the examiner taps once, but not to tap when the examiner taps twice. A dysexecutive patient may find it difficult to withhold a response in the second situation. Confabulation, indifference to failure and perseveration of responses are common qualitative features of dysexecutive syndromes.

**Pathologies**

Focal damage to the frontal lobes occurs most commonly as a result of trauma, stroke or neurosurgical excision. The celebrated case of Phineas Gage involved a railwayman whose ventromedial frontal lobes were destroyed by a metal rod. Gage survived for some years, but with a much altered personality, such that his ‘friends and acquaintances said he was “no longer Gage”’. The frontal variant of frontotemporal dementia presents with changes in personality and behaviour, often involving apathy, disinhibition, and loss of empathy and interest in others. Similar features can occur as a result of subcortical pathologies, because of disruption of the looping pathways mentioned above. These include
Delirium and dementia

Part 4: Mental health problems and mental illness

Focal pathologies affecting the basal ganglia or cerebellum and diffuse pathologies affecting the white matter, for example disease of the small blood vessels of the brain and multiple sclerosis. The notion that cerebellar pathology can give rise to features similar to disorders of the frontal lobe has been enshrined in the concept of the 'cerebellar cognitive affective syndrome'. Bilateral damage restricted to the region of the anterior cingulate cortex can give rise to a state of profound 'will-less-ness' or abulia, akinetic mutism.

Praxis

Definition
Praxis is the ability to learn and perform skilled actions such as writing, gesturing, using a toothbrush or playing a musical instrument. Skilled actions may be transitive, involving another object such as a piano, or intransitive, such as waving. Although praxis may not be an obvious element of cognition, it clearly involves a form of knowledge, and it is crucial to our wellbeing, as it provides the output channel for all the other cognitive processes. ‘Dyspraxia’ involves a deficit in the higher-order control of motor function, not accounted for by sensory loss, by more basic motor deficits such as weakness, tremor, dystonia or ataxia, or by dementia.

Neural basis
Praxis is associated with the dominant hemisphere, which controls the more skilled hand and language. Regions of the left frontal and parietal lobes contain the motor engrams for skilled actions and are required to select and implement these. Performance of skilled oral movements depends particularly on the inferior frontal lobe and insula.

Assessment
Praxis is assessed by asking patients to copy arbitrary hand positions (e.g. tip of thumb touching tip of little finger), to perform mimes of transitive and intransitive actions (e.g. brushing hair, stopping traffic), and to perform learned skilled movements of the mouth (e.g. blowing out a match).

Pathologies
The terminology of dyspraxias has been used inconsistently. The term ‘limb kinetic dyspraxia’ refers to a type of dyspraxia in which movements are performed adequately but dysfluently. The term ‘ideomotor dyspraxia’ has been used to refer to failure to produce intransitive gestures, impairment in the use of single objects or, more broadly, a disorder of the production system for skilled actions. ‘Ideational dyspraxia’ has been used to refer to failure to produce transitive actions, impairment in the use of a series of objects, as in striking a match or, more broadly, a disorder of the conceptual system that contains knowledge of tool functions and actions.

Dyspraxia can occur as part of the behavioural syndrome resulting from focal left hemisphere damage of whatever cause and early in the course of neurodegenerative diseases, including Alzheimer’s disease and corticobasal degeneration. Oral (or buccofacial) apraxia may accompany Broca’s aphasia.

These disorders of skilled movement imitation and selection are sometimes associated with symptoms of motor disinhibition: imitation behaviour (involuntary imitation of the examiner’s movement), utilization behaviour (involuntary utilization of objects that come into view, e.g. the donning of several pairs of spectacles), and alien limb behaviour, involving apparently purposeful limb movements disavowed by the patient. Grasp, pout and palmo-mental reflexes can occur in association with dyspraxia and with dysexecutive syndromes, as they reflect a loss of the motor inhibition normally exercised by the frontal lobes (grasp: the patient’s hand grasps the examiner’s despite a request not to do so; pout: a puckering of the lips when a spatula is placed against them; palmo-mental: a puckering of the chin on stroking the ipsilateral thenar eminence).

DELIRIUM AND DEMENTIA

The two most commonly encountered forms of cognitive impairment are dementia and delirium (Table 35.3). The distinction is important, as the two forms of disorder have very different causes and management. The hallmark of delirium is impairment of sustained attention, with resulting impairment of memory and reasoning. Delirium generally has a subacute onset over hours to days and is associated with alterations of arousal (high or low), disturbances of the sleep–wake cycle, fleeting delusions, hallucinations and disturbed behaviour. Dementia by contrast is usually of insidious onset, and the capacity for sustained attention is
Vascular dementia is heterogeneous as it can result (i) from multiple infarcts giving rise to cognitive impairments that depend on the brain regions affected; (ii) from disease of small blood vessels, causing diffuse white matter damage and a subcortical dementia; and (iii) from strategic infarction in a region crucial to cognition such as the thalamus. The Hachinski Ischaemic Scale (Table 35.5) has some value in identifying vascular dementia. Frontotemporal dementia is a collective term used to describe a group of disorders in which the major pathological finding is atrophy of the frontal or temporal lobes, or usually both, causing three major dementia syndromes: a behavioural variant, presenting with gradual loss of vocabulary and associated knowledge of the world; and a progressive non-fluent aphasia variant. Table 35.6 provides a more wide-ranging, but not comprehensive, list of the causes of dementia.
A PRACTICAL APPROACH: HISTORY-TAKING, THE MMSE AND BEYOND

History-taking

Cognitive assessment begins at the start of the clinical encounter. Difficulties encountered in giving a history due to problems with attention, memory, language or executive function may reveal the presence of cognitive disorder. Cognitive symptoms should be clarified in the usual way, with enquiries about the precise nature of the problem (e.g. ‘poor memory’ may mean, among other things, absent-mindedness, word-finding difficulty, problems with spatial orientation or face recognition, or a true anterograde memory deficit), its duration and tempo, any precipitants, variability, and relieving or exacerbating factors. It can be helpful to enquire specifically about the following areas:

- Concentration: absent-minded errors
- Memory: for recent events, faces, routes
- Language: word-finding, comprehension, reading, writing, spelling
Box 35.5 Consensus criteria for the clinical diagnoses of probable and possible dementia with Lewy bodies

These operational diagnostic criteria for dementia of the Lewy body type (DLB) were developed at a consensus meeting bringing together proponents of the previous diagnostic criteria from healthcare professionals in Nottingham and Newcastle.

- The central feature required for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention and of frontal subcortical skills and visuospatial ability may be especially prominent.
- Two of the following core features are essential for a diagnosis of probable DLB, and one is essential for possible DLB:
  - Fluctuating cognition with pronounced variations in attention and alertness
  - Recurrent visual hallucinations that are typically well formed and detailed
  - Spontaneous motor features of parkinsonism.
- Features supportive of the diagnosis are:
  - repeated falls;
  - syncope;
  - transient loss of consciousness;
  - neuroleptic sensitivity;
  - systematized delusions;
  - hallucinations in other modalities.
- A diagnosis of DLB is less likely in the presence of:
  - stroke disease, evident as focal neurological signs or on brain imaging;
  - evidence on physical examination and investigation of any physical illness or other brain disorder sufficient to account for the clinical picture.

*These criteria for vascular dementia are based upon the Hachinski Ischaemic Score, originally derived on the basis of cerebral blood-flow patterns in people with dementia. On the weighted scale, a score of 7 or more is taken to indicate vascular dementia, while a score of 4 or less suggests that this is an unlikely diagnosis.

WHAT CAN FORMAL NEUROPSYCHOLOGY ADD TO CLINICAL ASSESSMENT?

A clinical neuropsychologist is primarily a clinical psychologist who will usually, in the UK, have a post-qualification diploma conferring full practitioner membership of the British Psychological Society’s Division of Neuropsychology. In addition to their more specialized skills in cognitive assessment, neuropsychologists possess the fundamental tools of the clinical psychologist, for example awareness of psychiatric diagnoses, that might provide additional or alternative explanations to neurological ones. Their remit has increasingly been extended to include evidence-based and functionally relevant rehabilitation.47

Cognitive assessment is part of a broader enquiry. The selection of tests administered will depend, for example, on the referral question being posed (which should be explicit), the approach to the question (e.g. battery v. hypothesis testing), the time available, the likely abilities and condition (both mental and physical) of the individual being tested, the relative importance of reliability and validity, and the question of whether and when repeat testing might be required.

At the outset it is crucial to establish a baseline – an estimate of an individual’s likely premorbid ability. The measures used, which must be interpreted in the light of factors such as educational and occupational achievement, are typically reading-based tasks such as the National Adult Reading Test (NART)48 and, more recently, the Wechsler Test of Adult Reading (WTAR).49 These tests rely on the observation that reading skills are relatively robust in the face of most causes of cognitive decline. The usefulness of both measures is limited by ceiling effects, educational and cultural effects, and disorders such as dyslexia. Alternatives include the ‘spot the word’ component of the Speed and Capacity of Language Processing (SCOLP) test50 or the ‘best subtest score’, where the Wechsler Adult Intelligence Scale (WAIS) has been administered.

The WAIS (in the UK, WAIS-III UK)51 is the most widely used measure of adult intelligence.52 Interestingly, test development was based not on theory but on practical and clinical perspectives53 by David Wechsler, who defined an individual’s intelligence as ‘the capacity to act purposefully, to think rationally, and to deal effectively with his (or her) environment’. Fourteen subtests contribute to four indices,

Table 35.7 Sensitivity, specificity and positive predictive value of the Addenbrooke’s Cognitive Examination (ACE): dementia positive predictive value (PPV) at different prevalence rates

Cognitive symptoms are often accompanied by other neuropsychiatric symptoms, which should be identified, in particular personality change, mood disturbance, psychotic phenomena, and altered eating habits, sexual behaviour or sleep.

Questions about the patient’s life history, including their career, main relationships, children and grandchildren, can provide revealing information about their linguistic ability, memory and ability to organize their thoughts.

It is vital to interview an informant, and generally advisable to do so in the patient’s absence. It is helpful, therefore, to explain at the start of the consultation that you generally speak to the patient and informant both together and separately. After initial history-taking in the presence of the informant, I usually speak to the informant on his or her own, before examining the patient on his or her own. It can be helpful to give the informant a questionnaire that systematically probes for relevant symptoms, such as the Cambridge Behavioural Inventory.43,44

Examination

The cognitive assessment should normally be part of a broadly based medical assessment including general history-taking, mental state, general medical examination and neurological examination.

Cognitive assessment is facilitated by using a pro forma that systematically samples the domains of cognition discussed above.45 The MMSE is the most widely used brief tool for cognitive assessment and is invaluable.21 It is insensitive, however, to mild or early deficits and to executive impairment. The Addenbrooke’s Cognitive Examination (ACE) incorporates and builds on the MMSE, providing a very useful profile of cognitive ability. Sensitivity, specificity and positive predictive values for dementia are available (Table 35.7).

Neither the MMSE nor the ACE tests praxis adequately. It can therefore be helpful to supplement the ACE with the clinical tests of praxis mentioned above.
two verbal (verbal comprehension and working memory) and two non-verbal (processing speed and perceptual organization). These results yield an overall full-scale IQ (FSIQ) and separate measures of verbal and performance IQ. It is important to recognize significant discrepancies between various abilities that might invalidate such overall averages. The Wechsler Abbreviated Scale of Intelligence (WASI) is a shorter, but reliable, four-subtest screening measure.\textsuperscript{54}

The Wechsler Memory Scale (WMS-III) is conveniently co-normed with the WAIS-III.\textsuperscript{55} It assesses diverse aspects of memory function across an age range of 16–89 years and yields index scores and a number of other functionally relevant measures in immediate, general (delayed) and working memory in both auditory (verbal) and visual domains. The Rivermead Behavioural Memory Test, now in its third revision, is a more straightforward tool.\textsuperscript{56} The WAIS-III and WMS-III provide comprehensive overviews of current cognitive function and memory. Their results can indicate areas requiring more focused neuropsychological testing.

Thus, although one can assess attention informally during testing and with the help of working memory tasks on the WAIS-III and WMS-III, the Test of Everyday Attention (TEA) would allow a more detailed evaluation.\textsuperscript{57} on the WAIS-III and WMS-III, the Test of Everyday Attention (TEA) would allow a more detailed evaluation.

No neuropsychological assessment is complete without an assessment of mood state, either informally or with the help of instruments such as the Hospital Anxiety and Depression (HAD) questionnaire. Competent neuropsychological assessment is time-consuming, multifaceted and challenging. Neuropsychological assessment instruments, and their interpretation, are becoming increasingly sophisticated. With experience, medically trained clinicians can often make confident diag-

**KEY POINTS**

- Cognition involves the capacities to acquire, store and use knowledge.
- Its key elements are consciousness (wakefulness), attention, perception, memory, language, executive function and praxis.
- Its key disorders are delirium and dementia, which have distinctive features, causes and treatments.
- A broad-brush distinction between cortical and subcortical types of dementia is clinically useful.
- A systematic approach to history-taking and bedside cognitive assessment with standard tests such as the MMSE and the ACE often allow a confident clinical diagnosis.
- Formal neuropsychological assessment is indicated where a high or low baseline complicates interpretation of standard clinical tests, in detailed definition of unusual symptoms, and in planning and monitoring treatment programmes.
noses of cognitive disorders on the basis of clinical assessment and the use of a screening tool such as the ACE. Expert neuropsychological help is especially valuable in the assessment of high-performing individuals with cognitive complaints who score at ceiling on screening tests; in individuals with pre-existing learning difficulties in whom the interpretation of poor performance on screening tests is unclear; in individuals with highly specific or unusual neuropsychological symptoms requiring more detailed exploration; and in the development and monitoring of treatment programmes.

REFERENCES

INTRODUCTION

The work of a neurologist consists of the diagnosis and treatment of a daunting array of disorders in a system of inconceivable complexity. Nevertheless, a systematic clinical approach, a working knowledge of common neurological conditions, and an informed, hypothesis-driven deployment of a few powerful investigations make the work not only possible but also enjoyable. This chapter begins by outlining a system for gathering relevant information from a patient so that a diagnostic problem can be formulated simply. It then discusses the disease processes that commonly give rise to these problems and how test results can help to distinguish between them. The chapter concludes with an outline of the principles of treatment of the common neurological conditions.

THE NEUROLOGICAL PATIENT

Neurological evaluation

A clear account of the symptoms and time course of a neurological complaint is without doubt the most valuable information that can be obtained during a clinical encounter. Many of the most common presenting symptoms – pain, sensory disturbance and dizziness – are subjective experiences, whose descriptions will differ in important ways, depending on the underlying cause, and therefore reward careful exploration. Episodes of blackout and collapse are usually described to, rather than seen by, the clinician, and different underlying mechanisms may be recognizable from the presence or absence of specific features. Although weakness can be quantified, and tremors or other movement disorders observed, knowledge of the circumstances of onset and the time course of any subsequent change is critical. Cognitive dysfunction can be tested informally with some specificity, but the patient’s account of their problems will often reveal the domain or domains in which abnormalities are most likely to be found.

Pain

Three types of pain fall within the remit of neurology: headache, facial pain and neuropathic pain.

Headache

Headache is the most common neurological symptom and is typically associated with a degree of anxiety disproportionate to the gravity of the underlying cause. This is because the vast majority of headaches belong to one of the primary headache syndromes, which are benign and usually treatable. Headache syndromes are stereotyped and follow a pattern of attacks and remissions. A large number of stereotypic headache syndromes are now recognized, but the clinical distinctions most important for practical purposes are between migraine, cluster headache and cervicogenic tension headache. The features by which each of these syndromes can be differentiated are listed in Table 36.1.

In contrast to the primary headache syndromes, cases in which headache is secondary to an underlying lesion or process will usually be found to harbour serious cranial pathology. The history in these cases is usually shorter and the evolution of the discomfort progressive. At any age, the possibility of a space-occupying lesion causing an increase in intracranial pressure needs to be considered in a patient who describes waking daily with a global headache that is partially relieved by assuming an upright posture. If position-dependent visual obscurations are also described (due to pressure changes sufficient to disrupt the function of the optic nerves), raised intracranial pressure becomes a racing certainty.

Severe headaches with a sudden onset typically present to the emergency department, where occasionally, although by no means always, an immediate computed tomography (CT) scan reveals the presence of blood in the subarachnoid space. Subarachnoid bleeding should always enter into the clinical differential of sudden severe headache. Onset is explosively abrupt – often likened to a sudden blow to the head; the greater the precision with which the patient describes the headache onset (e.g. ‘just as I was reaching for a tin of baked beans on the shelf’), the more likely it is to represent a haemorrhagic event. Obtaining a history of a primary syndromic headache in addition to the presenting event should not be considered reassuring in cases with a
high clinical suspicion: people with migraine have subarachnoid haemorrhages at the same rate as the rest of the population (about 10 cases per 100,000 person-years).

In patients over age 60 years, a unilateral persistent ‘boring’ discomfort associated with more widespread tenderness over the scalp, pain in the masseter muscles when chewing (jaw claudication) and a significantly raised erythrocyte sedimentation rate (ESR) may be secondary to giant cell arteritis. This frequently overlooked cause of headache is of great importance, as it often responds well to steroids and, untreated, may cause permanent loss of vision.

**Facial pain**

Trigeminal neuralgia is the archetypal facial pain syndrome. It is diagnosed on the strength of a classic history of paroxysmal, shooting discomfort in the distribution of one or more divisions of the fifth cranial nerve, typically in response to local stimulation (touching, shaving, eating or teeth-cleaning). Attacks occur in clusters punctuated by periods of spontaneous remission. Trigeminal neuralgia is commonly idiopathic, but it may be secondary to vascular or infiltrative lesions anywhere along the path of the nerve, or rarely to an inflammatory process in the brainstem. Secondary cases may be associated with a trigeminal sensory deficit.

Facial pain due to herpes zoster (post-herpetic neuralgia) can affect the branches of the trigeminal nerve, producing a vesicular eruption in the distribution of the affected branch (almost always the opthalmic) in the active stages and residual scarring in the post-infectious period.

Patterns of facial pain that do not have any of the characteristics of primary or secondary trigeminal neuralgia are termed ‘atypical’, are seldom associated with identifiable pathology, and show a variable response to neuropathic pain medication.

**Neuropathic pain**

Pain is a common and potent cause of disability in neurological disorders and may be a feature of either central or peripheral nervous system disease. Pain of neuropathic origin is usually described as having a ‘burning’, ‘electric’ or ‘tingling’ quality and can be aggravated by superficial stimulation (e.g. contact with bedclothes). The latter phenomenon supports the idea that nociceptive hyperexcitability is the responsible mechanism, at least in peripheral nerve disease.

**Visual symptoms**

Although most patients with gradual visual failure are seen by an optician or ophthalmologist, those with a more rapid history, a fluctuating course, or symptoms of diplopia (double vision) or oscillopsia (visual instability) are usually considered to require neurological evaluation.

**Visual failure**

In the absence of any visible abnormalities in the external components of the eye, monocular visual impairment may be caused by damage (commonly inflammatory or infiltrative) to the optic nerves. Optic nerve fibres carrying

information from the nasal half of the retina (which responds to changes in the outer, or temporal portions of the field of vision) cross the midline at the optic chiasm, joining fibres from the temporal half of the opposite eye, to form the optic tract. Damage to the visual system posterior to the chiasm therefore results in visual loss in one or other visual field (homonymous hemianopia). A lesion at the chiasm itself causes loss vision in both temporal fields (bitemporal hemianopia). These patterns of loss may be hinted at by a patient who ‘can only see things on the left (or right’) or complains of ‘blurring around the edges’. Visual deficits above or below a horizontal midline suggest damage to the retinal vessels. In common with many, if not all, neurological complaints, the pattern (complete, partial, variable, progressive or stuttering) and speed (sudden, over seconds to minutes, or over hours to days) is of crucial importance to a judgement of the likely pathology.

Diplopia
Diplopia arises from a change in the alignment of the eyes in relation to the visual world, due to limitation of movement of the orbit in one or more directions. Diplopia may be due to oculomotor nerve dysfunction, failure of transmission at the neuromuscular junction, distortion of the orbit by a solid mass, or infiltration of the ‘strap muscles’ of the eye. The relative positions of the two images may provide clues as to the aetiology: diplopia that is fatiguable or variable suggests a problem at the neuromuscular junction; progressive or painful diplopia suggests an infiltrative cause; horizontally spaced images are produced by limitation of abduction or adduction; vertical diplopia maximal on down-gaze is typical of an isolated fourth nerve palsy.

Oscillopsia
An inability to maintain stable fixation on the visual environment is a common symptom of loss of oculomotor control at the level of the cerebellum or its connections with the oculomotor centres in the brainstem. The symptom is usually accompanied by the other cardinal symptoms of cerebellar dysfunction (walking and balance difficulties, clumsiness and slurring of speech), and nystagmus (see below) is an expected finding on examination. Nystagmus without an accompanying history of oscillopsia is longstanding and often congenital.

Weakness
Muscle weakness implies damage involving (i) the precentral gyrus of the cerebral cortex or the white-matter tracts that transmit impulses through the hemispheric subcortical white matter, midbrain, brainstem and spinal cord; (ii) any part of the network of lower motor neurons that convey impulses to effector muscles; or (iii) the muscles themselves.

Hemispheric lesions
A lesion affecting motor regions of the cerebral hemispheres will give rise to weakness of the face or limbs on the side opposite to the lesion. The arm, leg and face may be differentially impaired because of the somatotopic organization of the motor strip: weakness confined to a single leg can be due to pathology confined to the medial portion of the precentral gyrus. Lesions of the dominant hemisphere are usually accompanied by language disturbance (see below), and relatively mild language involvement in comparison to the degree of weakness suggests a predominantly subcortical localization of the lesion. The speed of onset of the problem is critically important to the likely process, which is most commonly vascular or neoplastic.

Brainstem lesions
Vascular, inflammatory or infiltrative lesions in the brainstem may also give rise to contralateral hemiplegia. In these instances, the weakness will be accompanied by additional difficulties, including incoordination, impaired motor control of the eyes, face, speech and swallow, disequilibrium, nausea and hemi-body sensory disturbance. More extensive brainstem lesions cause weakness affecting all four limbs (tetraparesis), together with one or more of these additional deficits.

Spinal-cord lesions
A lesion within the spinal cord produces weakness, and usually some form of sensory alteration, in structures whose innervation depends on the cord at or below the level of the lesion. Lesions involving only one half of the cord will produce weakness of one or both limbs on the same side (although sensory impairment may be bilateral – see below), but weakness or stiffness of both legs (spastic paraparesis) or all four limbs (tetraparesis), usually with accompanying bladder dysfunction, and without the additional features of a brainstem lesion (see above), infallibly implicates the spinal cord as the site of damage. The presence of paraparesis (i.e. sparing of the arms) implies that the lesion is below the T1 segment of the cord – the lowest level at which nerve fibres travelling to or from the arms form part of the motor or sensory tracts. A description of numbness or sensory alteration with an upper limit (sensory level) may indicate whether such a lesion lies within the thoracic or lumbar segments.

Lower motor neuron lesions
The lower motor neuron originates in the anterior horn of the spinal cord grey matter, emerging from the cord at segmental intervals, along with the posterior (sensory) roots, to form the spinal nerves. Those formed in cervical and lumbar regions are incorporated into plexuses, from which nerve trunks, carrying both efferent (motor) and afferent (sensory) information to and from the peripheries, emerge. It is rare for the motor components of any of these structures to be selectively disrupted. Unless the anterior horn itself or the ventral roots alone are the pathological focus, a lower motor neuron lesion is therefore accompanied by sensory change, whose distribution may suggest the location of damage. These patterns of sensory and motor
loss are described below, in the section dealing with sensory symptoms.

**Muscle pathology**

In contrast to a lower motor neuron lesion, muscle pathology is never accompanied by sensory symptoms. Myopathy is suggested by a proximal distribution of weakness, resulting in symptoms such as difficulty rising from a chair or raising the arms above the head. Weakness may be accompanied by an aching discomfort in these regions.

**Sensory symptoms**

Subjective alteration of sensation can be either positive (usually described as ‘tingling’) or negative ('numbness') and can point the way to a range of important diagnoses if attention is paid to the anatomically relevant details.

Contiguous areas of numbness or tingling at the distal extremities (usually beginning with the soles of the foot, and often slowly progressive) raises the possibility of a peripheral neuropathy. More extensive involvement, including proximal regions of the upper and lower limbs at onset, suggests the presence of a more widespread process involving the plexus or the cell bodies of sensory neurons (dorsal root ganglionopathy).

When symptoms are more focal, radiculopathy (segmental damage to the nerve root in the intervertebral foramen) or mononeuropathy should be considered. The most common mononeuropathies are carpal tunnel syndrome (which commonly presents with tingling in the first three fingers) and ulnar neuropathy (tingling in the fourth and fifth fingers). Both presentations may overlap with those of compression of the lower cervical nerve roots, although the latter are normally accompanied by discomfort in the neck. The distinction is often clinically evident after exploration of the accompanying motor involvement and the distribution of insensitivity to cotton-wool or a metal point (see below). Analogous symptoms occur in the lower limbs, due to compression of the common peroneal nerve, tibial nerve (tarsal tunnel syndrome) and the lumbar-sacral nerve roots, which produce distinct patterns of altered sensation over the lower leg and foot. A list of landmark symptom sites that may be helpful in unravelling these distinctions is provided in Table 36.2.

Compression of the median or ulnar nerves may be bilateral, but other combinations of two or more discrete areas of sensory alteration in the limbs suggest a pattern of mononeuritis multiplex, which is frequently associated with more widespread systemic pathology.

**Abnormal movement**

The most common movement disorder is tremor, whose diagnosis requires distinction from the more unusual hyperkinetic patterns of involuntary (chorea, myoclonus and hemiballismus) and quasi-voluntary (tic disorders) phenomena.

</table>
**Tremor**
Any rhythmic, repetitive, involuntary movement of the extremities or head may be classified as a tremor, the hand being the most common site. Many cases, particularly in patients under the age of 40 years, represent a benign physiological phenomenon (‘essential tremor’): in these cases, the problem tends to be exaggerated by states such as stress, fatigue and anxiety and disappears after the intake of small quantities of alcohol. A clear history of isolated tremor in the previous generation is often obtained. Some forms of physiological tremor may be task- or activity-specific, such as writing, or orthostatic tremor.

A drug history is important: statins, inhaled β agonists, sodium valproate, lithium, tricyclic antidepressants and neuroleptic agents may be implicated and not infrequently prescribed in combination. Caffeine intake is another common modifiable factor.

In people in older age groups, tremor is more likely to be a manifestation of parkinsonism. A parkinsonian tremor is present at rest, typically worse during attention-demanding mental tasks, and not present during reflexive movements. Tremor may remain the dominant or even sole clinical feature of Parkinson’s disease over many years.

Tremor can be purely factitious but, even in cases of unusually coarse or bizarre patterns, midbrain (rubral) or cerebellar pathology and Wilson’s disease are important diagnostic considerations, especially in younger patients.

**Chorea**
A choreiform movement disorder is more complex and widespread than a tremor, in keeping with its derivation from the Greek word meaning ‘dance’. In general terms, it is less predictable, in both spatial and temporal terms, than the simple oscillatory movements that characterize a tremor. Unilateral chorea may appear as a feature of a focal ischaemic or inflammatory lesion. Chorea is a recognized feature of autoimmune disease, including systemic lupus erythematosus (SLE) and the antiphospholipid syndrome. Sydenham’s chorea refers to an immunologically mediated complication of streptococcal infection. Florid chorea is a feature of the autosomal dominant neurodegenerative condition Huntington’s disease (HD) and is a presenting feature of inherited metabolic conditions such as Wilson’s disease and storage disorders.

**Myoclonus**
Brief isolated involuntary small-volume movements are referred to as ‘myoclonus’ or ‘myoclonic jerks’. The movements may be observed and in some instances elicited by startle, cutaneous stimulation or posture (asterixis). Commonly, however, the presence of myoclonic jerks is inferred from a history of intermittent acts of sudden clumsiness or from a description. The most dramatic and noticeable examples appear as movements of the shoulder girdle, limbs or face, but small-volume jerks may be observed in the outstretched fingers, axial musculature or the palate.

A history of myoclonus is associated with a number of primary epilepsy syndromes, including juvenile myoclonic epilepsy. Myoclonic jerks are seen following recovery from anoxic brain injury (post-anoxic myoclonus) and in metabolic encephalopathies: the prominence of the movement may correlate with the severity of the condition. Stimulus-sensitive small-volume jerks of the outstretched fingers are associated with the early stages of neurodegenerative disorders, including Alzheimer’s disease (AD). Startle myoclonus is typical, but not diagnostic, of Creutzfeldt–Jakob disease.

**Hemiballismus**
Hemiballistic movements involve complexes of muscles acting in a coordinated but involuntary fashion to bring about dramatic ‘flinging’ movements of one arm or leg. Movements are of sudden onset and brief duration. They occur following injury to the contralateral subthalamic nucleus, typically ischaemic or haemorrhagic, and are usually self-limiting within a period of weeks. Hemiballismus is to be distinguished from the equally unusual ‘alien limb phenomenon’, in which a patient engages in complex goal-directed activities such as picking up objects or removing items of clothing without any sense of agency; the arm is described as having a life or will of its own. The alien limb syndrome may follow injury or degenerative change in the frontal or parietal cortical regions.

**Tic disorders (stereotypies)**
The movement disorders described above are involuntary phenomena, but a tic is a willed movement, executed in response to an irresistible impulse. Tic disorders are therefore a form of compulsive behaviour manifesting in brief motor acts involving the limbs, face or muscles of phona
tom (vocal tics). Although these acts may in some instances resemble myoclonic jerks, they are typically more complex, requiring the mutual coordination of more than one muscle group, and they may involve a pattern that develops in a predictable fashion over time. At the extreme end of a spectrum of severity lies Tourette’s syndrome, characterized by multiple motor and vocal tics.

**Disturbances of consciousness**
The patient who has suffered their first ever blackout is usually eager to know whether they have epilepsy and the likelihood of recurrent events. The answers to these two important questions are clearly linked, and so the first clinical decision to be made is whether the event was due to cerebral or circulatory disturbance (‘fit or faint’).

This distinction may be difficult to make, but the greater the amount of first-hand information available from a witness to the attack, the easier it becomes. A witness’s description of a convulsive epileptic seizure can be decisive: a period of unconsciousness with recovery over minutes, including a period of confusion, a prolonged postictal period of myalgia, headache and fatigue, all suggest epilepsy. In contrast, premonitory light-headedness, a rapid recovery, retained memory of events right up to the onset of the blackout, and awareness during emergence from
unconsciousness are all suggestive of a faint. Shaking movements, even a brief convulsion, may be described during a faint, but a prolonged phase of tonic muscular contraction and clonic (convulsive) movements of the limbs, preceded or accompanied by vocalization, are all definite hallmarks of epilepsy. Urinary incontinence more commonly accompanies an epileptic event, but its description does not exclude a haemodynamic cause. Soreness of the sides of the tongue or mouth due to tonic contraction of the jaw muscles is a fit marker but by no means a feature of all cases.

A well-described complex partial seizure, characterized by sequences of purposeless movements of the face, hands or feet, often accompanied by a vacant, staring expression and an unresponsive state, and continuing for seconds to minutes (cf. stereotypies) should be easily recognizable. Complex partial seizures are often marked by the preceding occurrence of a sensory aura (e.g. a hallucination of smell, taste or familiarity – déjà vu). Epileptic auras may also occur in isolation (simple partial seizures).

In an absence attack, the phenomenon of vacancy and unrousability is not accompanied by abnormal movements and indeed may occur during the continued performance of other activities, such as walking or driving.

Bizarre motor phenomena, psychiatric morbidity – latent or declared – and evidence of awareness during the episode are suggestive of a factitious event, or ‘pseudo-seizure’. It is important to remember that pseudo-seizures and genuine epileptic attacks may occur in the same individual, and that seizures of frontal origin are often associated with seemingly bizarre motor phenomena.

**Cognitive decline**

In unskilled hands clinical cognitive evaluation can be a frustratingly time-consuming exercise, but for the experienced observer it can be extremely diagnostically rewarding. An important principle is that clinical data should be gathered not only from the patient but also from a close associate, preferably not in the presence of each other, as this may inhibit the disclosure of diagnostically important information.

The differential diagnosis of cognitive decline varies with both the patient’s age and the pattern and rate of progression of their symptoms. The incidence of AD increases exponentially with age, such that around one in five people over the age of 80 years is clinically affected, and an even higher number harbour presymptomatic plaque and tangle pathology. In common with all biological processes, higher brain function declines with normal ageing, leaving the principal diagnostic dilemma in an elderly patient with cognitive dysfunction one of distinguishing incipient AD from age-related decline. In such borderline cases, the diagnostic category of mild cognitive impairment (MCI) proves to be a useful compromise: patients with cognitive complaints but defective performance on only a single domain of performance are put into this category, in the knowledge that after a year as many as 50 per cent will have deteriorated to a condition consistent with early AD. Although a history of insidious cognitive decline in a patient over 65 years of age is more likely to represent the onset of AD than any other pathological process, below this cut-off AD and frontotemporal lobar degeneration (FTLD) are approximately equally common. The onset of vascular dementia is also more common in late middle age than old age and is particularly likely in people with one or more vascular risk factors.

**Clinical examination**

A great deal of critical diagnostic information will have been gathered during the interview stage of the clinical encounter, including the characteristics of the patient’s gait and speech, the presence and characteristics of any abnormal movements, and a crude assessment of cognition. Formalizing, elaborating and, where possible, quantifying these observed abnormalities is one purpose of the clinical examination; the other is to look for clues to underlying pathology that cannot be seen without specific testing.

**Higher cognitive function**

Adequate bedside or clinic-based cognitive evaluation can be achieved using a minimum of equipment. The most effective and time-efficient tools are those that rely on more than one cognitive domain but that produce differential patterns of performance, depending on the nature of the deficit. Spontaneous speech, for instance, which contains myriad clues to the integrity of the language system (rate of production, phonological and syntactic integrity, vocabulary), can be examined while the patient is prompted to recall recent notable news items.

Similarly, both working and verbal episodic memory can be evaluated by asking the patient to repeat and, after a delay, recall a word list or name and address. Immediate recall is impaired by working memory dysfunction, while problems with delayed recall would implicate learning and storage. An analogous test of non-verbal memory (particularly useful when evaluating a patient with anaphasic disorder) consists of asking the patient to copy, and later reproduce from memory, three simple geometric designs (e.g. a wire cube, a five-pointed star and intersecting pentagons), a task that makes concurrent demands on visuospatial and constructional skills. Non-verbal memory may, in any case, be impaired independently of memory for verbal material.

Verbal fluency, using both initial letter and semantic category as a cue, is another clinical technique with compound utility: patients with executive deficits characteristically experience greater difficulty searching for words beginning with a particular letter than they do for words belonging to the same semantic category (essentially, an exaggeration of normal performance, presumably due to the fact that neural states corresponding to semantically related items are mutually activating). In contrast (and for similar reasons),
patients with semantic dementia often produce more words per minute in the letter than the category condition. Patients with frontal variant FTLD may involuntarily perseverate on a single word and are often unable to inhibit a tendency to produce obscenities or words with sexual connotations. Patients with AD often repeat the same word several times during the course of the test, due to their defective memories.

Naming errors are a further source of diagnostically important information: a series of relatively low-frequency but visually distinct pictures can elicit several kinds of highly informative error pattern: phonological errors (i.e. distortions of the correct phonological form of the word) suggest that the patient has a problem in the verbal output system; circumlocutions (‘a beautiful creature that jumps’), semantic errors, and overuse of category, generic or highly prototypical terms (e.g. ‘animal’, ‘dog’, ‘item’ or ‘thing’) implies a breakdown at the level of meaning, or semantic memory; and the patient who scrutinizes a line drawing or traces the outline with their finger before producing the name of something conceptually distinct but vaguely visually similar (e.g. ‘ball’ in response to a picture of an apple) is likely to have profound visuospatial impairment. These distinct patterns point clearly to dysfunction in the left inferior frontal, bilateral anterior temporal, and posterior occipitoparietal regions, respectively.

Cranial nerves

With the exception of cranial nerves I and II, which transmit special sensory modalities, the cranial nerves emerge from nuclei that are located in the upper (III–VIII) and lower (IX–XII) parts of the brainstem. They are best examined from the eyes downwards, beginning with visualization of the optic fundus.

The optic fundus

A normal optic disc (Figure 36.1a) appears pale pink in colour, with a smooth, well-defined border, flush with the surrounding retinal surface. The retinal vessels can be clearly seen radiating from its centre, with pulsation often visible. The disc may become swollen, as a result either of...
inflammation in the nerve (optic neuritis) or of interstitial fluid accumulation caused by impaired venous drainage secondary to raised intracranial pressure. The edges of a subtly swollen disc (Figure 36.1b) lose their clarity, while more established swelling causes the surface to protrude away from the retina (Figure 36.1c). Haemorrhages may also be visible in severe cases (Figure 36.1d).

Optic disc swelling is a sign of an acute and active process and should never be ignored. Chronic damage to the optic nerve (usually following resolution of one or more inflammatory events) results in an atrophic appearance, recognizable by its sickly pale colour and shrunken area (Figure 36.1e).

Although identification or exclusion of optic nerve swelling is an essential goal of fundoscopy, the peripheries of the retinal surface may also reveal the presence of retinitis pigmentosa, whose spiculated appearance (Figure 36.2) is associated with a variety of metabolic disorders.

Before or after fundal examination, the pupils may be examined for shape, regularity, equality, and contraction in response to light. The level of the eyelids should also be noted: complete closure (ptosis) on one side will be obvious, but partial ptosis may require specific inspection. Partial ptosis, together with reduction in pupillary diameter (miosis) in the same eye, form the defining features of Horner’s syndrome. This results from interruption of the long sympathetic pathway that runs from the hypothalamus to the smooth muscle of the eye, via the upper thoracic segments of the spinal cord.

**Eye movements**

Deviation of the orbit may be evident on immediate inspection and is not always pathological: sequentially occluding the two eyes and looking for a compensatory movement of the deviated eye towards the midline can confirm a lifelong squint. Uncompensated deviation indicates paralysis of the oculomotor muscle or muscles acting in the opposite direction. This may be due to infiltration of the muscle, but more commonly it indicates loss of innervation. Loss of function of the sixth nerve results in deviation of the globe towards the midline due to weakness of the lateral rectus muscle. An eye that is deviated laterally and inferiorly indicates weakness of the medial, superior and inferior recti, all of which are supplied by the third nerve, and is frequently accompanied by enlargement of the pupil, as it also transmits the fibres that mediate reflex constriction.

Pursuit movements in response to movement of a target in the vertical and horizontal planes confirm complete or partial failure in one or more of these directions and may bring out a previously unseen palsy of the fourth nerve by demonstrating loss of radial intortion of the globe (evident in the normal condition from subtle rotatory movement of the scleral vessels on down-gaze). Double vision will be reported with a paralytic, but not a compensated, squint: images are reported as separated horizontally in a sixth nerve palsy, diagonally in a third nerve palsy and obliquely in a fourth nerve palsy. In the latter, two images of a pen held horizontally in front of the eyes will form an arrowhead shape whose tip points to the side of the lesion.

Nystagmus (rhythmic oscillations of the eye) may be visible with the patient looking straight ahead (primary position of gaze) but is more commonly evoked by voluntary eye movement. The direction of oscillation is diagnostically important: horizontal nystagmus is caused by a lesion to the cerebellar circuitry on the side to which it is maximal. Down-beating nystagmus suggests a lesion at the base of the brainstem. Unilateral nystagmus combined with limitation of horizontal movement indicates interruption of the upper brainstem tracts between the third and sixth nerve nuclei (internuclear ophthalmoplegia).

**Facial weakness**

For most of its length, the seventh (facial) nerve consists only of motor fibres innervating the muscles of facial expression. For clinical purposes, a lesion of the facial nerve therefore results in an inability voluntarily to elevate the forehead (frontalis), forcibly close the eyelids (orbicularis oculi), widen the mouth, and purse or tighten the lips (orbicularis oris). A seventh nerve lesion may occur anywhere between the base of the pons (where its nucleus is situated in close proximity to that of the sixth nerve) and the main nerve trunk as it passes through the parotid gland. Facial weakness caused by a more central lesion (i.e. in the contralateral motor cortex or underlying white matter) is recognizable by sparing of the frontalis muscle, which receives input from both cerebral hemispheres. Thus, an upper motor neuron seventh nerve palsy affects only the muscles of the lower face.

The most common cause of an isolated global or lower motor neuron facial weakness is Bell’s palsy, in which the nerve swells and becomes trapped by the bony stylomastoid foramen. Bilateral Bell’s palsy rarely, if ever, occurs; bilateral facial weakness implies an alternative pathology such as sarcoidosis or Guillain–Barré syndrome.
Facial sensation
Sensation over the skin of the face, the buccal and nasal mucosa, the teeth and the nasal sinuses is mediated by the ophthalmic, maxillary and mandibular nerves, which are subdivisions of the trigeminal or fifth cranial nerve. The mandibular nerve also carries motor fibres to the muscles involved in opening and closing the jaw. Damage may occur to one or more of the three divisions; the trunk of the parent nerve; the sensory fibre tract, which extends caudally from the main nucleus in the pons to below the cervicomедullary junction; and to white matter of the contralateral hemisphere.

Patterns associated with all these lesion sites are clinically recognizable, and they are distinguishable from cases without an organic cause: the ophthalmic division has a distribution that includes the scalp as far back as the vertex (i.e. it does not terminate at the hairline), the nose, and the area between and around the eyes (including the corneas – tested by lightly stroking the cornea with a small twist of cotton-wool to elicit reflex closure of the eyelid); the maxillary division includes the upper lip and cheeks, and the mandibular the lower lip, chin and temples. Damage to the trigeminal tracts produces symptoms and signs that cross these boundaries, often forming a puzzle- or mask-like distribution. The skin over the angle of the jaw, the ear cartilage and the occiput fall outside the distribution of trigeminal divisions.

The lower cranial nerves
Brainstem lesions produce dysfunction in the nuclei of cranial nerves VIII–XII and accompanying deficits in the long motor and sensory tracts. Skull-base pathology can impinge directly on the extracranial portions of the nerves, causing isolated dysfunction in one or more of these structures: a lesion of the glossohypharyngeal nerve causes loss of sensation over the posterior tongue and palatal regions, depriving the sensitive gag reflex of its afferent arm; a patient with tenth nerve dysfunction complains of hoarseness, swallowing difficulty and a tendency to aspirate, due to muscular weakness in the palate and vocal folds, and loss of the efferent arm of the gag reflex; damage to the accessory nerve (XI) produces weakness of shoulder-shrugging and head-turning (away from the side of the lesion); and damage to the glossohypharyngeal nerve gives rise to weakness and wasting of the tongue.

More diffuse damage to the motor systems subserved by the lower cranial nerves produces a picture of generalized loss of function in the muscles of articulation and swallowing. Where the lesion involves central structures (e.g. bilateral internal capsular infarcts) or a combination of upper and lower motor neuron pathology (the progressive bulbar palsy of motor neuron disease), speech takes on a strangled quality, the jaw jerk is exaggerated, and emotional lability is exhibited. These features are absent when the lower motor neuron or neuromuscular junction alone is involved (e.g. due to carcinomatous meningitis, Guillain–Barré syndrome or myasthenia gravis).

Evaluation of the limbs
Examination of the limbs includes observation of posture and muscle bulk, assessment of resting muscle tone, classification and distribution of any loss of power, and elicitation of the tendon reflexes. This information allows the critical distinction between upper and lower motor neuron weakness to be made. Gait, coordination and sensation are tested at the end of the examination.

Muscle posture and bulk
Involuntary posturing of the arms or legs suggests an upper motor neuron lesion as the cause of motor disturbance, while wasting of muscle implies damage to a peripheral component or lower motor neuron. By definition, the former is situated proximal to the anterior horn cell (i.e. in or above the descending motor tracts in the spinal cord) and the latter distal to it (i.e. in or below the exiting motor nerve root). Certain patterns of muscle wasting are strongly suggestive of an underlying lesion: distal symmetrical wasting implies degeneration of the peripheral nerves (peripheral neuropathy); unilateral thenar or hypothenar wasting suggests median and ulnar nerve lesions, respectively; and global atrophy of the small hand muscles implies a lesion to the T1 nerve root.

Muscle wasting occurs when individual motor neurons die back, depriving single muscle fibres of trophic support. When this process is widespread (as occurs in amyotrophic lateral sclerosis, ALS), focal contractions of small areas of denervated muscle (fasciculations) may be seen. The deltoids and triceps in the arms and the quadriceps in the legs are the best places to examine for this ominous sign.

Muscle tone
For normal posture to be maintained, skeletal muscle needs to maintain a baseline level of activity at rest, and it is the balance of activity in the extensors and flexors of the legs and arms that is evaluated when muscle tone is tested.

Testing is performed in the upper limbs by passively flexing and extending the arm at the elbow and then pronating and supinating the hand at the wrist. In the normal subject, a scarcely perceptible degree of resistance is detected, as compared with the heavy passivity associated with a chronic lower motor neuron lesion, and the increased resistance (often described as a ‘catch’) evident following upper motor neuron lesions. In the lower limb, the leg is picked up briskly at the knee joint; increased tone will cause the heel to be lifted off the examination couch, while normal tone allows the heel to be dragged along the surface.

Power
The ability to resist an appropriate force applied by the examiner against the direction of action of a muscle or muscle group is an indication of normal power. The important word here is ‘appropriate’, as applied both to the patient and to the muscle being tested: a healthy 30-year-old can usually generate more power than an octogenarian...
patient with arthritis, while biceps flexion generates more force than finger abduction.

The five-point grading system provides a convenient metric for quantifying muscle strength (Table 36.3). The distribution and the grade of weakness provide useful information as to the likely origin of the problem: symmetrical weakness affecting the proximal groups (including flexion and extension of the neck) suggests a disease of muscle, while distal weakness implies a neuropathic origin. Weakness disproportionately affecting the anti-gravity muscles (those that bend the arms and straighten the legs) is likely to arise from a central (upper motor neuron) lesion, while a global pattern is more typical of peripheral (lower motor neuron) dysfunction. Spastic weakness of both legs indicates a lesion in the cord; if there is no additional weakness in the arms or hands, then the lesion lies below the level of T1. A spastic quadriparesis suggests a lesion at or above C4. Hemiplegic weakness is usually due to a lesion in the contralateral hemisphere, but it may also be caused by a process compromising one half of the cord. Compression neuropathies also produce highly recognizable combinations of (usually unilateral) weakness, although they are easily confused with lesions at the level of the cervical and lumbar nerve roots. Disentangling these possibilities often relies on evidence gained from the tendon reflexes and the sensory examination.

### Sensation

One rule transforms sensory testing from a painful exercise in time-wasting into a useful data-gathering process: know what you are trying to find. This, after all, why it is performed at the end of the examination. A patient with symptoms and signs of a peripheral neuropathy often shows a ‘glove and stocking’ pattern of sensory loss – so look for one, using either a pin or a tuning fork. A patient with a spastic paraparesis probably has a lesion in the cord between T1 and L1, and the line on the torso below which sensation is reduced or absent provides more precise localizing information – so examine for a ‘sensory level’; a spastic hemiparesis due to a cord rather than a hemispheric lesion will often be accompanied by a ‘dissociated’ sensory impairment (impairment of joint position sense on the side of the weakness, and reduction in light touch appreciation on the other) – a diagnosis clinched. Nerve and root entrapments can also be disentangled by exploring the skin over the distribution of, say, the ulnar nerve (fourth and fifth fingers) and the C8 nerve root (ulnar border of the hand and forearm) with the tip of a pin.

Some patients are, admittedly, poor sensory witnesses, and it is often better to hand them a pin and ask them to demonstrate the distribution of the sensory deficit themselves. Patients with a consistent and anatomically meaningful loss will quickly distinguish themselves from those with patchy and inconsistent impairments that are rarely if ever associated with organic disease.

### Reflexes

The monosynaptic muscle stretch reflex is elicited by striking an anatomically accessible tendon and watching for reflex contraction in the muscle to which it attaches. The contraction may be normal, exaggerated or absent. Exaggerated (brisk) reflexes indicate loss of central modulation and thus indicate a central lesion at a level higher than the reflex being tested. Since the afferent and efferent arms of a monosynaptic stretch reflex are carried through one or two adjacent nerve roots, an isolated absent reflex suggests damage at root level, often due to impingement by a protruding intervertebral disc. Knowledge of the root levels through which commonly elicited reflex arcs are transmitted is therefore essential to interpretation (Table 36.4). A generalized absence of reflexes suggests a more widespread process, involving either multiple nerve roots or individual nerve fibres, or both. Absent or diminished reflexes may be brought out by asking the patient to perform a muscle-tensing manoeuvre. Contrary to popular belief, the effects of reinforcement are not evanescent but last for 5–10 s.

### NEUROLOGICAL ILLNESSES

Many of the diagnostic categories used in modern neurology have their origins in the remarkably astute observations...
of nineteenth- and early-twentieth-century clinicians. Since then, the understanding of neurological disease has benefited, perhaps more than any other branch of clinical medicine, from advances in the basic biological sciences. The categorization of neurological disease as it is currently understood is briefly outlined below, in order to orient the reader to the diversity of pathophysiological processes that underpin many of the common acute and chronic neurological conditions. In view of the size and diversity of the subject, what follows is intended as an index rather than a work of reference.

**Chronic conditions**

It is useful to consider the pathophysiological processes causing chronic neurological disease under a series of broad causative headings. A small but important subgroup of conditions affecting the nervous system consists of inherited disorders, which include diseases of both central and peripheral regions of the nervous system. Within acquired neurological disease, a large percentage of patients will turn out to have a primary degenerative pathology, and similarly large numbers of patients will be affected by vascular and inflammatory processes. Autoimmune processes are increasingly recognized as a mechanism underlying neurological dysfunction of various kinds. Several infectious agents continue to cause morbidity; and metabolic and nutritional deficiencies, although unusual, are potentially amenable to straightforward treatment, and should never, therefore, be overlooked.

**Inherited disorders**

The important groups of dominantly inherited neurological disease include the young-onset movement and cognitive disorders (HD, familial AD), and the inherited spinocerebellar ataxias (SCA), of which 29 genetically distinct varieties have so far been described and the most common of which are now susceptible to genetic testing. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is an unusual cause of premature cerebrovascular disease but recognizable in patients with young-onset stroke, a background that includes classical migraine or depression, and imaging appearances of confluent white-matter lesions in the brainstem and hemispheres (particularly the temporal lobes). Diseases of peripheral nerve (the hereditary motor and sensory neuropathies) and muscle (the muscular dystrophies) have also been extensively subcategorized using molecular or genetic criteria, allowing many cases to be given highly specific diagnostic labels.

Few recessive conditions primarily affecting the central nervous system are known; though some of the familial neuropathy subtypes show this pattern of inheritance. Those with a neurological component are generally of metabolic origin and will be mentioned under that heading.

An important subgroup of inherited neurological disease is caused by mutations carried not in the cell’s nucleus but in the mitochondria, producing abnormalities of cellular energy production. The effects of these disorders depend on the distribution of defective mitochondria within the organs, but almost all have some form of neurological involvement, which includes excessive muscle fatigue, optic nerve degeneration, and a severe and rapidly progressive encephalopathy.

**Neurodegenerative disorders**

Details of causation in many of the neurodegenerative conditions have not been defined completely, and in consequence few of these progressive illnesses are currently amenable to treatment. Improved understanding of the molecular basis of this group of conditions may well render the term obsolete, replacing it with a variety of mechanistic categories derived from molecular-level description. This process is already emerging: a number of clinical conditions that previously were considered to be of disparate origin (AD, frontotemporal dementia, corticobasal degeneration, progressive supranuclear palsy) are now considered under the umbrella term ‘tauopathies’, indicating the formation of abnormal aggregates of tau protein within the brain. Common neurodegenerative appearances that do not fall into the tauopathy category include prion disease, disorders of alpha synuclein, and appearances associated with ubiquitin-containing inclusions. Prion diseases (e.g. Creutzfeldt–Jakob disease in humans and scrapie in sheep) cause dysfunction and destruction of brain tissue by the relentless, self-catalysing propagation of prion protein aggregates. Pathological markers of other conditions are composed of aggregates of different material: alpha synuclein is seen in the brain of patients with Parkinson’s disease and dementia with Lewy bodies. Ubiquitin inclusions are a more recently defined pathological entity and are found in the brain of a subset of patients with frontotemporal dementia and of patients with motor neuron disease.

**Vascular disease**

Sporadic cerebrovascular disease should always be considered as a potential cause of central nervous system symptomatology in patients over the age of 50 years and is particularly likely in heavy smokers, patients with a history of diabetes, lipid disorders or hypertension, and patients with a family history of vasculopathy. Both acute and chronic ischaemic injury can produce signs of dysfunction clinically localizable to the cerebral hemispheres and brainstem. Acute vascular injuries are dealt with below. Chronic damage, usually to the hemispheric white matter, is a potent and common cause of cognitive decline, often characterized by slowed but accurate mental processing (‘subcortical dementia’). Vascular cognitive impairment does not, contrary to popular dogma, invariably proceed in a stepwise rather than a insidiously progressive fashion, and it frequently coexists with a degenerative pathology such as AD. Unlike pure neurodegenerative conditions, however,
progression in vascular cognitive impairment is susceptible to modification by good risk-factor management. Vascular insufficiency causing injury to the spinal cord also occurs but is considerably less common than compressive or inflammatory processes.

**Inflammatory conditions**

Demyelination, or the loss of the myelin layer from nerve cells, is the final common pathway of neuronal damage from a number of processes, including inherited and acquired metabolic disorders, autoimmune conditions and infection. Sporadic cases of demyelinating illness are, however, most commonly associated with an immune-mediated inflammatory aetiology.

Myelin is a layer of phospholipid that ensheathes the axons of many neurons, both central and peripheral, providing electrical insulation and vastly increasing the speed of impulse transmission. The myelin sheath surrounding peripheral nerves is formed by Schwann cells, while axons in the central nervous system are myelinated by oligodendrocytes. This difference between central and peripheral myelin is critical, as demyelination due to an inflammatory process occurs either centrally (e.g., in multiple sclerosis, MS) or peripherally (the demyelinating polyneuropathies), but rarely in both together.

MS is the most common inflammatory disorder of the central nervous system and should be considered as significantly more likely than vascular disease in young adults with acute central deficits. MS is a complex diagnosis that requires clinical and magnetic resonance (MR) evidence of the dissemination of inflammatory lesions over time and space, and laboratory evidence of central nervous system inflammation. These data may be considered in relation to accepted diagnostic criteria, of which the revised McDonald criteria are currently the most commonly applied. The disease can affect any of the white-matter tracts of the central nervous system and can therefore produce most types of central deficit: common patterns include monocular visual loss (optic neuritis), cerebella ataxia, disorders of eye-movement control, and spastic paraparesis. Deficits due to inflammatory damage tend to evolve over a period of hours rather than the seconds to minutes characteristic of a vascular insult. In the majority of cases, the disease is manifested by a series of acute attacks, the effects of which may partially or fully resolve (relapsing and remitting MS) or result in further decline (secondary progressive MS). Primary progressive MS, in which the patient’s functional status gradually declines without the occurrence of an acute episode, is also a recognized disease pattern. The cause or causes of MS are still poorly understood, but it probably involves a combination of inherited susceptibility and one or more environmental factors.

Inflammatory demyelination in peripheral nerves occurs acutely – in Guillain–Barré syndrome (see below) – and in the context of chronic inflammatory demyelinating polyneuropathy (CIDP). Patients with the latter condition give an insidious history of numbness and tingling of the peripheries, weakness and clumsiness of the limbs, and walking difficulty. Clinical examination reveals an absence of upper motor neuron or other central features, and diagnosis is based on exclusion of alternative causes of peripheral neuropathy (importantly, diabetes, vitamin B12 deficiency, monoclonal gammopathy and connective tissue diseases), elevated cerebrospinal fluid protein content, and characteristic appearances on peripheral nerve biopsy. Like MS, CIDP can follow a relapsing–remitting or chronically progressive course.

**Infectious causes of chronic neurological disease**

The transmissible causes of chronic neurological illness most important to consider are the human immunodeficiency virus (HIV) and *Treponema pallidum* (the infectious agent responsible for syphilis).

HIV infection can produce neurological manifestations at most levels in the nervous system. Moving from centre to periphery, it can be responsible for an acute encephalopathy or more prolonged dementia; central demyelinating lesions; a parkinsonian state and other movement disorders; chronic meningitis; a myelopathy with vacular imaging changes in the spinal cord; a mononeuritis multiplex; and an inflammatory myopathy. HIV infection also increases the likelihood of cerebral lymphoma and of acute viral and bacterial infections affecting the nervous system (see below).

Neurological manifestations of syphilis (neurosphilis) occur as a late complication in under 10 per cent of the (currently few) patients in whom a primary treponemal infection was left untreated. The spectrum of neurosyphilis is broad, but patterns fall into one or more of three broad categories: chronic meningitis associated with obliterator vascular disease (meningovascular syphilis); tabes dorsalis (demyelination and degeneration within the posterior columns of the spinal cord); and general paresis (a neurodegenerative dementia associated with florid psychotic symptoms). Neurological infection with the infectious agent may also remain asymptomatic. Neurosyphilis still, therefore, enters into the differential diagnosis of stroke, myelopathy, myopathy and dementia, particularly in younger patients.

A diagnosis of syphilis infection can be made using a number of serological tests such as the sensitive Venereal Diseases Research Laboratory (VDRL) test or the more specific *T. pallidum* haemagglutination assay (TPHA). Suspected neurosyphilis can be confirmed by demonstrating additional changes (pleocytosis or high protein levels) and positive serological tests in the spinal fluid.

A less well-known spirochaetal cause of neurological illness is *Borrelia burgdorferi*, the agent responsible for Lyme disease. The organism is transmitted by tick bites, and its manifestations are initially systemic (diffuse muscular pain) and dermatological (a spreading erythematous discoulouration of the skin). If infection is left untreated, bilateral facial
weakness, mononeuritis multiplex, lymphocytic meningitis and encephalopathy may emerge. The early stages are responsive to treatment with doxycycline, but neurological involvement requires intravenous administration of an antibiotic that crosses the blood–brain barrier (usually ceftriaxone).

**Nutritional deficiencies and metabolic disorders**

The complex molecular-level structure of the nervous system means that it may, in principle, be vulnerable to chronically low levels of a number of nutrient types, including glucose, fatty acids and amino acids. In practice, however, it is the vitamins – specifically, those in the B, A and E groups – that are classically associated with chronic neurological disorders, as they are essential to widespread metabolic processes and are not manufactured by the body. Dietary deficiency or failure of absorption may therefore be associated with a group of disorders whose importance is emphasized by their complete reversibility.

Thiamine (vitamin B1) deficiency produces an acute syndrome of midbrain and brainstem dysfunction known as Wernicke's encephalopathy. In its classic form, the syndrome comprises acute confusion, eye-movement abnormalities and ataxia. It is a common complication of alcoholism, but it is also seen in association with anorexia nervosa and with hyperemesis of pregnancy, and following gastric surgery. The treatment of any acute encephalopathic illness, ophthalmoplegia and ataxia should include the intravenous administration of thiamine. If left untreated, this reversible deficiency state may give rise to an amnestic and psychotic state (Korsakoff's syndrome) or to coma and death.

Although one of the central functions of vitamin B12 is the maturation of red blood cells, neurological manifestations in the form of memory dysfunction may occur well before the development of a megaloblastic anaemia. More chronic deficiency can give rise to a peripheral neuropathy and a spinal-cord syndrome caused by degeneration (subacute combined degeneration) of the posterior and lateral columns.

Among the metabolic causes of neurological (and often psychiatric) illness, Wilson's disease and porphyria are rare but effectively treatable and therefore important to consider in appropriate clinical settings.

Wilson's disease is a recessively inherited disorder of copper metabolism. Unbound circulating copper is deposited in the liver, cornea and brain (particularly the basal ganglia), giving rise to the major clinical features: liver dysfunction; corneal discolouration (Kayser-Fleischer rings); movement disorders, including tremor, rigidity, bradykinesia and bizarre dystonic posturing (often misdiagnosed as a functional phenomenon); and psychiatric symptoms, ranging from anxiety and depression to psychosis. Wilson's disease should be considered in all young patients with a movement disorder and in patients with psychiatric symptoms together with liver dysfunction.

Porphyria is a genetically determined disorder of haem biosynthesis. Its clinical manifestations are dominated by episodes of abdominal pain, but the frequently accompanying neurological and psychiatric symptoms include polyneuropathy, transient sensory or motor symptoms in the limbs, seizures, reversible cognitive decline and behavioural abnormalities. Porphyria is a rare condition but should be suspected in any patient with unexplained or atypical recurrent neurological episodes, psychotic behaviour in the context of acute abdominal episodes, and a positive family history.

**Acute neurological events**

**Stroke**

Any acute and persistent neurological deficit of vascular origin, whether caused by cerebral ischaemia or intracerebral haemorrhage, is referred to as a stroke. Fully reversible deficits of vascular origin are always ischaemic and occur when perfusion to affected tissue is re-established before permanent neuronal damage has taken place. The majority of completed strokes also have an ischaemic basis, typically as a result of an atheromatous or cardioembolic thrombus occluding a cerebral end-artery (i.e. any portion of the anterior, middle or posterior cerebral arteries distal to the circle of Willis, or any of their branches). A stroke may also follow dissection of one of the vertebral or carotid arteries in the neck – a common aetiology in patients under the age of 40 years, usually presenting with a prior history of neck pain and trauma. Carotid dissection may be accompanied by Horner's syndrome on the side opposite the hemisphere, due to disruption of the carotid sympathetic plexus. Around 15–20 per cent of strokes are caused by a haemorrhage into the substance of the brain, an event that is often difficult to distinguish clinically from an ischaemic event.

The neurological deficit that follows an ischaemic stroke depends on the distribution and extent of the lesion: the middle cerebral artery is implicated in a majority of cases, producing a contralateral hemiparesis (worse in the arm), homonymous quadrantanopia and dysphasia (when the dominant hemisphere is involved); isolated anterior cerebral artery territory infarction is rare but is associated predominantly with contralateral leg weakness and personality change (disinhibition); posterior cerebral artery stroke typically gives rise to brainstem-related and cerebellar signs, or a homonymous hemianopia; a small infarct of the internal capsule caused by obstruction of a penetrating branch of the middle cerebral artery typically causes complete contralateral hemiparesis.

It is now recognized that survival and recovery after stroke are optimized by management on an acute stroke unit under the care of a specialist team, with seamless transition through all stages of management, including initiation of secondary preventive strategies and rehabilitation pre- and post-discharge. Above all, it should be recognized...
that stroke is a medical emergency, for which strategies relying on the ‘healing power of nature’ alone are no longer acceptable. Acute management is aimed at identifying factors critical to recovery (particularly swallowing and communication ability), stabilizing or correcting critical physiological parameters such as blood pressure and cardiac rhythm, and establishing whether the mechanism of the stroke was ischaemic or haemorrhagic (on CT). If the mechanism is ischaemic, and symptom onset was less than 3 h previously, then thrombolytic therapy with intravenous Alteplase can be considered. Modern MR imaging modalities are used to define the location, vascular territory, extent of the hypoperfused area and of the wider region, or ‘ischaemic penumbra’ in which the reversible physiological changes of ischaemia are beginning to occur.

Epilepsy

The term ‘epilepsy’ is applied to any self-limiting disturbance of consciousness, cognition, motor function or sensation caused by a transient disturbance of normal electrochemical stability in the brain. For the sake of simplicity, epileptic attacks are further subclassified into generalized and partial seizures: in a generalized attack the electrical disturbance affects the entire brain and, as a result, consciousness is lost; when the disturbance is restricted to a localized area, the attack is referred to as partial. Most (though not all) generalized seizures are associated with stiffness and rhythmic jerking movements of the trunk and limbs (convulsions). Partial seizures include subjective sensory or psychological experiences (auras), uncontrollable muscular contractions affecting a single limb (focal motor or Jacksonian seizures); and automatic motor behaviours with reduced environmental awareness (complex partial or temporal lobe seizures).

Generalized attacks often develop from partial seizures as the focal electrical disturbance spreads (secondary generalized seizures), but they may also occur as a primary phenomenon. Primary generalized epilepsy is an idiopathic entity, probably with a genetic component, while partial and secondary generalized seizures usually indicate the presence of a structural lesion in the brain acting as an epileptogenic focus. The latter include congenital areas of neuronal dysplasia, sclerosis of the hippocampal formation, and later acquired changes such as vascular, traumatic and neoplastic disease.

The brain’s electrochemical stability usually returns to normal, either spontaneously or in response to administration of a rapidly acting anticonvulsant drug (such as diazepam), within minutes of the onset of the attack and corresponds to the gradual recovery of normal function over minutes. When recovering from a generalized seizure, patients usually pass through a period of disorientation and confusion, and there may be postictal neurological deficits, including focal weakness (Todd’s paralysis) or, in rare cases, psychotic behaviour, which may last for hours. Symptoms of exhaustion, headache, nausea, malaise and depression follow recovery (the postictal phase) and may take several days to clear.

Most seizures can be kept under satisfactory control with one or two anticonvulsant drugs. Carbamazepine is usually the drug of first choice for partial seizures, and sodium valproate for primary generalized attacks. Lamotrigine is often effective as second-line therapy in either situation. Special consideration is given to starting anticonvulsant treatment in women who use hormonal contraceptive methods, as carbamazepine, phenytoin and topiramate induce the metabolism of the hormones, whether delivered orally or by injection, resulting in reduced effectiveness. Sodium valproate and levetiracetam do not have this effect and so are drugs of choice in this patient group. Refractory seizures arising from a small underlying epileptogenic focus may, in selected cases, be brought under control by surgically resecting the lesion.

When a single seizure or consecutive series of seizures lasts for 30 min or longer, the situation – referred to as status epilepticus – is life-threatening and requires urgent medical intervention. Management of status epilepticus begins with the resuscitative stage of securing the airway, assessing for and treating cardiopulmonary problems, and treating hypo- or hyperglycaemia and other reversible metabolic derangements. A protocol of escalating intervention is then followed until the seizure terminates. A typical emergency schedule begins with an intravenous bolus of a rapidly acting agent such as lorazepam followed by an intravenous infusion of phenytoin. In refractory cases, the patient should be transferred to an intensive treatment unit (ITU) for general anaesthesia and the ventilatory support and continuous close monitoring that this necessitates.

Meningitis and encephalitis

The infectious meningitides are rapidly developing and potentially fatal infections involving the membranous material between the surface of the brain and the skull vault (the meninges). Bacterial meningitis is most often due to Streptococcus pneumoniae (pneumococcal meningitis), with Neisseria meningitidis (meningococcus), Haemophilus influenzae and Listeria monocytogenes accounting for most of the remainder. In certain groups, such as immune-compromised, homeless or alcoholic people and those from the developing world, mycobacterial infection (TB meningitis) is another common mechanism. Meningeal involvement with viral infection (viral meningitis) is not a grave condition, but diagnosis depends specifically on exclusion of the bacterial variety. In contrast, suspected viral encephalitis calls for the urgent initiation of antiviral therapy.

A patient with meningitis will be severely unwell, irritable, and sometimes drowsy, delirious or fitting. There may be signs of cardiovascular instability due to haematogenous infection. Symptoms (if they can be reported) will be dominated by intense photophobic headache, nausea, vomiting and neck stiffness. Meningeal pain results in severe restriction of movement in adjacent structures, resulting in stiff-
ness of neck flexion or back pain on straight-leg-raising (Kernig’s sign), or both.

A rapidly spreading purple and red rash over the trunk, limbs and mucous membranes accompanies (and may precede) meningococcal infection. Encephalitis may present in a similar fashion but usually manifests as mild to moderate confusion, fever and headache.

Management of suspected meningitis or encephalitis begins with prompt administration of broad spectrum intravenous antibiotics or aciclovir, or both: delaying to wait for the results of diagnostic tests may prove fatal. Confirmation and refinement of the diagnosis requires examination of the cerebrospinal fluid, obtained at lumbar puncture. If consciousness is impaired or there are focal neurological deficits, brain imaging is required to exclude obstructive hydrocephalus or an intracranial space-occupying lesion, which would make lumbar puncture hazardous. Definitive diagnosis depends on the results of culture, antigen detection or DNA analysis, which take days to obtain. Values obtained from emergency microbiological and biochemical assays within hours allow, however, for exclusion or further refinement of the suspected diagnosis (Table 36.5).

**Acute neuromuscular syndromes**

It is helpful to think of peripheral weakness as originating from dysfunction in some part of the motor pathway between the motor root and the effector muscle. Acute illnesses characterized by progressive neuromuscular weakness may be caused by pathology affecting the nerve, neuromuscular junction and muscle. Prompt recognition is vital in view of the potential involvement of bulbar and respiratory muscles, failure of which may have catastrophic consequences if not recognized at an early stage.

Acute inflammatory demyelinating polyneuropathy (AIDP, or Guillain–Barré syndrome) is a condition involving the peripheral nerves and nerve fibres. The syndrome usually follows a respiratory or gastrointestinal infection and is typically characterized by sensory change (‘pins and needles’ or numbness) and weakness in the feet, which spreads proximally, usually over a period of hours to days. Preceding low back pain is often described. A small proportion of patients begin to recover before profound motor weakness ensues, but the majority will develop weakness of all four limbs and the respiratory, facial and bulbar muscles and, in severe cases, autonomic involvement, causing haemodynamic instability. Each of these outcomes requires careful monitoring in the context of a specialist neurosciences unit, and in many cases ventilatory support will be required. The diagnosis is based on a typical clinical picture of ascending weakness and areflexia; a raised cerebrospinal fluid protein; and slowing of conduction times on nerve conduction studies, suggesting a peripheral demyelinating process. A variant of the condition in which the inflammatory target is the axon rather than the myelin sheath is also recognized. Other than supportive measures, the mainstay of treatment consists of intravenous immune globulin, which has been shown in clinical trials to shorten the duration of disability and dependence if started within 2 weeks of symptom onset. Long-term follow-up has shown that around 80 per cent of patients make a full functional recovery within 12 months, although the axonal variant carries a poorer prognosis for full recovery. Around 5 per cent of cases go on to suffer further episodes, following which their illness is classified as CIDP.

The neuromuscular junction is the point at which a motor axon synapses on to a muscle endplate (an excitable region of muscle fibre membrane from where action potentials are initiated, resulting in muscle contraction). Propagation of an action potential down the axon will cause release of a neurotransmitter (which in skeletal muscle takes the form of acetylcholine) that binds to receptors on the endplate. Myasthenia gravis is an autoimmune-mediated condition caused by antibodies directed against the acetylcholine receptor, blocking neurotransmission and causing variable weakness. At a clinical level, this mechanism is distinguishable from diseases of peripheral nerve or muscle by its characteristic fatiguability (i.e. the harder the muscle has to work, the weaker it becomes). Weakness may begin in the muscles of eye movement and opening, in the facial and bulbar muscles, or in the limbs. Diagnosis is based on the

demonstration of antibodies directed against the cholinergic receptor, which are found in around 65 per cent of cases. Electrodiagnostic studies, including repetitive nerve stimulation to demonstrate the decremental muscle response analogous to fatigability, and recording spontaneous activity in individual nerve fibres (single-fibre electromyography, EMG) are often helpful. In equivocal cases, intravenous infusion of a short-acting drug (edrophonium) that inhibits the metabolism of acetylcholine results in temporary restoration of movement or power in patients with the disease. Treatment consists of regular doses of longer-acting cholinesterase inhibitors to relieve the symptoms of weakness, together with immunosuppressive drugs to reduce the circulating receptor antibody load.

Diseases affecting muscle fibres themselves may be dystrophic or associated with other inherited conditions (see above), but it is the inflammatory myopathies that may present as an acute weakness. This group of conditions usually gives rise to proximal and symmetrical weakness, and muscle pathology typically causes an increase in the circulating levels of creatine kinase (CK), which is released from damaged muscle. Diagnosis usually depends on histological findings of a muscle biopsy specimen, at which two patterns of inflammatory process are described: polymyositis (a pure inflammatory muscle disorder), and dermatomyositis (in which associated skin abnormalities are additionally seen). In older patients, some cases of dermatomyositis turn out to be of paraneoplastic origin.

NEUROLOGICAL INVESTIGATIONS

Imaging

Neurological diagnosis has been revolutionized by the advent of modern brain imaging techniques. The localization of a brain or spinal-cord lesion, which formerly depended on demonstrating a clear-cut neurological deficit, is achievable earlier and with greater certainty, improving the likelihood of successful treatment – albeit at the cost of performing vast numbers of normal scans and of revealing symptomless and incidental anomalies. So, although neurologists have not been rendered redundant by imaging, our remit has changed: in the pre-imaging era, the neurologist was lead counsel for the prosecution; today, he or she is more like a judge, carefully sifting through evidence, evaluating it against clinical facts and deciding on its importance.

Neurological practice is aided by evidence from both structural and functional imaging techniques. Although MR imaging has become the modality of choice for most central nervous system disease, CT still has a place by virtue of its rapidity, making it suitable for emergency diagnosis. CT angiography is the favoured modality for non-invasive investigation of intracranial vascular disease. The large associated X-ray dose, however, limits its repeated use in a single individual. Using MR, high-resolution anatomical images of the brain or spinal cord are acquired by placing the site of interest within a powerful magnetic field and detecting the radiofrequency emissions of hydrogen ions within an array of small subdivisions (voxels). This information is used to create a three-dimensional image, which can be reconstructed in the three canonical planes (axial, coronal and sagittal). Pathological changes give rise to alterations in the signal obtained using different acquisition parameters (sequences), whose specificity to the underlying process (e.g. inflammation and infarction) can be diagnostically important.

Functional magnetic resonance imaging (fMRI) identifies regional changes in cerebral blood flow time-locked to periods of cognitive activity. The resulting signal change – known as the blood oxygen level-dependent (BOLD) effect – has been firmly established as spatially and temporally linked to regional changes in neural activity. fMRI is primarily a research tool used to investigate the cerebral basis of cognition, but it is beginning to find a clinical role, particularly in the fields of degenerative and vascular disease and rehabilitation.

Both structural and functional MR have the advantage of non-invasiveness, but other functional techniques, particularly positron-emission tomography (PET) and single-photon-emission computed tomography (SPECT), rely on measurements of energy emissions from intravenously injected metabolically active compounds that have been altered to incorporate a radioactive isotope into their molecular structure. The distribution and magnitude of radioactivity thus reflects the location and concentration of the compound. Interpretation also depends on the biological properties of the compound: regional radioactivity after inhalation of 15O reflects changes in local blood flow (like fMRI). 18F-Fluorodeoxyglucose (a glucose analogue incorporating a radioisotope of fluorine) will be taken up in proportion to a region’s metabolic activity, which is a precursor of neurodegeneration and therefore an early diagnostic marker in dementia. Pittsburgh compound B (PiB) binds with high affinity to amyloid plaques and is consequently of interest as a disease-specific marker for Alzheimer’s disease.

Information about regional cerebral blood flow can be obtained by mapping the emissions of gamma radiation following injection of technetium-99m-labelled hexamethylpropyleneamine oxime (99mTc-HMPAO) using a SPECT scanner. On the same principle, the marked reduction of striatal dopaminergic neurons that underlies Parkinson’s disease can be demonstrated by mapping the uptake of a radiolabelled agent, 123I-ioflupane, that binds to dopamine transporters. Although the resolution of SPECT is coarser than that of fMRI or PET, 99mTc has a half-life of approximately 6 h (compared with 2 min for 15O and 1.5 h for 18F), and emissions can be measured after, rather than during, the injection period, enhancing its suitability to the clinical context, particularly in the field of dementia.
Psychometry

Cognitive problems are an integral component of the neurodegenerative dementias and contribute to disability in other central nervous system pathologies, such as stroke, closed head injury and MS. Although useful clinical information can be acquired at the bedside, formal psychometric testing allows deficits of specific cognitive abilities (cognitive speed, attention, executive function, language, praxis, visuospatial processing) to be dissected and quantified with more accuracy and with reference to age- and premorbid intelligence quotient (IQ)-adjusted norms. The need to differentiate between incipient dementia and a potentially reversible depressive state, or an organic from a factitious memory problem, are other important clinical scenarios in which obtaining a psychometric profile can be helpful.

A neuropsychological report will contain summary information about a patient’s intellectual performance (full-scale IQ), broken down into verbal and non-verbal components (verbal and performance IQ), together with an estimate, typically based on the National Adult Reading Test (NART), of their optimal level of intellectual functioning (premorbid IQ). Differences of 20 or more IQ points between verbal and performance subscores, or between full-scale score and premorbid estimates, give rise to concern.

Although differences across the six verbal and five performance subtests of the Wechsler Adult Intelligence Scale (WAIS; Table 36.6) may provide an indication of specific areas of cognitive weakness, including short-term working memory, the thoughtful and attentive reader will notice that these do not include any measures of long-term memory. Recognition memory is therefore tested using both verbal and non-verbal material. A series of items (pictures or words) are shown one by one to the subject during an initial exposure, and later re-presented, interspersed with previously unseen items (foils) during a test phase. The patient simply has to identify those items they have seen before. The more demanding task of freely recalling previously seen material can be assessed using a word-list learning paradigm, or by reproduction of a geometrical design from memory. A patient with a true isolated episodic memory deficit should still be capable of skill acquisition and other forms of automatic implicit learning, so failure on tasks that demonstrate implicit learning in a patient with an amnestic profile are highly suggestive of a factitious aetiology.

There is no single test for the integrity of semantic memory (the long-term store of information relating to word-meaning and general knowledge). However, patients who overgeneralize when given pictures to name (e.g.

responding ‘animal’ to all pictures of living things), and those who provide inaccurate or impoverished definitions of specific nouns (e.g. ‘It’s an animal; got four legs and a tail; I think they live abroad’ when asked ‘What is an ostrich?’), are likely to have a deficit in this domain.

Executive function describes the individual’s ability to self-monitor, plan and implement strategies for completing tasks, follow a set of rules, and select or inhibit information depending on its current relevance. Clearly this is a complex construct but nonetheless one that appears to depend on the integrity of cortical regions in the dorsal and lateral regions of the frontal lobes. Tests such as the Wisconsin Card Sorting Test, in which the subject is asked to group a sequence of geometrical designs that vary in three dimensions (shape, colour and number), and then told to change strategies at various points in the test, are sensitive to executive dysfunction. An inability to switch from one rule to another is particularly suggestive of this functional deficit.

Electrophysiology

Clinical electrophysiology can provide information relevant to cerebral, peripheral nerve and muscle dysfunction and their aetiologies.

Electroencephalography (EEG) provides a record of the background activity and rhythmicity, and of transient additions to these patterns, within the cerebral cortex. The wave patterns in a normal record can be decomposed into four basic frequencies: the slowest activity (≤ 3 Hz), referred to as the delta rhythm, is prominent during deep (non-rapid eye movement, REM) sleep; waveforms with a frequency of 4–7 Hz (theta rhythm) may emerge during drowsiness; alpha activity (8–12 Hz) dominates the record in the posterior regions and is accentuated with eye closure; the beta rhythms (>12 Hz) are seen in frontal brain regions and dominate the record when the patient is alert. Disturbances of the normal distribution of these underlying rhythms, particularly in the form of excessive presence of the slower rhythms, are non-specifically indicative of a functional disturbance (encephalopathy). This information needs to be interpreted with reference to the clinical scenario, as it is rarely specific to a particular mechanism and may be related, for instance, to the cerebral effects of drugs, metabolic disturbances or neurodegenerative change. Periodic bi- or triphasic discharges are, however, typical of the later stages of sporadic Creutzfeldt–Jakob disease (sCJD) but are not seen in the variant form (vCJD), so this finding can have important diagnostic implications.

The emergence of other patterns of transients (termed spikes or sharp waves, depending on their amplitude and duration) represents intermittent, synchronous activity within a neuronal population and may suggest a predisposition to epilepsy; their distribution (i.e. widespread or localized to one hemisphere or lobar region) can provide evidence for an epileptic tendency of generalized or focal origin. One of the most important tasks for the clinical neurophysiologist is therefore to distinguish such epileptiform activity from other transient elements such as sleep spindles, which are normal physiological phenomena, and from the contaminating artefacts caused by body or eye movements.

Occasionally, cerebral activity may be recorded while a clinical seizure is occurring, either serendipitously or as part of a prolonged recording that aims to capture the cerebral basis of the event (video telemetry). The simultaneous occurrence of electrophysiological and clinical evidence of epilepsy enables a firm diagnosis of an epileptic seizure (rather than a predisposition to seizures) to be made, while clinical activity in the absence of a neurophysiological correlate is strongly suggestive of a factitious explanation.

The principle of recording cerebral activity from voltage changes detected by scalp electrodes is also employed in evoked potential studies. In this paradigm, EEG changes are time-locked to a sensory stimulus, such as a simply alternating visual pattern (e.g. an alternating chequerboard display), an auditory click or electrical stimulation of the peripheries. The time taken for the expected electrophysiological signal to emerge is indicative of the integrity of the white-matter pathways within the visual system, brainstem and spinal cord, respectively.

Peripheral neurophysiological testing relates to abnormalities of motor and sensory nerves and skeletal muscle. Following the application of an electrical stimulus to the skin directly overlying the course of a peripheral nerve, a response can be measured from an electrode overlying either a muscle or a portion of skin that is supplied by fibres carried in the stimulated nerve. These recordings provide information about the function of motor and sensory components, respectively, within the nerve being tested. The results are normally considered in terms of the amplitude of the response or its velocity (calculated by dividing the distance between stimulating and recording points by the millisecond delay between the two events). A reduction in amplitude is interpreted as indicating loss of or damage to individual axons, while slowed conduction times are caused by damage to the myelin sheath. Depending on the site or sites of any abnormal findings, nerve conduction studies can distinguish between diffuse processes (peripheral neuropathy), focal damage due to entrapment or trauma, and multifocal disruption of nerve integrity (mononeuritis multiplex).

Electromyography provides a recording of electrical activity within a muscle, either from a surface electrode or via a needle inserted into the body of the muscle itself (needle EMG). Observed activity relates to activity within a group of motor units (defined as a single motor neuron and the collection of individual muscle fibres on which it synapses), at rest and during contraction. In a normal motor unit, no activity is seen at rest, while damage to the axonal component of a motor unit results in spontaneous discharges (fasciculation and fibrillation). During slow incremental contraction, action potentials from increasing
numbers of motor units are observed (recruitment), and any abnormal features during this process – such as increased or decreased amplitude and duration of the action potentials, the number of units recruited, and the rate of recruitment – are used to determine whether the pathology is in the muscle or in the axon (myopathic vs. neuropathic EMG). The presence of spontaneous activity and neuropathic features in the absence of any evidence of peripheral nerve dysfunction on the nerve conduction study suggests pathology originating from a more proximal component of the motor neuron, up to and including the anterior horn cell.

**The cerebrospinal fluid**

Cerebrospinal fluid examination is routinely performed in acute neurological illness, particularly central nervous system infection, and in patients with more indolent neurological conditions affecting either central or peripheral structures. Cerebrospinal fluid is obtained from a patient by inserting a 20 or 22 gauge spinal needle through the lumbar theca, under local anaesthetic, between the spinous processes of the L4 and L5 vertebrae, which are palpable in the midline at the level of the top of the iliac crest. Cerebrospinal fluid pressure can be measured by collecting the initial specimen in a vertical glass tube and measuring the height of the column. A low-pressure headache (relieved by lying down) occurs in up to a third of patients due to continued cerebrospinal fluid leakage after withdrawal of the needle. It normally settles spontaneously within days but sometimes necessitates infusion of a sample of venous blood obtained from the patient to seal the defect (blood patch).

A number of important laboratory measurements can be made on the cerebrospinal fluid: suspected bacterial, mycobacterial or fungal infection may be confirmed by immediate microscopy; evidence of viral or partially treated bacterial infection may be inferred from the type and density of white cells present; malignant cells may be identified in cases of central nervous system lymphoma or malignant meningitis; a translucent yellow tinge due to the breakdown products of haemoglobin (xanthochromia) forms 12 h after leakage of blood into the subarachnoid space and persists for at least 2 weeks, allowing a diagnosis of subarachnoid haemorrhage to be made even if blood was not, or is no longer, visible on CT; elevated protein content suggests acute or chronic inflammation, and the appearance on a cerebrospinal fluid electrophoresis of immunoglobulin bands that are not matched by similar patterns in a serum specimen in a vertical glass tube and measuring the height of the column. A low-pressure headache (relieved by lying down) occurs in up to a third of patients due to continued cerebrospinal fluid leakage after withdrawal of the needle. It normally settles spontaneously within days but sometimes necessitates infusion of a sample of venous blood obtained from the patient to seal the defect (blood patch).
